Navigating Environmental Challenges:
Historical Lessons Guiding Future Directions

Hynes Convention Center | Boston, Massachusetts
13–17 November 2011

SETAC®

Abstract Book

SETAC North America 32nd Annual Meeting

Table of Contents

Platform Abstracts

Poster Abstracts

Indices

This book comprises the abstracts of the presentations for the platform and poster sessions of the 32nd Annual Meeting in North America of the Society of Environmental Toxicology and Chemistry (SETAC), conducted at the John B. Hynes Veterans Memorial Convention Center in Boston, Massachusetts, 13–17 November 2011. The abstracts are reproduced as accepted by the Scientific Program Committee and appear in numerical order. In each abstract, the presenting author's name is underlined.

The author index cross-references the corresponding abstract numbers. Session and keyword indexes are also included.

International Standard Serial Number 1087-8939

SETAC

A Professional Society for Environmental Scientists and Engineers and Related Disciplines Concerned with Environmental Quality

The Society of Environmental Toxicology and Chemistry (SETAC), with offices in North America and Europe, is a nonprofit, professional society established to provide a forum for individuals and institutions engaged in the study of environmental problems, management and regulation of natural resources, education, research and development, and manufacturing and distribution.

Specific goals of the society are:

- Promote research, education, and training in the environmental sciences
- Promote the systematic application of all relevant scientific disciplines to the evaluation of chemical hazards
- Participate in the scientific interpretation of issues concerned with hazard assessment and risk analysis
- Support the development of ecologically acceptable practices and principles
- Provide a forum (meetings and publications) for communication among professionals in government, business, academia, and other segments of society involved in the use, protection, and management of our environment

These goals are pursued through the conduct of numerous activities, which include:

- Conduct meetings with study and workshop sessions, platform and poster presentations, and achievement and merit awards
- Publish scientific journals, a newsletter, and special technical publications
- Provide funds for education and training through the SETAC Scholarship/Fellowship Program
- Organize and sponsor chapters and branches to provide a forum for the presentation of scientific data and for the interchange and study of information about local and regional concerns
- Provide advice and counsel to technical and nontechnical persons through a number of standing and ad hoc committees

SETAC membership currently comprises more than 6000 individuals from government, academia, business, and nongovernmental organizations with backgrounds in chemistry, toxicology, biology, ecology, atmospheric sciences, health sciences, earth sciences, environmental engineering, hazard and risk assessment, and life cycle assessment.

If you have training in these or related disciplines and are engaged in the study, use, or management of environmental resources, SETAC can fulfill your professional affiliation needs.

All members receive the SETAC Globe newsletter highlighting environmental topics and SETAC activities, reduced fees for meetings, and discounts on SETAC books. All members receive online access to monthly issues of *Environmental Toxicology and Chemistry* (ET&C) and quarterly issues of *Integrated Environmental Assessment and Management* (IEAM), the peer-reviewed journals of the Society. Members may hold office and, with the Emeritus Members, constitute the voting membership.

If you desire further information, contact the Pensacola Office if you are in Latin America, Asia/Pacific, or North America or the Brussels Office if you are in Europe or Africa.

Environmental Quality Through Science®

1 Environmental Radiation: Comparing Risk Thresholds and Improving Risk Assessment M.E. Bates, US Army Corps of Engineers, Environmental Lab, Engineer Research and Development Center; L.J. Valverde, US Army Corps of Engineers, Headquarters; J.T. Vogel, US Army Corps of Engineers, Environmental Lab, Engineer Research and Development Center; I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center. In the months following the March 2011 nuclear disaster at the Japanese Fukushima I nuclear power plant, the eyes of the public, worldwide, turned a new scrutiny towards nuclear policy. In the United States, this scrutiny often focuses on the US Nuclear Regulatory Commission (NRC) and questions whether current regulations adequately protect the public from risks of nuclear harm. The question of appropriate risk protection can be addressed in two parts, asking whether current regulatory risk thresholds are reasonable and asking whether the calculated risks being compared to the thresholds accurately capture the risk inherent in the system. To address the first question, NRC risk benchmarks are compared with those of other public agencies. A comparison with agencies not under particular public scrutiny finds NRC risk thresholds among the most conservative of the assessed agencies, suggesting that NRC's current regulatory framework is consistent with broader social ideals. Learning from the lessons in Japan, the second question implies that, at least in the Fukushima scenario, the true risks of disaster were likely underestimated in the nuclear risk calculations. To improve nuclear risk assessment, the accident suggests that it is important to bring systemic reasoning to the risk management process and evaluate the resilience of the system to minimize the potential for surprise.

2 Human Health Risks of Petroleum Coke as Fuel for Electric Power Generation B. Magee, ARCADIS; C. Ryan, K. Gordon, A. Bielecki, New Brunswick Power Corporation. The New Brunswick Power Corporation sought regulatory approval for a performance project with a mixture of petroleum coke and heavy fuel oil (HFO) as fuel at their electric power generation station in Lorneville, New Brunswick. Petroleum coke is a less costly fuel than HFO, but the human health risks posed by handling of petroleum coke and emissions from the combustion of the petroleum coke/HFO mixture required detailed assessment. A comprehensive multipathway human health risk assessment was performed in accordance with United States Environmental Protection Agency (USEPA) combustor risk assessment guidance. The results of this risk assessment demonstrated that use of petroleum coke as fuel was acceptable, and the performance project was undertaken. Data from emissions testing performed during the combustion of the fuel mixture were subsequently used to update the risk assessment in support of environmental permits to allow use petroleum coke/HFO as a routine fuel. This presentation will present the results of the risk assessment showing that petroleum coke is an environmentally acceptable fuel. In addition, in response to worker concerns about the handling of petroleum coke, a comprehensive literature review was performed, and a toxicological dossier on petroleum coke was prepared. The presentation will summarize the major findings of the literature review.

3 Incorporating Multi Criteria Decision Analysis in an Integrated Life Cycle Sustainability Assessment of Palm Oil Biodiesel Y. Manik, Univ of Maine, Research Group of Industrial Ecology, LCA and System Sustainability (IELCASS); A. Halog, Univ of Maine, Research Group of Industrial Ecology, LCA and System Sustainability (IELCASS), Univ of Maine, Assistant Professor of Industrial Ecology and LCA. In the next few decades, worldwide production of palm oil demand is estimated to increase, particularly as an anticipation of the worldwide biodiesel demand. The massive growth of palm oil is causing enormous potential environmental problems, such as climate change, eco-toxicity, loss of biodiversity as well as societal issues like land conflicts and workers' rights. On the other hand, palm oil industry contributes significantly to the GDP and creates employment for millions of workers nationwide. In the pursuit of sustainable development, an integrated life cycle sustainability assessment framework is needed to enable to support policy and regulation formulation as well as for operational decision making. This study aims to demonstrate how various techniques, such as Life Cycle Assessment, Life Cycle Costing enhanced with Ecological Economics approach, and Social Impact Assessment are combined altogether to develop an integrated instruments that will be employed as a decision making tool within a Multi Criteria Decision Analysis of the integrated life cycle sustainability asesement of palm oil biodiesel, in which the multidimensionality of the sustainability goals and the complexity of socio-economic aspects are taken into account.

4 Modeling Aeolian Transport of Contaminants for Long-Term Risk Assessment: Sensitivities to Succession, Disturbance and Future Climate J.J. Whicker, Los Alamos National Laboratory, Waste and Environmental Services; T. Kirchner, New Mexico State Univ; B.D. David, J.P. Field, Univ of Arizona, School of Natural Resouces and Dept of Ecology and Evolutionary Biology. Aeolian processes dominant redistribution of contaminated soil from protected, nonpublic areas to non-protected, public areas in semiarid sites. Wind transport rates are controlled by vegetation cover, yet long-term changes in vegetation associated with cycles of disturbance and succession is ignored by current sediment transport models. An empirically-based wind transport model (VMTran-Vegetation Moderated Transport) was developed to predict contaminant transport over 1000-year regulatory periods. VMTran simulates transport considering vegetation succession and ecosystem disturbances of three types (surface fire, crown fire, and drought-induced plant mortality) using disturbance rates for current and projected future climate. Simulation results for a Dept of Energy landfill show about 20% of surface contamination was transported offsite in 1000 years without considering disturbances whereas disturbances raised the amount eroded to about 80% of original concentration. More than 90% was eroded offsite under predicted future climate changes. Thus, consideration of vegetation succession and ecosystem disturbance is critical when evaluating public risk for long-term stewardship.

5 Application of Decision-analytic Methods to Evaluate the Practicability of Green Roofs on DOD Buildings D. Wang, Carnegie Mellon Univ; A.C. Bourne, US Army Corps of Engineers, New England District; Z.A. Collier, I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center. In the effort to comply with current sustainability initiatives, like the Army's net zero strategy for energy, water, and waste, Department of Defense (DOD) installations are faced with numerous options to meet environmental goals while continually upholding their missions. Among other innovative technologies, green roofs have the potential to be effective in reducing energy consumption, reducing storm water runoff, and improving water quality in addition to a host of other environmental benefits. Since green roof technologies are relatively new, there isn't extensive documentation on how to determine if installing a green roof is the right choice for specific installation needs, or how to make tradeoffs between various roof design parameters. In order to determine the practicability of green roof installation on new and existing DOD buildings, an integrated decision framework is proposed. This framework assesses the need for green roof installation, and the scope and engineering design of such projects from the standpoint of cost-effectiveness, landscape position, potential energy and water savings, and other sustainability efforts already in place. It uses multi-criteria decision analysis (MCDA) to compare green roofs with other innovative technologies, as well as to evaluate alternative green roof designs. Use of this logical and explicit decision-analytic tool will provide structure to the overall green roof evaluation process and will help installation managers to make informed and appropriate roof choices for a specific building.

6 Environmental Monitoring using a Probabilistic-Possibilistic Approach M. Ragheb, Univ of Illinois at Urbana-Champaign, Dept of Nuclear, Plasma and Radiological Engineering. An approach for Environmental Monitoring through a coupled Probabilistic-Possibilistic formulation is presented. Probability density functions based on sensors data, measurements and observations are coupled to membership functions, based on numerical or statistical modeling and defining the desired operational levels of the associated variables in the form of an information granule: g = (X) is (Y), where X is a measurable or observable quantity or random variable subject to the laws of probability theory, and Y is a linguistic variable, semantic or agreed-upon meaning; quantifiable by simulation, modeling or expert opinion and subject to the laws of possibility theory. Examples of g can be the propositions: g_1 = (radionuclide concentration) is (excessive), g_2 = (radiation level) is (tolerable). Use of the Algebra of Logic allows a description of the overall environmental or ecological system operation and the connections among its subsystems in the form of an Operational Tree as the complement of a Fault Tree. In the definition of g, X is represented by a probability density function (pdf) $p_X(u)$, and Y is a fuzzy variable represented by a membership function $\mu_Y(u)$. The Performance Level, PL , or the degree of truth of the proposition g can be estimated as the mathematical expectation of the observable X, as a value over the unit interval [0,1]. For continuous and discrete functions it can be estimated as: $PL = \int \mu_Y(u)\, p_X(u)du$, $PL = \sum \mu_{Yi}(u)p_{Xi}(u)$. Estimation of the performance levels of the

subsystems as well as the overall system allows for objective monitoring and assessment of its status. Evolution of effective monitoring would include learning from incidents, evaluation and correction of process safety, and the development of methodologies for anticipating and predicting accidents from the observation of their precursors and thus avoiding their occurrence rather than reactively responding to them.

7 Relative Risks of Radionuclide Releases: Nuclear vs. Coal-Fired Power Plants S. Zemba, Cambridge Environmental Inc. Comparisons of the environmental impacts of power generation al Comparisons of the environmental impacts of power generation alternatives are multi-dimensional, and can involve difficult comparisons of very different types of effects (e.g., climate change from due to emissions from fossil-fuel facilities, potential large-scale radionuclide releases from nuclear power plants, and ecological effects of hydro-electric projects). However, even "apples to apples" comparisons are sometimes ignored because some impacts are not widely recognized. Coal-fired power plants, responsible for a large share of worldwide electricity generation, emit radionuclides to the atmosphere in stack emissions, but do not garner the considerable attention focused on accidental releases of radioactivity from nuclear power plants. Coal contains trace levels of various radionuclides; when coal is combusted in power generation facilities, it creates a source of radionuclide emissions to the atmosphere which emissions then deposit and accumulate in soil. To compare, the effects of these emissions with the effects of more widely recognized atmospheric releases of radionuclides, our presentation will build on a detailed risk assessment of soil contamination found in the aftermath of the 1986 Chernobyl accident, using the "no action" exposure estimates based on Cs^{137} uptake into agricultural products. Comparative estimates of radioactivity releases, combined with consideration of land use patterns, food production data, and other information will then be used to extrapolate the Chernobyl study to make order-of-magnitude estimates of human health risks associated with the recent accident at the Fukushima nuclear power plant. We will then compare these risks with cumulative risk estimates constructed for long-term emissions from a hypothetical conventional coal-fired power plant, based on available emissions information from the literature and the application of multi-pathway risk assessment methods, including air dispersion and deposition modeling, soil mixing and accumulation, and uptake into agricultural products from soil.

8 We're Still Cleaning Up After the Manhattan Project: Lessons Learned Some Seventy Years Later K.G. Keil, S.M. Bousquet, US Army Corps of Engineers, Buffalo District. The Formerly Utilized Sites Remedial Action Program (FUSRAP) has its origins in the Manhattan Project, when, in 1942, the US Army Corps of Engineers began development of the first atomic bomb. At that time, the Federal Government contracted with private industries, mostly in the northeastern US, to perform the uranium extraction, refining, and milling necessary to make an atomic weapon. It was not until several years later, after World War II ended, that these functions were transitioned to newly-created national laboratories. In the meantime, in the haste and secrecy of the war effort, the radioactive by-products of this weapons production began to leave its footprint on the industrial sites and the surrounding environment. Today, operating under FUSRAP and the CERCLA principles, the US Army Corps of Engineers is responsible for addressing residual contamination at 22 of these sites, 11 of which reside within the Buffalo District's boundaries. Using case studies and examples from these sites, this presentation will explore the time, effort, and cost incurred while characterizing and communicating environmental impacts and human health risks from the residual radiation to the surrounding public and stakeholders. In addition, the time, effort, cost, and risk reduction involved in remediating these sites to currently acceptable standards will be explored. Questions addressed will include: For those sites which have undergone public health assessments, dose reconstructions, or cancer surveys, do these other evaluation tools corroborate or contradict the CERCLA risk assessments used to make remedial action decisions conducted for the site, or risk perception of the site? What are the costs and benefits to human health and the environment in characterizing and remediating each of these sites? How are environmental impacts and benefits weighed vs. human health issues in the cleanups? What are the relative risks across the sites, and how does that impact priority of cleanup among the sites? What are the real vs. perceived risk drivers at the site, and how does risk perception affect the cleanup? What is reasonable future land use, and how does that impact cleanup decisions? Who (or what) benefits most from these cleanups?

9 A SETAC Pellston Workshop on the Risks from Pesticides to Pollinators: State of the Science T. Steeger, USEPA, Environmental Fate and Effects Division; F. Streissl, European Food Safety Authority (EFSA), PRAPeR Dept; A. Alix, Ministry of Agriculture, DGAl – SPRSPP – SDQPV – BRMMI; T. Moriarty, USEPA; D.L. Fischer, Bayer CropScience, Global Development North America, Dept of Ecotoxicology; C. Lee-Steere, Sole Trader; R. Fischer, Bundesamt für Verbraucherschutz und Lebensmittelsicherheit (BVL); M. Miles, Dow Agrosciences, Field Effects and Exposure; R. Johnson, Univ of Nebraska – Lincoln, Dept of Entomology; M. Fry, American Bird Conservancy; C. Brittain, Leuphana Univ of Lüneburg, Institute of Ecology and Environmental Chemistry. In recent years, a number of countries have reported declines in native and managed pollinators. Modern crop management practices, which often include the use of plant protection products or pesticides, have been identified as a potential factor responsible for these declines. To ensure the safety of pesticides regulatory authorities have adopted a number of measures, including requiring an assessment of the potential impact of these products on a broad range of taxa in the agricultural environment. Included in these assessments are the potential impacts of pesticides to terrestrial arthropods such as pollinating insects and honey bees (*Apis mellifera*) in particular. Consistent with the objectives of the Pellston workshop, participants considered risk assessment strategies for supporting a regulatory decision-making and risk management process for assessing the risks of pesticides to pollinators. The risk assessment process is typically tiered, iterative, and consists of three phases: problem formulation, analysis (exposure assessment and effects assessment) and risk characterization. This presentation will provide a broad overview of the risk assessment process employed by regulatory authorities globally in support of their decision making.

10 Exposure Characterization – Report of the Exposure Workgroup froom the SETAC Pellston Workshop on Assessing the Risk of Pesticides to Pollinators J.D. Wisk, BASF Corporation, Ecotoxicology; J. Pistorius, Julius Kuhn-Institut, Institut für Pflanzenschutz in Ackerbau und Grünland; M. Beevers, California Agricultural Reseach, Inc.; R. Bireley, California Dept of Pesticide Regulation; Z. Browning, Browning's Honey Company, Inc.; M. Chauzat, French Agency for Food, Environmental and Occupational Health Safety; A. Nikolakis, Bayer CropScience; J. Overmyer, Syngenta Crop Protection, LLC, Ecological Sciences, Americas; R. Rose, United States Dept of Agriculture, Animal and Plant Health Inspection Service; R. Sebastien, Health Canada Pest Management Regulatory Agency; B.E. Vaissiere, French National Institute for Agricultural Research; M. Vaughan, Xerces Society for Invertebrate Conservation. In the Workshop exposure workgroup, participants reviewed the various ways that honey bees (*Apis mellifera*) and non-*Apis* bees can be exposed to both non-systemic and systemic pesticides. Techniques that are employed to measure pesticide residues in matrices relevant for assessing bee exposure were summarized, and higher-tier semi-field and field study designs for refining bee exposure assessments were discussed. For tier 1 contact exposure estimates to foliar-applied products, published insect residue data can be used to develop an exposure nomogram where exposure estimates can be calculated based on application rates. For predicting oral exposure for sprayed products, participants proposed forming an industry coalition to compile pollen and nectar residue data from both published and proprietary studies to develop a nomogram that can be used to predict concentrations in pollen and nectar based on field application rates. Recognizing the limited field pollen and nectar residue data available for systemic compounds applied as seed treatment coating or soil applications to develop exposure models, participants recommended the proposal by the ICPBR for a default value of 1 mg/kg in pollen and nectar, as a Tier 1 point estimate of exposure for a screening-level assessment. Semi-field or tunnel tests using bee-attractive crops like Phacelia, oilseed rape, mustard or buckwheat are recommended to refine the oral exposure assessments for honey bee colonies to both systemic and non-systemic products sprayed on foliage. Semi-field studies are also recommended for assessing exposure to systemic pesticides used as seed dressings or applied as soil treatments. However, the actual crop being assessed should be used, as there may be different rates of uptake, distribution and metabolism of a compound in different plant species. Semi-field and field exposure studies can also be conducted using solitary nesting non-*Apis* bees such as blue orchard bees (*Osmia lignaria*) or alfalfa leafcutter bees (*Megachile rotundata*). Studies conducted with Megachile can also be used to evaluate potential dermal and/or oral exposure via contaminated nesting material. For assessing exposure to sprayed pesticides or systemic pesticides used as a

seed treatment, or applied as a soil treatment or trunk injection, field studies can also be conducted with the above non-*Apis* species to evaluate worst-case exposure because of the limited foraging range of these species.

11 Laboratory Assessment of Pesticide Hazards to Honey Bees and Non-*Apis* Bees J. Pflugfelder, Agroscope Liebefeld-Posieux ALP; J. Frazier, Penn State Univ; P. Aupinel, INRA, Unite experimentale d'entomologie; P. Bachman, Monsanto Company; A. Decourtye, INRA, Lab Neurobiologie; C. Scott-Dupree, Univ of Guelphy, School of Environmental Sciences; A. Dinter, Dupont de Nemours Deutschland; J. Ellis, Univ of Florida, Entomology; V. Grim, Hemholtz Centre for Environmental Research, Ecological Modeling; Z. Haung, Michigan State Univ, Entomology; R. C F Nocelli, CCA-UFSCar, Ciencias Biologicas; H. Thompson, Central Science Lab; B. Warren-Hicks, Consultant. For the risk assessment of pesticides to honeybees the laboratory assessment of hazards is the first step in a tiered testing approach. Tier 1 testing is conducted under controlled conditions with defined criteria on groups and individual bees and larvae to yield statistically valid determinations of the intrinsic activity of active ingredients. These tests proiduce an LD50 for acute contact and topical exposure, NOEC for chronic toxicity to adults and to bee larvae as the basis for a differentiated risk assessment if the product is a foliar spray or a systemic pesticide. Extrapolating these effects observed on individual bees to effects on the whole colony remains a major challenge. We suggest harmonizing the test procedures that are well developed, along with acknowledging an urgent need for the adaptation of new methods and provide perspectives on methods requiring further development and research. Extending similar tests to non-*Apis* bees requires further protocol development and standardization, along with agreements on which species offer the most advantages for laboratory, semi-field, and field testing. Sub-lethal impacts of pesticides on adults and larvae of both *Apis* and non-*Apis* bees are being documented in the scientific literature, but we still do not know to which extent *Apis mellifera* can serve as a surrogate. This needs to be defined and the development of a tiered test system for non *Apis* species requires significant effort and is a high research priority.

12 A SETAC Pellston Workshop on the Risks from Pesticides to Pollinators: Report of the Risk Assessment Breakout Group A. Alix, Ministry of Agriculture, DGAl – SPRSPP – SDQPV – BRMMI. The intent of the global SETAC Pellston workshop was to bring together the best available science regarding exposure and effects assessment methodologies for honey bees (*Apis mellifera)* and non-*Apis* bees and to provide specific recommendations for determining the potential risk to insect pollinators from pesticide products in a cost effective way. The workshop intended to characterize exposure routes and produce related tiered standardized test method(s) to assess exposure from systemic and non-systemic pesticide products to bee species. Hazard endpoint(s), applicable to risk assessment for the honey bee, and tiered standardized test method(s) to consistently identify and measure hazard endpoint(s) were defined. A risk assessment process that can serve at both a screening-level and as a basis for more refined assessments where needed was proposed. The fourth objective of the workshop was to evaluate information on risk of pesticides to non-*Apis* bees. The resulting risk assessment process is predicated on first defining protection goals, and then identifying the appropriate assessment endpoints, i.e., explicit expressions of the actual environmental value that is to be protected, which can be used toward evaluating those goals. In developing this risk assessment process, breakout group members relied heavily on recommendations provided by other workshop breakout groups on exposure assessment and effects (hazard and field) assessment. The ratio of exposure to effects remains the basis of the risk assessment process defined in this section and is consistent with the regulatory processes reflected at the Pellston workshop. The risk assessment process then progresses towards higher tiers, which aim at evaluating the potential impact in the field, under more realistic exposure conditions. The highest tier approaches, i.e., full field studies, are intended to reproduce expected conditions of exposure for bees relative to how products will ultimately be used. These studies will be used to characterize the potential level of risk and identify the choice of risk management measures, if needed.

13 Measuring Pollinator Exposure to Imidacloprid from Hardwood Trees Treated to Control the Asian Longhorned Beetle J. Pettis, USDA/ARS Bee Research Lab ; J.D. Johnson, Univ of Maryland, Dept of Toxicology; P. Lewis, USDA,APHIS,PPQ; R. Rose, USDA,APHIS,PPQ,EDP. Animal and Plant Health Inspection Service (APHIS) has undertaken an eradication program to remove and prevent the further spread of Anoplophora Glabripennis, the Asian longhorned beetle (ALB) in New York City. Several hardwood species can serve as host for ALB and imidacloprid (IMI) is used to treat uninfected trees in ALB infested areas in part to save the trees and prevent expansion of beetle range. In Staten Island, trunk injections of imidacloprid, a neonicotinoid, were used because the water table is high and water contamination by the soluble pesticide could be significant, whereas in the drier soils in the boroughs of Queens and Brooklyn soil injections of the twenty+ susceptible species of trees were more appropriate. We chose red maple, Acer rubrum, as our target tree as pollinators use the nectar and pollen of this tree during the early spring and it is a dominant species in this area. Imidacloprid and six of its metabolites, were monitored in red maple flowers, pollen collected by honey bee hives placed in the immediate areas, and red maple leaves over a 6-year treatment protocol to assess the environmental presence of the pesticide as a potential threat to foraging honey bees, a non-target species. Results show that soil injected trees had higher amounts of IMI in flowers than trunk injected trees. IMI partitioned mostly to the leaves as expected since this systemic pesticide moves through the xylem (Sur and Stork,2003) but flowers had detectable amounts suggesting that phloem transport also takes place but at a slower rate. Male flowers had higher amounts than female flowers. Pollen loads collected by honey bees placed at the test sites had detectable levels of imidacloprid. Repercussions on honey bee health will be discussed.

14 Examples of Higher-tier Studies – Semifield Studies A. Schur, Eurofins-GAB GmbH, Ecotoxicology, Eurofins Agroscience Services; I. Tornier, Eurofins Agroscience Services. The existing European guideline OEPP/EPPO No. 170 (4) for honey bee (*Apis mellifera* L.) testing of plant protection products are used as basis for tests under laboratory, field and semi-field conditions. In the presentation methods and results of tests under semi-field conditions will be summarized and discussed. The OEPP/EPPO No. 170 (4) guideline was mainly developed in the northern part of Europe. In the past years, higher tier tests were more adapted to the needs of testing pesticides in the southern European zone and in different kinds of crops. However, within such tests different parameters, such as bee mortality, flight intensity in the crop, behaviour of the bees and the conditions of the colonies and brood development are assessed before as well as after the application of a plant protection product. Within the presentation different kinds of methods according to the guideline will be presented which are used in different kinds of crops, e.g., *Phacelia tanacetifolia*, winter oil-seed rape, citrus, melon, peach as well as in the northern, central and southern part of Europe. In addition, results will be shown generated within the studies for the water-treated or untreated control, the toxic reference treatment (dimethoate) in comparison to different kinds of test compounds. The results of the mortality, flight intensity and bee colony assessments shows, that there is a wide range in the results assessed in different studies, but also within the replicates of the same treatment group of one study. This causes difficulties in the evaluation of results and in the risk assessment of a compound. Beside standard tests including the above mentioned parameters, studies are often combined with the assessment of residues in e.g., nectar and pollen, detailed assessments on behaviour and sub-lethal effects, detailed assessments on brood development and the comparison of different treatment scenarios (e.g., pre-flowering application, evening application compared).

15 Large-scale Field Study to Assess Side-effects of the Insecticide Spirotetramat to Honey Bee Colonies Under a Realistic Field Scenario in a Melon Crop T. Stadler, Laboratory of Environmental Toxicology-IMBECU-CONICET, Institute of Medicine and Experimental Biology; H.J. Schnorbach, Bayer CropScience BCS AG-D-AD; C. Maus, Bayer CropScience BCS AG-ACO-M-PS. Spirotetramat (Movento®) is an insecticide which acts as a lipid biosynthesis inhibitor that is being used on a great variety of crops to control a broad spectrum of sucking pests. An intrinsic larvicidal potential of the compound was shown in lower tier tests with artificial exposure conditions (confinement or feeding of very high concentrations). In order to achieve higher-tier data to conduct a scientifically sound risk assessment of actual field use, a replicated large-scale field trial design was developed to test for potential side effects under realistic use conditions of the product. The study was conducted in western Argentina. Two application scenarios were tested. In particular brood development was evaluated, but other endpoints such as mortality, foraging activity and hive weight development were also assessed. Nine field plots at least 3 km apart were randomly assigned to receive either treatment scenario 1 (4 x 75 g a.s./

ha), treatment scenario 2 (2 x 88 g a.s./ha) or control (water) applications (i.e., 3 replicates per treatment group). Two bee hives were set up per plot. Each hive contained a queen-right colony of ca. 18,000 bees. The hives were set up on the plots 2.5 weeks before the first brood assessment. Four further weekly in-field brood assessments were conducted, starting 5 days after the first application. Study duration was nine weeks. No adverse effects were recorded during the study. The comb area containing brood of all stages fluctuated in the control as well as in treatment groups on the different assessment days, indicating the typical natural variability of this endpoint. No treatment-related effects on brood and colony strength were found, nor were there any treatment-related differences in mortality. Likewise, foraging activity, nectar and pollen storage and hive weight development were unaffected in both treatment groups. It is therefore concluded that the tested uses of spirotetramat on melons are reasonably safe to honey bees. The results of the study reveal that replicated honey bee field studies conducted under practical agricultural conditions provide an excellent tool to reliably assess the risk of plant protection products to bees, as they provide maximum realistic insights in a holistic approach that monitors the exposed bee colonies along with all relevant environmental factors influencing its health, and are at the same time capable to overcome the natural variability of the testing system.

16 Do Reported Levels of Pesticides in Hive-stored Pollen Pose a Serious Risk to Honey Bees? D.L. Fischer, Bayer CropScience, Global Development North America, Dept of Ecotoxicology; C. Henderson, Univ of Montana, Bee Alert Technologies, Inc. Several recently published studies have used multi-residue analytical methods to screen samples of pollen stored in bee hives for presence of pesticides. These papers have sometimes suggested the levels and frequency of pesticide detections are alarming and emphasized that because residues of multiple pesticide active ingredients commonly co-occur in samples, synergistic toxic effects may be occurring. The occurrence of systemic pesticides in hive samples is sometimes emphasized as reason for additional concern. We applied risk analysis methods for honey bees and pesticides recently developed by the ICPBR Bee Protection Group to evaluate whether recently published measurements of pesticide levels in hive-stored pollen pose a serious risk to honey bees. Our analysis indicates the reported chemical exposures likely pose minimal risks to honey bees. This was true for the individual chemicals assessed one at a time as well as for a worst-case theoretical mixture containing a 95th percentile concentration for every chemical in the respective data sets. Contrary to what has often been assumed, our analysis revealed that systemic pesticides are found less frequently and at lower levels in hive-stored pollen than non-systemic pesticides, and risk estimates for systemic compounds were if anything lower than for non-systemic pesticides. Our analysis indicates that one should not assume a serious risk exists based on the mere presence of residues in bee hive samples. A risk analysis, such as that presented here, needs to be undertaken before conclusions about risk can be drawn.

17 In Vivo and In Vitro Estrogenicity and GC/MS/MS and LC/MS/MS Quantification of Estrogens in Aqueous Mixtures of Raw and Pelletized Poultry Litter L.T. Yonkos, Univ of Maryland, Wye Research and Education Center; D.J. Fisher, Univ of Maryland, Wye Research and Education Center; E.A. Friedel, Univ of Maryland, Wye Research and Education Center; V.S. Wilson, USEPA, ORD, NHEERL, TAD, Reproductive Toxicology Branch, USEPA, Office of Research and Development; S.R. Hutchins, USEPA, ORD, GWERD; J.M. Lazorchak, USEPA, Office of Research and Development, National Exposure Research Laboratory, USEPA, Molecular Ecology Research Branch; T.V. Reddy, USEPA, NERL; N.W. Shappell, USDA-ARS-RRVARC, Biosciences Research Lab, USDA-ARS; P.A. Van Veld, Virginia Institute of Marine Science; R.C. Hale, Virginia Institute of Marine Science, Environmental and Aquatic Animal Health. Abundance, degradation, and bio-activity of estrogens were examined in aqueous solutions of poultry litter from three Delmarva broiler integrators, a pelletized litter sample, a biosolids sample from a regional WWTP, and an estrone (E1) positive control allowed to stand static for 28 days. Litter and biosolids samples were generated to be analogous to organically fertilized agricultural runoff. Estrogens, 17β-estradiol (E2) and E1, were quantified in aqueous samples via GC/MS/MS and LC/MS/MS at day 0, 9, and 28. Likewise, estrogenicity was investigated using a pair of in vitro assays (E-screen and K_{bluc}) on days 0, 9, and 28 and in vivo by exposing mature male fathead minnows (*Pimephales promelas*) continuously (day 0 – 9) to investigate vitellogenin (Vtg) induction (plasma protein and liver Vtg mRNA). All three raw litter samples showed a significant increase in E1 and E2 between day 0 and day 9 before decreasing by day 28. In vitro estrogenicity showed a corresponding increase to day 9 with EEQ (E2 equivalent) levels paralleling E2 concentrations measured via GC/MS/MS. All litter samples (raw and pelletized) induced Vtg with plasma protein and mRNA concentrations correlating strongly with peak (day 9) E2 concentrations. Increases in estrogens between day 0 and day 9 are likely explained by microbial deconjugation of glucuronide and sulfate groups to produce native/bioactive E1 and E2. Results indicate that fecal estrogens can persist and estrogenicity actually increase in aqueous solutions days to weeks after introduction. Results and implications to natural waters will be discussed.

18 Sex Differentiation as a Target of Endocrine Disrupting Compounds in Early Life Stage Fathead Minnows (*Pimephales promelas*) J.K. Leet, Purdue Univ, Forestry and Natural Resources; J.J. Amberg, United States Geological Sciences, Upper Midwest Environmental Sciences Center; A. Olmstead, US Environmental Protection Agency, Mid-Continent Ecology Division; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; L.S. Lee, Purdue Univ, Dept of Agronomy Crop, Soil & Environmental Sciences; M.S. Sepulveda, Purdue Univ, Forestry & Natural Resources and School of Civil Engineering, Purdue Univ, Forestry & Natural Resources. The occurrence of endocrine disrupting chemicals (EDCs) in concentrated animal feed operation (CAFO) waste, and the potential effects of these chemicals on aquatic ecosystems have been of recent concern. There is evidence that exposure to EDCs during enhanced windows of sensitivity can lead to alterations in fish sex differentiation. Fathead minnows (*Pimephales promelas*) are commonly used as a model fish species in endocrine disruption studies, however limited knowledge exists on molecular pathways associated with sex differentiation in early life stages of this species. A method has been developed to determine genetic sex in early life stage fathead minnows by use of a sex-linked DNA marker. Changes in the expression of genes important in sex differentiation (cyp19a, sox9, dmrt1) could be used as a way to evaluate effects of EDCs on gonadal development and sex differentiation. For example, cyp19a expression doubles in females from 10 to 15 days post hatch (dph) and is 6 fold higher by 20 dph, but does not significantly change in males during this time. This period in development has also been found to be a sensitive window for fathead minnows exposed to EDCs. We hypothesize that the expression of cyp19a and other genes involved in sex differentiation and gonad development will be altered in a sex specific manner when fathead minnows are exposed to androgens, estrogens, or mixtures of EDCs during sex differentiation. Preliminary data from our lab show that fathead minnow embryos exposed to trenbolone (a potent synthetic androgen) respond with significant alterations in expression of such genes. Evaluation of these molecular markers in combination with this new method of sex identification is being used for developing efficient tools to evaluate sex specific responses of EDCs on early life stage fish. These tools will help us gain knowledge of the molecular pathways controlling sex differentiation in fathead minnows and how EDCs may alter these processes.

19 Endocrine-disrupting Potency of By-products in Flame Retardants P. Leonards, Institute for Environmental Studies, VU Univ, Chemistry & Biology, VU Univ, Institute for Environmental Studies; S. Brandsma, VU Univ, Institute for Environmental Studies. Some brominated flame retardants (BFRs) have unintended negative effects on the environment and human health (e.g., endocrine effects). Some of them show a strong bioaccumulation in aquatic and terrestrial food chains, some are very persistent, and some show serious toxicological effects such as endocrine disruption. During the last decade an increasing number of reports have presented evidence of these negative effects caused by specific BFRs. Less toxic alternatives appear to be available already but comprehensive information on their possible toxicological effects and exposure are lacking. The European Commission-funded project ENFIRO investigates halogen-free substitution options for specific BFRs resulting in a comprehensive dataset on viability of production and application, environmental safety, risk assessment, and a life cycle assessment. In total 15 halogen-free flame retardants (HFFRs), consisting of metal-, organic-, and nano-based FRs, as substitution options for decaBDE, TBBP-A, and brominated polystyrenes were selected. These HFFRs were assessed in a toxicity screening to provide information on the hazard characterization. Toxicity profiling of the 15 HFFRs and 3 BFRs was carried out with a battery of in vitro assays (e.g., cytotoxicyt, thyroid hormone disruption, estrogenicity, androgenicity, mutagenicity) and showed that

three organic HFFRs had estrogenic potency. These HFFRs were chemically fractionated on polarity and the fractions re-tested in the estrogenic in vitro assay. Compounds present in the active fractions were chemically identified with LC-MS, LC-ToFMS and GC-ToFMS, and showed that not only the flame retardants but also by-products in the flame retardant product were responsible for the estrogenic potency. In conclusion, the combination of mode of action screening and chemical identification is a powerfull tool to study and identify potential endocrine disrupting chemicals.

20 Regulation of the Transcriptional Control of the Largemouth Bass Vitellogenin Receptor by Androgens and Waste Water Effluent Mixtures G.A. Dominguez, Univ of Florida, Center for Environmental and Human Toxicology; K.J. Kroll, N. Denslow, Univ of Florida, Physiological Sciences; T. Sabo-Attwood, Univ of Florida, Dept of Environmental and Global Health. There is increasing concern surrounding the presence of androgenic compounds in environmental settings such as effluents of industry and waste water treatment (WWT) facilities. Although numerous investigations have revealed the physiological effects on female fish, such as decreased fecundity, reduced egg size and spawning events, exposed to androgen-related and – suspected compounds minimal studies have explored specific mechanisms of action. While major efforts have focused on estrogen disruption in teleosts through estrogen-driven mechanisms of vitellogenin (VTG) production in the liver, fewer studies have focused on pathways that control yolk accumulation into growing oocytes, a process essential for successful reproduction. One gene important to proper egg development is the vitellogenin receptor (VTGR) as it sequesters circulating vitellogenin (VTG) into developing oocytes. To begin to address the molecular mechanisms that control the transcription of this gene, we cloned the full length cDNA and partial promoter for the VTGR of largemouth bass. Using quantitative real-time PCR we show maximal expression of the VTGR in gonadal tissues during primary oocyte stages of growth whereas the levels decrease during VTG stages of oocyte development when maximal VTG synthesis is observed. Further analysis using reporter gene assays driven by a partial VTGR promoter reveal activation by androgens including 11-ketotestosterone (11-KT, 100 nM) and trembolone (100 nM) whereas estrogens failed to produce a response. Furthermore, extracts collected from a waste water effluent holding pond also showed similar activation by comparison to 11-KT and trembolone. Inhibition of these androgenic responses was diminished with co-exposure to the androgen receptor antagonist flutamide. Outcomes of these studies reveal, for the first time, that androgens, not estrogens, control the expression of VTGR in female fish which is mediated through androgen receptors and may be a target of complex environmental mixtures. These mechanisms may also explain endpoint effects observed in female fish exposed to androgens and androgen-containing mixtures and highlight the importance of elucidating the role of androgens in females and endocrine disrupting capacity of proper egg development.

21 Intersex Fish Influenced by Factors Other than Municipal Wastewater Effluent K. Kellock, Univ of Georgia, Interdisciplinary Toxicology Program; C. Jennings, P. Ely, USGS Georgia Cooperative Fish and Wildlife Research Unit; B. Trushel, USGA Georgia Cooperative Fish and Wildlife Research Unit; R. Bringolf, Univ of Georgia, Interdisciplinary Toxicology. Recent reports of intersex fish (males with oocytes in their testicular tissue) in water bodies around the world have stimulated widespread concern about the effects that chemicals are having in the environment. Estrogens and estrogen mimics in the aquatic environment are known to induce intersex and other forms of endocrine disruption in fish. Intersex fish can have decreased sperm production, decreased sperm motility and decreased fertilization success compared to histologically 'normal' male fish. Recently, a high incidence of intersex fish were reported in some rivers in the southeastern US but to date, a systematic evaluation of the extent, severity, and causes of intersex fish has not been completed in Georgia. Therefore, our objectives were to (1) assess intersex condition in black bass collected from rivers and impoundments across Georgia, and (2) determine estrogenic potency (a measure of the estrogens and estrogen-like substances) of surface waters where fish were collected. Fish (N>15) and water samples were collected near municipal wastewater effluent discharges in each of four rivers and from a river that receives no major wastewater effluent discharges. Fish were also sampled from 11 impoundments with no major wastewater inputs to determine if a natural 'background' rate of intersex could be established for fish from relatively unpolluted water bodies. Gonads from all fish were examined and the incidence and severity of the intersex condition were compared among sites. The overall percentage of intersex for male bass collected in rivers was 11% while 52% of male fish collected from impoundments were intersex. Incidence of intersex varied substantially (0-100%) among impoundments and surface area of the impoundment was a strong predictor of incidence. Severity of intersex also varied among impoundments but was not predicted by surface area. Potency of estrogens in surface waters was determined by use of an in vitro yeast-based reporter gene (YES) assay. The specific mechanism(s) causing intersex remain unknown, but the high incidence of intersex males in some impoundments suggests that factors other than municipal wastewater are involved.

22 Mode of Action-based Screening of Endocrine Disrupting Chemicals in Wastewater Effluents R. Marfil-Vega, USEPA, ORISE Research Participant to the National Risk Management, Univ of Cincinnati; M.A. Mills, USEPA, National Risk Management Research Laboratory; S.F. Nakayama, National Institute for Environmental Studies, Center for Environmental Health Sciences; M.W. Hornung, M. Gilbert, K.M. Crofton, USEPA, National Health and Environmental Effects Research Laboratory; K.B. Paul, The Hamner Institutes for Health Sciences, Institute for Chemical Safety Sciences, Integrated Systems Toxicology Division, NHEERL, ORD, USEPA; K. Tadele, USEPA, Student Services Contract at National Risk Management Research Laboratory. Endocrine disruption encompasses the disturbance of different metabolic pathways, comprising the nuclear receptors for steroid and thyroid hormones, among many others. Emerging contaminants both from natural and industrial origin, such as the steroid and thyroid hormones themselves, commercial and industrial chemicals, and pharmaceutical and personal care products (PPCPs) that are known to be endocrine disruptors are often detected in environmental samples. An ongoing multi-laboratory and multi-disciplinary effort to monitor and characterize emerging contaminants in wastewater treatment plant effluents is aimed at determining the endocrine disrupting activity of these effluents, and the specific chemicals that may underlie these effects. Synthetic progestagens, which are agonist of the progesterone receptor, are used for oral contraception, alone or in combination with synthetic estrogens. Combined formulations present a higher amount of progestagens than estrogens; therefore, there is an elevated potential risk for progestagens to reach the environment from wastewater treatment plants discharges. In regard to the thyroid hormone, the complexity of its homeostasis allows for structurally diverse chemicals that may disrupt its different biological endpoints. Known thyroid disruptors, such as perchlorate, thiouraciles, thiocianates, PCBs, dioxins, furans, and pesticides, are commonly found in the environment. But other chemicals that may be present in wastewater effluents (thyroid hormones, benthiazoles and some PPCPs) need to be considered to account for the total thyroid disruption activity of these samples. In the current work, we will be presenting the initial results from monitoring progestogens and selected thyroid disruptors in wastewater effluents, in combination with the chemical quantification of the disruption potency of the effluents against a battery of in vivo and in vitro bioassays (i.e., thyroid gland explant culture assay, thyroid peroxidase inhibition assay, and human pregnane-X and progesterone cell-based nuclear receptor reporter assays).

23 Application of the Transthyretin Binding Assay in Effect-Directed Analysis of Sediments: Identification of Thyroid Hormone Disrupting Compounds M. Lamoree, Institute for Environmental Studies, VU Univ, Chemistry & Biology, Institute for Environmental Studies, Chemistry & Biology; T. Hamers, Institute for Environmental Studies, VU Univ; E. Simon, BioDetection Systems; P. Leonards, Institute for Environmental Studies, VU Univ; J. Weiss, Joint Research Centre – European Commission. In Effect-Directed Analysis (EDA), (in vitro) bioassays, sample fractionation techniques and chemical analysis are used in an iterative manner in order to identify the compounds that are responsible for an observed biological/toxicological effect. In EDA studies, various bioassays have been implemented that have an endpoint related to endocrine disruption, with the emphasis on estrogenic and androgenic effects. To extend the scope of EDA, we have used the radioligand T4*-TTR binding assay (shortly, TTR assay) to determine the thyroid hormone like (TH-like) activity to direct our fractionation for the identification of unknown thyroid hormone disrupting environmental contaminants. From a human and animal health perspective, the thyroid function is vital for the normal development of the central nervous system of the fetus. To assess what classes of environmental toxicants are capable of interfering with the thyroid hormone system, an inventory of the different classes of compounds with reported TH-like activities was

made. Compounds that are known to influence the thyroid system are, among others, hydroxylated polybrominated diphenyl ethers, hydroxylated polychlorinated biphenyls and triclosan. More recently, also polyfluorinated compounds were shown to have moderate TH-like activities. In the framework of the EU funded Modelkey project we have carried out EDA studies at several locations connected with European river systems using a variety of bioassays. Sediment extracts were fractionated using sequential reversed and normal phase liquid chromatography. In the course of this project, we identified several different classes of environmental toxicants in fractions of the responsive sediment extracts, by conventional gas chromatography coupled with mass spectrometric detection as well as liquid chromatography coupled with high resolution mass spectrometry. A selection of these compounds was tested in the TTR assay in order to assess whether they were responsible for the observed TH-like activity in the fractions of the sediment extracts.

24 The Role of Sediment in the Bioavailability of Steroid Hormones 17b-Estradiol and Trenbolone J. Sangster, Univ of Nebraska – Lincoln, Dept of Civil Engineering; S. Bartelt-Hunt, Univ of Nebraska, Civil Engineering; N. Conoan, Univ of Nebraska – Omaha, Dept of Biology; A.S. Kolok, Univ of Nebraska Medical Center, Environmental, Agricultural and Occupational Health. There is growing concern about the impact of steroidogenic compounds in aquatic systems. Steroids released into the environment have been shown to sorb to sediments in aquatic environments, however other studies have suggested that steroids can move through sediment beds, and that fish and other aquatic organisms can facilitate this mobility. In this study, we investigated the effect of sediment-associated 17B-estradiol and trenbolone on vitellogenin expression in fathead minnows, a ubiquitously distributed freshwater organism. Two natural sediments were selected to represent a diversity of soil properties, one predominantly clay and one predominately sand. Sediment contaminated with either trenbolone or 17B-estradiol was placed in a glass aquaria along with 20 sexually mature female (trenbolone) or male (17B-estradiol) fathead minnows. Both positive (aqueous steroid) and negative (lab water) control experiments were performed. Ten fish were randomly collected from each tank at 7 days with the remaining harvested at 14 days. Livers and gonads were collected from each individual and relative hepatic vitellogenin (Vtg) expression was quantified using ribosomal L8 as a normalization standard. After exposure to 17B-estradiol-contaminated sediments, male fathead minnows exhibited no inappropriate expression of Vtg relative to the negative control group reguardless of the sediment type used. By comparison, female fathead minnows exposed to sediment-associated trenbolone did exhibit a reduction in Vtg expression relative to negative controls when the clay sediment was used. However, female fathead minnows exposed to trenbolone associated with sand exhibited no inappropriate expression of Vtg relative to the negative control. Taken together, we observed differential bioavailability for an estrogenic compound (17B-estradiol) and an androgenic compound (trenbolone) when associated with sediment. Additionally, differential bioavailabilty was observed for trenbolone depending on sediment type. Liquid chromatography tandem mass spectroscopy will be performed on sediment extracts and water samples obtained over the exposure period to evaluate steroid desorption and transformation over the exposure period.

25 Adverse Outcome Pathways: Definition and Utilization G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division. A challenge for both human health and ecological toxicologists is the transparent application of mechanistic (e.g., molecular, biochemical, histological) data to risk assessments. The adverse outcome pathway (AOP) is a conceptual framework designed to meet this need. Specifically, AOPs portray causal and predictive linkages between molecular-cellular disruption (initiation of a toxicity or disease pathway) and adverse outcomes of regulatory significance in individuals or populations. Collecting, analyzing and communicating toxicological data through the use of AOPs enhances aspects of risk assessments related to extrapolation of chemical effects across biological levels of organization, species and chemical structures. AOPs also provide a platform for assessing cumulative risk of chemical mixtures. This presentation will provide an overview of the AOP concept relative to other frameworks (e.g., mechanism/mode of action, toxicity pathways), review the outcomes of various meetings and workshops focused on the development and application of AOPs, and present an overview of utility of the concept in different risk assessment/regulatory scenarios. The contents of this abstract do not reflect USEPA policy.

26 Establishing Adverse Outcome Pathways of Thyroid Hormone Disruption in an Amphibian Model M.W. Hornung, USEPA, National Health and Environmental Effects Research Laboratory; S.J. Degitz, J.E. Tietge, US Environmental Protection Agency, Mid-Continent Ecology Division. The Adverse Outcome Pathway (AOP) provides a framework for understanding the relevance of toxicology data in ecotoxicological hazard assessments. The AOP concept can be applied to many toxicological pathways including thyroid hormone disruption. Thyroid hormones play a critical role in vertebrate morphological and neural development, and are important for maintenance of multiple physiological functions. Control of thyroid hormones is conserved across vertebrates via regulation by the hypothalamic-pituitary-thyroid axis (HPT). It has been well-established that disruption of the ability of the HPT axis to maintain normal levels of thyroid hormones can occur through exposure to various anthropogenic chemicals in the environment. Understanding the capacity of these chemicals to disrupt thyroid hormone levels and produce an adverse effect in the organism is critical for making sound risk assessment decisions. Furthermore, linking the initial molecular event in which a chemical interacts with the biological target to the processes leading to the adverse outcome, can provide a basis for developing predictive chemical structure activity relationships for thyroid hormone disruption. The molecular initiating events that can lead to decreased circulating thyroid hormone include inhibition of iodide uptake by the thyroid via the sodium-iodide symporter, inhibition of thyroid peroxidase which directly catalyzes the production of hormone, and induction of thyroid hormone metabolizing enzymes, including the thyroid hormone deiodinases. The amphibian provides an excellent model for developing AOPs that cover the various potential pathways to thyroid hormone disruption because amphibian metamorphosis is dependent upon thyroid hormone and is an easily quantified apical endpoint. The development and application of in vitro, ex vivo, and in vivo assays as they are applied to understanding disruption of thyroid hormone regulation in vertebrates will be presented. These assays include in vitro enzyme assays that measure the ability of a chemical to directly inhibit thyroid hormone synthesis, ex vivo assays that may be used to assess thyroid hormone release and metabolism, and final confirmation of an adverse effect with an in vivo metamorphosis assay. Developing a suite of AOPs for thyroid hormone disruption can provide an integrated set of mechanistic tools for identifying and verifying potentially active chemicals. This abstract does not necessarily reflect EPA policy.

27 From Molecular Mechanism of Action to Ecological Risk Assessment: The Aryl Hydrocarbon Receptor and Avian Species Sensitivity to Dioxin-like Compounds S.W. Kennedy, Univ of Ottawa, Dept of Biology, Environment Canada, National Wildlife Research Centre; R. Farmahin, Univ of Ottawa, Dept of Biology, Environment Canada, National Wildlife Research Centre; D. Crump, Environment Canada, National Wildlife Research Centre; G.E. Manning, Univ of Ottawa, Dept of Biology; S.P. Jones, Environment Canada, National Wildlife Research Centre; S.J. Bursian, Michigan State Univ, Dept of Animal Science; T.B. Fredricks, Monsanto Company; J.P. Giesy, Univ of Saskatchewan, Biomedical Veterinary Sciences & Toxicology Centre, Michigan State Univ, Dept of Animal Science; M.J. Zwiernik, Michigan State Univ, Dept of Animal Science; M.E. Hahn, Woods Hole Oceanographic Institution; S.I. Karchner, Woods Hole Oceanographic Institution, Biology. An important goal of environmental toxicology is the development of methods that allow prediction of the sensitivity of wild species to adverse effects of environmental contaminants. We are conducting studies to determine if it is possible to predict the sensitivity of any wild avian species to the embryotoxic effects of any 'dioxin-like' compound (DLC) based on a detailed molecular and biochemical understanding of how DLCs interact with the aryl hydrocarbon receptor 1 (AHR1). A series of laboratory studies were conducted using AHR1-dependent reporter gene expression assays, AHR1 binding assays, primary hepatocyte cultures and egg injection studies. The results of these studies, in combination with sequence information for the AHR1 ligand binding domain (LBD) of 75 bird species, were used to develop an approach for predicting the sensitivity of birds to polychlorinated dibenzo-*p*-dioxins (PCDDs), dibenzofurans (PCDFs) and biphenyls (PCBs). The results indicate that the sensitivity of avian species to DLCs can be predicted from the AHR1 LBD genotype. This research represents an example of how the knowledge of the fundamental mechanisms of action of a class of environmental chemicals can be used to develop methods of use for environmental risk assessment.

28 Building Chemical Categories for Ecotoxicological Endpoints T. Schultz, Univ of Tennessee; R. Diderich, OECD. There is discontinuity between chemical and biological spaces so substances, which are "similar" in molecular structure, are often dissimilar in terms of their toxicity. This difference leads to difficulties in forming toxicologically meaningful groups, especially for chronic endpoints. Identification of a consistent pattern of toxic effects via a chemical category increases the confidence in the reliability of the results for all category members. However, this is predicated on a priori binning the chemical into the correct category. Thus, category formation is the key to category-based assessments. Most scientific and regulatory decisions are made using a weight of evidence approach using all available and relevant information. Using a weight of evidence approach requires the identification of information needs which are endpoint specific. The question becomes how does one identify a mechanistically plausible and transparent means of organizing information to characterize the weight of evidence and provide a basis for testable hypotheses for a chemical category. The Adverse Outcome Pathway (AOP) has been put forth as a way of building categories for complex endpoints by integrating the sciences that explain each important element of the complexity. This is more transparent and internally consistent to each endpoint as it can be the result of a causal chain of effects that are dependent on the chemical structure, the biological response processes for the species, sex and life stage, as well as the exposure scenario. AOP-based categories shift the emphasis away from statistical similarity to intrinsic chemical and biological activity. They aid in developing hypotheses which can be tested. They encourage expert discussion about chemical and toxicity mechanisms and modes of action. And, they enable all chemicals in the category to be assessed in a defensible manner when only a few members are tested. AOPs are useful in assessing ecological health where the focus is on the health of populations and not so much the individual, where protection of the population focuses on shorter-term survival and longer-term reproduction, and where protection of ecosystems are often based on surrogate species testing with the effects extrapolated to many taxa and species.

29 Experimental Approaches to Systematic Discovery and Development Reproductive Adverse Outcome Pathways in Fish D.L. Villeneuve, USEPA, Mid-Continent Ecology Division; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; D. Bencic, USEPA, Office of Research and Development; T. Collette, USEPA, National Exposure Research Laboratory; S. Edwards, USEPA; D. Ekman, USEPA, National Exposure Research Laboratory; N. Garcia-Reyero, Jackson State Univ, Dept of Chemistry; J.M. Lazorchak, USEPA, Office of Research and Development, National Exposure Research Laboratory, USEPA, Molecular Ecology Research Branch; E.J. Perkins, US Army, Engineer Research and Development Center, Environmental Laboratory, Environmental Processes and Effect Division. Adverse outcome pathways (AOPs) are conceptual frameworks that portray causal and predictive linkages between key events at multiple scales of biological organization, providing connectivity between molecular initiating events at the cellular level (e.g., initiation of toxicity pathways) and adverse outcomes of regulatory significance (i.e., at the individual and/or population level). Proposals to make greater use of high throughput in vitro screening, quantitative structure-activity relationships, and other types of alternative data for screening, prioritization, and hazard assessment are dependent, in part, on the ability to identify major adverse outcome pathways, and develop associated assays and computational tools for predicting and ranking chemical hazards. This presentation will describe a program of research that was undertaken to systematically discover, characterize, and develop AOPs for reproductive toxicity in fish and other vertebrates. Specifically, it illustrates how hypothesis-based experimentation anchored to conceptual systems models can guide AOP development. It also examines ways in which toxicogenomic data (i.e., transcriptomics, metabolomics) can be used to accelerate discovery of novel AOPs and improve our understanding of AOPs in a dynamic systems context that considers feedback processes and intersections/interactions between multiple pathways. Although the examples will focus on AOPs for reproductive toxicity in fish, the concepts employed are broadly applicable to a wide range of other adverse outcomes and model systems. The contents of this abstract neither constitute nor reflect official USEPA policy.

30 New Predictive Computer and In Vitro Based Tools in Ecological Risk Assessment for Faster and More Effective Prioritization of Chemicals T. Steeger, USEPA, Environmental Fate and Effects Division; M. Panger, USEPA, Environmental Fate and Effects Division. The US Environmental Protection Agency (USEPA) Office of Pesticide Programs (OPP) currently relies heavily on in vivo testing where data are largely based on measurement endpoints directly linked to reproduction, growth, and survival. OPP is committed toward increased use of in vitro methods and computer-based predictive models that allow more efficient use of resources and reduce the number of animals used in testing. The Adverse Outcome Pathway (AOP) concept spirited by the USEPA Office of Research and Development (ORD) Mid-Continent Ecology Division provides a framework for linking initial molecular or cellular effects measured by in vitro assays to an adverse outcome of relevance in risk assessment (i.e., effects seen in individuals or populations). This conceptual framework, once sufficiently developed, would better enable risk assessors to make use in vitro methods and information collected at multiple levels of biological information to estimate whole organism and population-level effects. Until libraries of data demonstrating linkages between molecular initiating events, key events and apical endpoints are developed, the utility of in vitro methods may be limited to identifying degradates of concern and possibly prioritizing the chemicals needing expedited reviews. The AOP concept though will lead to greater qualitative and eventually quantitative use of in vitro, high through-put (HTP) assays in risk assessment. This presentation will provide an overview of the current and future use of these tools in the ecological risk assessment of conventional pesticides.

31 Impact of the Polychaete Worm Nereis Diversicolor on Mercury Speciation in Intertidal Mudflats T. Sizmur, Univ of Reading, Soil Research Centre, Soil Science Dept; S. Edmonds, Acadia Univ, Biodiversity Research Institute; A. Godfrey, Acadia Univ; J. Canario, INRB IP/IPIMAR; A. Redden, M. Mallory, G. Gibson, N. O'Driscoll, Acadia Univ. Central Nova Scotia is a biological mercury (Hg) hotspot as evidenced by elevated Hg concentrations in organisms feeding at higher trophic levels. The Minas Basin in the Bay of Fundy, Nova Scotia is home to the highest tidal amplitudes in the world giving rise to extensive intertidal mudflats. Some areas of mudflats in the Minas Basin contain elevated concentrations of methyl mercury (MeHg), due to the availability of inorganic matter and to the reduction of Fe(III) and/or SO_4^{2-} during organic matter oxidation by sediment microorganisms. Recent observations indicate a change in the ecology of the mudflats leading to an increase in the abundance of polychaete worms such as *Nereis diversicolor*. *N. diversicolor* feed on organic detritus and microorganisms associated with surface sediments and live in permanent U- or Y-shaped burrows which they ventilate and oxygenate with fresh seawater, increasing the sediment-water interface by up to three times. Sediments were collected from four intertidal mudflats in the Minas Basin at Wolfville (MeHg: 569 pg g^{-1}), Windsor (MeHg: 546 pg g^{-1}), Hantsport (MeHg: 358 pg g^{-1}) and Kingsport (MeHg: 448 pg g^{-1}) and incubated 10 *Nereis diversicolor* (collected from the Wolfville site) in microcosms containing 300 g of sediments alongside worm-free control microcosms for 14 days. Hg(II) and MeHg concentrations were determined in samples taken from surface and bulk sediments of all treatments and sediments from the oxygenated burrow walls of the worm-inhabited Wolfville and Windsor treatments. MeHg concentrations in the surface sediments were consistently lower than in the bulk samples. The percentage of MeHg in surface samples of worm-inhabited microcosms decreased in Wolfville (1.5 to 1.2 %) and Windsor (1.4 to 0.8 %) sediments compared to the worm-free treatments. However, %MeHg in burrow walls of worm-inhabited Wolfville (1.6 %) and Windsor (1.2 %) treatments were similar to surface sediments of control treatments. This research indicates that the worms reduced MeHg concentrations in the surface sediment, possibly due to feeding and bioaccumulation in their tissues. In addition mercury was demethylated in the burrow walls due to ventilation of burrows with aerated seawater and subsequent aeration of the surrounding sediment. This has important implications for mercury biogeochemical cycling in coastal ecosystems.

32 Comparison of Mercury Localization, Speciation, and Histology in Multiple Fish Species from Caddo Lake, a Fresh Water Wetland J. Smith, Univ of North Texas; M.M. Chumchal, Texas Christian Univ, Biology Dept; J. Schulmeier, Dermatopathology Associates; G. Verbeck, Univ of North Texas; B.W. Matherne, Univ of North Texas, Dept of Biological Sciences; B. Barst, Université du Québec, INRS-ETE; A. Roberts, Univ of North Texas. Mercury (Hg) contamination is a global problem with implications for both ecosystem and human health. Concentrations of Hg in Caddo Lake (TX/

LA, USA) fish are within the range of those reported by other authors to result in reduced fitness and reproduction. Measures of melanomacrophage aggregates (MA) in fish have been correlated with exposure to a variety of environmental contaminants including Hg and also vary in tissue of residence based on fish species. Mercury has been shown to accumulate in MA in gar from Caddo Lake. However, the mechanistic relationship between MA and Hg is unknown. Gar from Caddo Lake show very high proportions of inorganic mercury in the liver, a tissue that, in gar, has extensive MA. Bass from Caddo Lake show much lower levels of inorganic mercury in liver than gar, and have no discernable MA. This study examined the livers and spleens of wild fish from Caddo Lake to determine associations between MA content, mercury speciation, localization, and tissue histology. Liver, spleen, and muscle samples from spotted gar (*Lepisosteus oculatus*), largemouth bass (*Micropterus salmoides*), channel catfish (*Ictalurus punctatus*) and bowfin (*Amia calva*), were collected from wetland habitat types. Evidence was sought for liver and spleen pathology association with mercury concentration and speciation in liver and spleen. Laser ablation ICP-MS was used to compare Hg accumulation between MA and histologically unremarkable parenchyma cells in liver and spleen.

33 Modelling Mercury Biomagnification Through Acidic Lake Food Webs M. Clayden, Canadian Rivers Institute, Univ of New Brunswick, Biology Dept; B. Wyn, North South Consulting; K. Kidd, Canadian Rivers Institute, Univ of New Brunswick, Biology; J. Kirk, D. Muir, Environment Canada, Water Science and Technology Directorate; N. O'Driscoll, Acadia Univ, Dept of Earth and Environmental Sciences. Kejimkujik National Park is a relatively remote and pristine area in southwestern Nova Scotia, Canada. Nonetheless, it receives mercury (Hg) and acidifying pollutants in precipitation due to its location downwind of industrial and urban centres in the northeastern United States and southern Canada. As such, the pH of lakes in the park has declined beyond naturally low levels, and Kejimkujik has been identified as a hotspot of biological Hg contamination in North America. Between 2006 and 2010, we conducted food web studies on 11 lakes in the park with a range of physical and chemical characteristics. Our aims were: 1) to compare Hg biomagnification in these lakes to near neutral systems; and 2) to determine whether chemical characteristics (e.g., pH, trophic status, metals) explained any among-lake differences in Hg biomagnification or its concentrations in lower trophic levels. To do this, we measured methyl Hg (MeHg) and total Hg (THg) in zooplankton, macroinvertebrates, fishes, sediments and water, as well as sources of energy (using S and C isotope ratios) and trophic position (using N isotope ratios) of the biota, and chemical characteristics of the lakes. As in other studies, we used the linear regression slope of log Hg versus N isotope ratios to model Hg biomagnification through the food web of each lake. Although our study lakes are acidic and oligotrophic (pH 4.6 – 6.0, total phosphorus (TP) 0.006 – 0.014 mg/L), regression slopes ranged from 0.16 ± 0.01 to 0.23 ± 0.01 (R^2 = 0.72 – 0.91; $p < 0.001$), similar to those from more neutral and eutrophic freshwater systems. We found that food web biomagnification of Hg was negatively correlated with trophic status across lakes (total nitrogen (TN), r = -0.72 p = 0.018; TP, r = -0.71, p = 0.022). Levels of Hg at the base of the food webs were also negatively related to TN (r = -0.66, p = 0.039) and pH (r = -0.81, p = 0.005), but positively related to dissolved organic carbon (r = 0.80, p = 0.006), and some metals (e.g., aluminium, r = 0.88, $p < 0.001$). Our results suggest that Hg biomagnification and its concentrations at the base of the food web and in fish are affected by chemical characteristics of the lakes. Further research will compare whether food web structure, including sources of energy, also influence Hg concentrations in the biota of these lakes.

35 Measurements and Model Results of Mercury Air-Sea Exchange Near Bermuda A.L. Soerensen, Harvard Univ, Departmen of Environmental Health; E. Sunderland, Harvard Univ; R. Mason, M. Andersson, P. Balcom, Univ of Connecticut. New global modeling results show evasion of elemental Hg (Hg(0)) from the ocean is comparable in magnitude to direct anthropogenic emissions. Results show that 80% of the Hg load deposited to the ocean surface reenters the atmosphere as the result of air-sea exchange, while 20% will accumulate in the subsurface ocean. Efforts to understand air-sea exchange on a global scale are currently constrained by sparse measurement data. However, the possibility of simultaneous measurements of Hg(0) in air and water now makes it possible to calculate air-sea exchange with a high temporal resolution and to validate model simulations of concentrations and fluxes at the air-sea interface. Here we compare air-sea exchange based on cruise observations and model simulations with a 3-hour average temporal resolution. Measurements of dissolved Hg(0) in seawater and total atmospheric gaseous mercury (TGHg) are from four cruises in the West Atlantic Ocean between 2008–2010. Seawater Hg(0) was estimated from equilibrium air concentrations determined every 5 minutes with a Tekran 2537A and collected using a continuous sparging set-up with a high water/air flow ratio that ensured gas:water equilibrium (seawater flow was 10-16 L/min and the Hg air flow 1.5 L/min). Water concentrations were calculated from these measured air concentrations using Henry's law. Atmospheric concentrations were measured every 5 minutes using another Tekran 2537A. Results show average atmospheric cruise concentrations of 1.4-2.3 ng/m3. Measured average seawater Hg0 concentrations ranged from 0.06-0.14 pM during the cruises, while the corresponding fluxes of Hg0 to the atmosphere predicted from the observational data were between 10-24 pmol/m2/hr, depending on wind speed and water temperature. Comparison of these observations to modeled results from the surface-slab ocean simulation for Hg in the GEOS-Chem biogeochemical model shows reasonable agreement. The model underestimates seawater concentrations in coastal regions and during a strong summer storm. We discuss recent improvements to the model to improve overall performance and present sensitivity results from a various air-sea exchange parameterizations.

36 The Presence and Measurement of Organic Mercury Species in the Arctic Troposphere P.A. Baya, H. Hintelmann, Trent Univ, Environmental and Life Sciences. Mercury (Hg) is a persistent atmospheric pollutant that exhibits long range transport and bio-accumulates in the aquatic ecosystem in the form of monomethylmercury (MMHg), the toxic form of mercury. The sources and fate of MMHg in the ecosystem and the contribution of the atmosphere is however still unclear. Even if the atmosphere is the major pathway of Hg contamination in the arctic, the direct and indirect atmospheric MMHg contribution to the aquatic ecosystem is not well understood due to the lack of known reliable measurement methods for organic Hg in the atmosphere. In the arctic open waters where there is net deposition of Hg, DMHg can be volatilized from surface water as suggested in various studies. The atmospheric DMHg may quickly degrade to MMHg and is then potentially deposited to snow packs on ice fields or back to open waters. Such a behavior would make DMHg a major source of MMHg to the arctic ecosystems. To establish the presence of organic Hg species in arctic troposphere, an analytical method was developed. The method is based on species specific Hg isotopic dilution and online ethylation of MMHg from air samples and trapping of ethylated MMHg and DMHg on Tenax traps. This study presents for the first time concentrations of organic mercury species (monomethylmercury and dimethylmercury) in the arctic lower atmosphere (Hudson Bay and Canadian Archipelago) measured during the CGCS Amundsen expedition in summer 2010. The Hudson Bay airshed is dominated by MMHg ranging from 3.9 – 8.1 (mean = 5.5 ± 2.0, n=5) pg/m^3, while concentrations of DMHg ranged from < LOD to 1.6 (mean = 0.8 ± 0.6, n = 4) pg/m^3. In the high Arctic however, DMHg concentrations are highest ranging from 1.8 to 9.6 (mean = 4.3 ± 2.1, n = 12) pg/m^3. MMHg levels were significantly lower than those measured in Hudson Bay ranging from < LOD to 5.2 (mean = 1.7 ± 1.7, n = 12) pg/m^3.These findings support the hypothesis that organic mercury species can be volatilized from the ocean and contribute directly to MMHg bio-accumulation in the arctic ecosystem. The concentrations of organic Hg in water as well as the extent of DMHg photodegradation may be important factors affecting the organic Hg species concentrations. The potential sources and factors affecting organic Hg species concentrations and compositions in arctic air will be further discussed in the presentation.

37 Methylmercury Cycling in High Arctic Wetlands: What Are the Controls on MeHg Production? I. Lehnherr, Univ of Waterloo, Earth and Environmental Sciences; V.L. St Louis, Univ of Alberta, Biological Sciences; J.L. Kirk, Research Scientist, Environment Canada; C.A. Emmerton, Univ of Alberta, Biological Sciences; J.D. Barker, Ohio State Univ. Some freshwater fish in the Arctic contain levels of methylmercury (MeHg) that pose health risks to Inuit peoples harvesting these species as traditional food. In temperate regions, wetlands are known sources of MeHg; however, the importance of wetlands to Hg methylation in the Arctic is unclear and the sources of MeHg to arctic freshwater ecosystems are still unidentified. The objective of this study was to quantify MeHg production in wetland ponds near Lake Hazen (81°N) in the Canadian Arctic and determine the biogeochemical controls on MeHg production. To quantify net in-pond

production of MeHg during the summer seasons of 2005, 2007 and 2008, mass-balance budgets were constructed for two wetland ponds (Ponds 1 and 2) by measuring external MeHg inputs from atmospheric deposition, MeHg losses from photodemethylation, and changes in MeHg storage in the water column. MeHg inputs from precipitation were small (0.026-0.051 ng/m2/d). Photodemethylation was a sink for 77–122% of MeHg produced in-pond, and was controlled by the attenuation of UV-A radiation in the water column. In-pond MeHg production ranged from 14-40 ng/m^2/d in Pond 1 and 1.7-1.9 ng/m^2/d in Pond 2, comparable to what has been reported for temperate lakes and wetlands. Flooding of the Pond 1 wetland in 2008 due to rising water levels in nearby Lake Hazen resulted in increased MeHg production. Additionally, potential rates of Hg(II) methylation were quantified in intact sediment cores (n=29) from a number of ponds using Hg stable-isotope tracers to identify the factors controlling MeHg production. Potential methylation rates were high and exhibited nearly as much intra-site as inter-site variability. Sediment MeHg concentrations were significantly correlated to methylation potential and sediment total-Hg concentrations. Furthermore, pond water MeHg concentrations were positively correlated with sediment MeHg concentrations, indicators of anaerobic microbial decomposition of organic matter (pCH_4, NH_4^+/NO_3^- ratio), and negatively correlated with UV-A exposure and particulate carbon. However, no correlation with sulfate was observed. Our results demonstrate that Arctic wetland sediments are sources of MeHg comparable to freshwater sediments in temperate latitudes and that MeHg concentrations in water are controlled by production in sediments – itself a function of anaerobic microbial activity, methylation potential and Hg(II) availability – as well as photodemethylation in the water column.

38 In Situ Optical Measurements as Proxies for Stream Mercury J. Shanley, G. Aiken, B. Pellerin, J. Saraceno, US Geological Survey; A. Riscassi, Univ of Virginia; C. Driscoll, Syracuse Univ; B. Beramaschi, US Geological Survey. Recent advancements in inexpensive in situ optical sensors permit continuous measurements that reveal information about the quantity and quality of stream organic matter. Due to the close relation between organic matter and mercury transport, we have applied in situ fluorescing dissolved organic matter (FDOM) as a proxy to generate continuous time series of aqueous mercury (Hg) concentrations. Typically only about 2% of organic matter fluoresces, but the measurement is highly sensitive and fairly specific to the fraction of DOM that is associated with Hg transport. We have measured FDOM in three northeastern USA forested research catchments and compared in situ FDOM to total dissolved Hg concentrations in discrete samples. Correlations of dissolved total Hg with in situ FDOM were somewhat lower than anticipated due to occasional interference of FDOM by high turbidity. However, with accurate and continuous turbidity measurements, one can compensate for this source of error. Optical turbidity measurements have the added advantage of serving as a proxy for particulate organic matter, which is often highly correlated to particulate Hg, the dominant form of Hg export in some streams. By combining these proxies, it is possible to quantify the majority of Hg flux in these streams. Because dissolved and particulate Hg both vary strongly but not always predictably with flow, these high frequency optical proxies greatly improve the accuracy of Hg flux calculations.

39 Molecular Mechanisms of Interest in Nanomaterial Toxicity in Aquatic Species: Beyond Oxidative Stress R. Klaper, Univ of Wisconsin-Milwaukee, School of Freshwater Sciences, Great Lakes Water Institute; D. Arndt, Univ of Wisconsin-Milwaukee, Great Lakes Water Institute, School of Freshwater Sciences; J. Crago, Univ of Wisconsin-Milwaukee, Great Lakes Water Institute; F. Goetz, Univ of Wisconsin-Milwaukee, School of Freshwater Sciences; J. Chen, Univ of Wisconsin-Milwaukee, Chemistry. Much of the focus of nanotoxicology to date has been on the impact of various particle types on acute mortality in various model systems. Mechanistic information on how a nanomaterial may cause toxicity has had a significant focus on oxidative stress. However, oxidative stress assays provide limited information regarding how an organism may interact with a particle type and how nanomaterials may differ in their interactions with organisms. Different molecular mechanisms may be triggered depending on nanomaterial chemistry. This presentation will discuss how nanomaterials with differing structure and surface chemistry differ in their impact on the molecular profiles of the model organisms *Daphnia* and rainbow trout. Several carbon-based nanomaterials were used in exposures including fullerenes (nC_{60}) and single-walled carbon nanotubes as well as fullerenes modified with hydroxylation and β-Cyclodextran, and single walled carbon nanotubes modified with PEG, carboxylic acid and NH_2. We have also tested the metal oxide titanium dioxide. Our research has shown that the environmental impact of manufactured nanomaterials clearly differs with nanomaterial and concentration and the mechanisms triggered by each nanomaterial also differs. In *Daphnia*, genomic expression data were gathered using high-throughput sequencing and monitored across particle types and exposure concentrations and durations using QPCR of individual genes to determine potential mechanisms that may be acting across different exposure types. Nanomaterial exposure causes the up or down regulation of genes associated with several important pathways that include oxidative stress but other important functions as well such as immune response, growth and molting, protein synthesis, reproduction and others. In rainbow trout microarrays of important immune genes indicate differences in the number of genes and expression profiles across particle types. In both studies we have found that individual gene expression and global patterns differ with nanomaterial functionalization or surface chemistry indicating that surface chemistry may be more important than just core chemistry in determining molecular responses of aquatic species to nanomaterials.

40 The Effects of Metal Nanoparticles on ROS Production and Developmental Processes in Marine Organisms S. Gilbert, Univ of North Carolina at Charlotte, Dept of Biology; M. McCarthy, Univ of North Carolina at Charlotte; L. Marston, North Carolina State Univ; D. Carroll, Wake Forest Univ, Center for Nanotechnology and Molecular Materials; N. Levi-Polyachenko, Wake Forest Univ, Dept of Plastic and Reconstructive Surgery; A. Ringwood, Univ of North Carolina at Charlotte. The importance of evaluating the biological effects of engineered nanoparticles on marine invertebrates is becoming increasingly evident. The manufacture and use of nanoparticles continues to rise and the probability of these nanoparticles entering the aquatic ecosystem is increasing. Thus, the purpose of these ongoing studies is to characterize the toxicity of various metal nanoparticle preparations on developmental forms of oysters, *Crassostrea virginica* and sea urchins, *Arbacia punctulata*. Studies are being conducted with embryos and larvae of both species to examine and compare the effects of metal nanoparticles on protostomic and deuterostomic development. Newly fertilized oyster and sea urchin embryos were exposed to three types of silver nanoparticles (seeds, prisms, and plates) over a range of concentrations, and then the percent normal development as well as reactive oxygen species (ROS) levels were assessed. Older sea urchin and oyster larvae were also exposed to a range of silver nanoparticle concentrations for 7 days and growth was assessed. Silver nanoparticles resulted in a change in ROS production in embryos, and there was evidence of shape dependent differences in toxicity. Similar studies were also conducted using TiO_2 nanoparticles. These basic studies are essential for addressing the potential impacts of engineered nanoparticles on fundamental developmental and cellular processes.

41 Phototoxicity of TiO_2 Nanoparticles Under Solar Radiation is Dependent on Solar UV Spectrum H. Ma, A. Brennan, US Environmental Protection Agency, Mid-Continent Ecology Division; S. Diamond, US Environmental Protection Agency, MED. Titanium dioxide nanoparticles (nano-TiO_2) are currently used in a broad range of applications from photocatalysts to personal-care products. Phototoxicity of these nanoparticles has become an important concern as some forms can be readily photoactivated under environmental UV radiation (i.e., solar radiation) and generate reactive oxygen species (ROS). In this study, photocatalytic ROS production and phototoxicity of nano-TiO_2 (Aeroxide P25) to Daphnid magna were investigated under different solar UV spectrum by applying a series of spectral filters (i.e., standard window glass, microscope slide, petridish glass, acrylic glass, 345 nm, 360 nm, and 400 nm cutoff filters) within a solar simulator. Photocatalytic ROS production was measured by APF [3' (*p*-aminophenyl) fluorescein] assay, a fluorescent-based ROS assay with great specificity to OH•. Phototoxicity was evaluated by immobilization of *D. magna*. Intracellular ROS production was determined by H_2DCFDA assay. Microscope slide, petridish glass, and standard window glass, which gradually block UVB (280–320 nm), had no impact on photocatalytic ROS production by nano-TiO_2; whereas the 345 nm and 360 nm cutoff filters, and acrylic glass (with an approximate cutoff at 380 nm), which gradually block UVA (320–400 nm) from solar radiation, decreased ROS production by 8%, 31%, and 94%, respectively, as compared to no filter, at 1000 ppb TiO_2. The 400 nm cutoff filter decreased ROS production by 100%, proving the band gap theory concept for TiO_2 nanoparticles, that only wavelength at

or below 388 nm can induce photoactivation. The impact of these spectral filters on phototoxicity of nano-TiO_2 was well in agreement with their impact on photocatalytic ROS generation of the nanoparticles. Standardized to control (no filter treatment), immobilization of *D. magna* by 500 ppb nano-TiO_2 under different filters showed the following order: no filter (100%) > standard window glass (92%) > 345 nm cutoff (57%) > 360 nm cutoff (15%) > acrylic glass (4%) > 400 nm cutoff (0%). A linear correlation was found between ROS production of nano-TiO_2 and its phototoxicity to *D. magna* (r=0.97, n=5, p< 0.001), suggesting that photocatalytic ROS production may be a predictor of phototoxicity for these nanoparticles. Intracellular ROS production was consistent with *D. magna* immobilization, indicating oxidative stress was involved in the phototoxicity. Findings from this study demonstrate that phototoxicity of nano-TiO_2 can occur under natural solar radiation and variation of solar radiation spectrum may have significant impact on phototoxicity of these nanoparticles.

42 Nanoparticle Uptake in Freshwater Aquatic Macrophytes Is Size and Species Dependent B. Glenn, Clemson Institute of Environmental Toxicology; S.A. White, Clemson Univ, Clemson Institute of Environmental Horticulture; S.J. Klaine, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX). Partitioning of 4nm and 18nm spherical gold nanoparticles (AuNPs) to aquatic macrophytes was investigated in vivo. Three morphologically distinct macrophytes were studied. *Myriophyllum simulans* Orch. and *Egeria densa* Planch. are submerged aquatic vascular plants while *Azolla caroliniana* Willd. is a free-floating aquatic fern. Since aquatic plants absorb the majority of their nutrients from the water column; it is logical to hypothesize that they may absorb nanomaterials in suspension. Each plant was exposed to nominal concentrations of 250µg/L AuNPs for 24hrs. Macrophytes were harvested at 6 time-points (1,3,6,12,18 and 24hrs), dried and then analyzed for gold concentration via inductively coupled plasma mass spectrometry. Concentrations were normalized to whole plant dry tissue mass. Here we show absorption of AuNPs via root uptake was size and species dependent. Electron microscopy revealed that 4nm and 18nm AuNPs adsorbed to the roots of each species. Root tissue was sectioned and transmission electron microscopy indicated that 4nm and 18nm AuNPs were absorbed by *A. caroliniana*, however only 4nm AuNPs were absorbed by *M. simulans*. *Egeria densa* did not absorb AuNPs of either size. AuNPs were confirmed in tissue using energy-dispersive X-ray spectroscopy. AuNP absorption by plants may be a function of salinity tolerance of each species.

43 Disruption of Intestinal Microbiota in Fish After Ingestion of Some NPs Indicates Potential for Effects of Dietary NP Exposure on Organism Health T. Henry, Univ of Plymouth, School of Biomedical and Biological Sciences, School of Biology; D. Merrifield, Univ of Plymouth, School of Biomedical and Biological Sciences. Nanoparticles are used in some food and food packaging applications and ingestion NPs can occur in organisms. In addition, food consumed by organisms can be contaminated by NPs if NPs are released into the environment. Ingested NPs could cause toxicity if they are absorbed and transported within organisms to vulnerable tissues and the issue of whether NPs are absorbed across epithelial membranes is a significant focus within the emerging discipline of nanotoxicology. However, it is possible that negative effects of NPs can occur in organisms without absorption of the particles across epithelial membranes. We evaluated whether ingested NPs [Cu-NPs, Ag-NPs, C_{60}, and single walled carbon nanotubes (CNTs)] incorporated into food pellets could affect the intestinal epithelium or microbial community structure within the gut of adult zebrafish. Zebrafish food (pellets) were prepared containing NPs (500 mg/kg food), and control food supplemented with either $CuSO_4$ or $AgNO_3$ (equivalent metal concentrations) or carbon black (equivalent carbon concentrations), and a control food without added metal or carbon. Adult zebrafish were fed for 14 d and intestines were sampled for assessment of microbial community: bacterial DNA extraction, PCR amplification of the 16S rRNA V3 region, separation of PCR products by DGGE analysis, and sequence analysis. Presence of lesions and absorption of NPs across intestinal epithelia were assessed by EM. No treatment effects on food palatability, feeding rate, fish behavior or mortality occurred; and no evidence of NP absorption was observed. Changes in intestinal microbial community structure were minimal for all Ag treatments relative to the control (similarity coefficients >91%), but Cu treatments caused substantial alteration of community structure (< 65% and < 43% similarity relative to control, for Cu and Cu-NP treatments respectively). For the metal NPs, Cu-NP treatment had greatest effect on microbial community structure and inhibited some endogenous and beneficial bacterial strains to non-detectable levels and was clearly more disruptive than elemental Cu exposure. Analysis of effects of carbon NPs on microbiota and intestinal epithelia are ongoing. The potential for some types of NPs to change intestinal microbial community structure could affect nutritional status, ability to defend against pathogens, and overall organism health.

44 Interactions of C_{60}, Multi-Wall Carbon Nanotubes (MWCNT), and Single Wall Carbon Nanotubes (SWCNT) with Natural Organic Matter, Bacteria and Biofilms J.R. Lawrence, M.J. Waiser, Water Science and Technology Directorate, Environment Canada; G. Swerhone, Water Sciences and Technology Directorate, Environment Canada; V. Tumber, Water Science and Technology Directorate, Environment Canada; J. Roy, Water Science and Technology Directorate, Environment Canada; A. Paule, Université de Toulouse, EcoLab Laboratoire d'écologie fonctionnelle; J.J. Dynes, Canadian Light Source Inc; D.R. Korber, Univ of Saskatchewan, Food and Bioproducts Sciences. The commercial production of nanoparticles (NP) (those with at least one dimension < 100 nm) has generated a need for research to support regulation of the nanotechnology sector. In the current study, scanning transmission x-ray microscopy (STXM) at the C 1s edge was used to study the fate of a variety of carbon nanomaterials in a complex natural river biofilm, demonstrating rapid aggregation and extensive coating with lipo-protein and carbonates. Although modified by sorption processes, these carbon-based materials were shown, using confocal scanning laser microscopy, conventional and molecular analyses, to have significant effects on community structure and function. Microbial biofilm communities were developed in rotating annular reactors during continuous exposure to 500 ug L^{-1} of each nanomaterial. Microscopy observations indicated that the communities were visibly different in appearance with changes in abundance of filamentous cyanobacteria, in particular. Microscale analyses indicated that fullerene did not significantly impact algal, cyanobacterial or bacterial biomass. In contrast, MWCNT exposure resulted in a significant decline in algal and bacteria biomass. Interestingly, the presence of SWCNT products significantly increased algal biomass but had no significant impact on cyanobacterial or bacterial biomass. Thymidine incorporation indicated that bacterial production was significantly reduced by all nanomaterials with the exception of fullerene. Biolog assessment of community carbon utilization patterns revealed few significant effects. PCA and ANOSIM analyses of denaturing gradient gel electrophoresis (DGGE) results indicated that the bacterial communities exposed to fullerene were not different from the control, the MWCNT and SWNT-OH differed from the control but not each other, whereas the SWCNT and SWCNT-COOH both differed from all other treatments and were significantly different from the controls. Fluorescent lectin binding analyses also revealed changes in microbial community structure during exposure to all tested nanoproducts. Observations indicated that at 500 ug L^{-1}, carbon nanomaterials significantly altered microbial community structure and function, supporting the need for further evaluation of their effects in aquatic habitats.

45 Effects of Silver Nanoparticles on Filter-feeding Tadpoles in Different Source Waters C.M. Fridgen, M. Xenopoulos, Trent Univ, Biology; C. Metcalfe, Trent Univ, Environmental and Resource Studies. Engineered silver nanomaterials (nAg) are widely used in a variety of products and have the potential to be released into the aquatic environment. Recent research has shown variable toxicity of nAg to aquatic organisms, which could be due to a range of factors, including the release of silver ion, the capping agent and the chemical composition of the water. In this study, we tested for the acute toxicity of a carboxy-functionalized capped nAg with a reported particle size of 2–10 nm sold by ViveNano (Toronto, ON, Canada) and $AgNO_3$ on the common bull frog tadpole (*Rana catesbieana*) reared in water from seven different sources (2 rivers, 2 natural ponds, 2 urban storm water ponds) and dechlorinated tap water. LC_{50} (96 h) values for the nAg varied significantly between water sources, ranging from 141±36 µg/L (tap water) to 474±21 µg/L (pond water). In all source waters, $AgNO_3$ at 100 µg Ag/L caused greater mortalities to the tadpoles than nAg at 200 µg Ag/L. However, in one source water (i.e., natural pond) with especially high dissolved organic carbon (DOC), $AgNO_3$ was not toxic. Out of all water parameters assessed (ph, common ions and nutrients) DOC was the only factor which showed correlation with the fate and toxicity of Ag. For treatments with $AgNO_3$, tadpole mortality was significantly reduced with increasing DOC (r=-0.94, p=0.001), but DOC had no significant effect on nAg toxicity. Using ICP-OES, we measured total Ag in the water column and tadpoles

at 0 and 96-hrs of exposure to nAg and $AgNO_3$. The amount of total silver that persisted in the water over 96 hrs was positively correlated with DOC (r=0.71, p=0.008) in the $AgNO_3$ treatments, but persistence was not related to DOC in the nAg treatments. Whole-body Ag content in the tadpoles was linearly correlated with mortality rate in the $AgNO_3$ treatment (r=0.72, p=0.012) but not in the nAg treatments. These data indicate that nAg is not as acutely toxic as $AgNO_3$ to the tadpoles and that DOC has little effect on the toxicity of this carboxy-functionalized material. While the free silver ion may be a toxic component of nanosilver products, trends for toxicity and fate of a carboxylated nano silver products did not follow the same trends as was observed with $AgNO_3$. More research will be conducted looking at chronic exposure of the carboxylated silver nanoparticles in various exposure waters.

46 Silver Nanoparticle Toxicity to Atlantic Killifish and Zebrafish in Complex Environmental Media: Laboratory, Mesocosm and Microcosm Studies A.J. Bone, Duke Univ, Nicholas School of the Environment; C.W. Matson, Duke Univ, CEINT, Baylor Univ, Environmental Science; B. Colman, Duke Univ, CEINT; R.T. DiGiulio, Duke Univ, Nicholas School of the Environment, CEINT. The increasing use of silver nanoparticles in consumer products and industrial applications has created concern over their inevitable release into the aquatic ecosystem. In this study, the effect of complex environmental media on silver nanoparticle toxicity was investigated using gum arabic coated silver nanoparticles (Ag-GA NP), polyvinylpyrollidone coated silver nanoparticles (Ag-PVP NP), silver nitrate ($AgNO_3$) treated mesocosms containing sediment and aquatic plants modeled after North Carolina wetlands. A follow up microcosm experiment was used to investigate the role of different sources of dissolved organic material (DOM) on silver nanoparticle toxicity. Surface water samples were taken from the mesocosms at 24 hours after dosing and compared to lab-incubated samples prepared by spiking water taken from untreated control mesocosms with Ag-GA NP, Ag-PVP NP and $AgNO_3$ in the lab at the same concentrations observed in the mesocosms at 24 hours. Mesocosm samples and lab-incubated samples were compared using acute toxicity testing for mortality to early life stage Atlantic killifish (*Fundulus heteroclitus*) and zebrafish (*Danio rerio*). Any differences in the toxicity between the lab-incubated water and the mescosm water could thus be attributed to the more complex environment created by introducing plants, sediment and general environmental conditions such as sunlight in addition to the natural water chemistry. In general, lab-incubated samples were more toxic than samples taken from the mesocosms. However, for Ag-PVP NP, mesocosm samples were more toxic than lab-incubated samples, indicating that an environmental factor unique to the mesocosms is causing increased toxicity of Ag-PVP NP. In addition, for mesocosm samples, both Ag-GA NP and Ag-PVP NP were more toxic than $AgNO_3$ on an equal mass basis. Therefore, the complex media is acting differently on Ag^+ to reduce its toxicity in a manner that does not translate to Ag-GA or Ag-PVP NP. Microcosm experiments using the same particles with four environmental scenarios (water only, sediment + water, plants + water, and plants+sediment+water) indicate that plants are the strongest protective factor and that sediment may have contributed to the increased toxicity of Ag-PVP NP. These results suggest that conventional laboratory testing and equation of silver nanoparticles to ionic silver on a mass basis may be inadequate for silver nanoparticle risk assessment.

47 Integration of Density Dependence and Concentration Response Models Provides an Ecologically Relevant Assessment of Populations Exposed to Toxicants S. Raimondo, US Environmental Protection Agency, Gulf Ecology Division, National Health and Environmental Effects Laboratory; H. Rutter, Student Services Contractor to USEPA; C.R. Jackson, B. Hemmer, US Environmental Protection Agency. The assessment of toxic exposure on wildlife populations involves the integration of organism level effects measured in toxicity tests (e.g., chronic life cycle) and population models. These modeling exercises typically ignore density dependence, primarily because information on density dependence functional forms is lacking for most species. The interactions between population density and toxicant exposure can be synergist or antagonistic, resulting in either under or overestimation of toxicant effects based on low density toxicity tests and density independent models. To explore the relationship between population density dependence and toxicant concentration, we simulated the exposure of a density dependent sheepshead minnow (*Cyprinodon variegatus*) population to five chemicals of various modes of action (estradiol, trenbolone, trifluralin, chlordane, pentachlorophenol). The functional form of density dependence was derived from laboratory density manipulation experiments that modeled the influence of adult density on juvenile survival and growth and adult survival and reproduction. Concentration-response models were developed from the chronic toxicity tests for all endpoints within each chemical where significant effects were measured. For each chemical, exposure was simulated across a wide range of densities and concentrations, applying density dependent mechanisms and concentration response curves at each density-concentration combination. The relationship between density and toxicant concentration for each chemical was modeled and described using population growth rate (PGR) contours. These contours identify compensatory and synergistic responses over a range of densities and concentrations for each chemical and demonstrate alterations to "carrying capacity" (PGR = 0) relative to stress and density, which provides the boundary of a population's tolerance to the model stressor. This work demonstrates how the integration of intraspecific interactions and organism toxicant response can provide a more ecologically relevant assessment of population response to toxicant exposure.

48 A Framework for Integrated Fish Monitoring: An Example Based on 20 Years of Data for Perch N. Hanson, Univ of Gothenburg, Dept of Plant and Environmental Sciences; L. Forlin, Univ of Gothenburg, Dept of Zoology; A. Larsson, Univ of Gothenburg, Dept of Plant and Environmental Sciences. Environmental monitoring is performed to provide information that can be used by environmental managers to protect ecological resources. Chemical and physical measurements have for a long time been used as the primary source of information. However, such measurements are not helpful when environmental degradation is caused by unexpected chemicals or processes. Biological measurements can be used to get an integrated picture of all stress that affects the ecosystem. Sub-organismal biomarkers provide information about the health and exposure of individuals, and can be used as early warning signals for new or unexpected chemicals. Biomarkers may also give some information about the cause of the stress. However, the ecological services that we want to protect are performed by populations. Therefore, effects on the population level may have higher relevance for management. The population level integrates everything that affects the population, including non chemical stress. A drawback with the population level is that it is difficult to establish causal relationships to identify the stressor. Fish are used frequently for environmental monitoring. Different types of strategies for fish monitoring include chemical measurements in fish tissue, biomarker responses, and the size and structure of fish populations and communities. All these parts are included in the program for Integrated Fish Monitoring, which is a part of the Swedish Environmental Monitoring Program. This program was started to provide reference data for investigations of potentially contaminated sites. However, the reference data has not been used to the extent that was intended. One of the reasons for this is that there is no guidance on how to integrate the responses of the different measurements in a way that is informative for environmental managers. Based on the program for Integrated Fish Monitoring, we have developed a framework for integrating responses from five lines of evidence (LOE); contamination, eutrophication, biomarkers of exposure, fish physiology, and the population level. Each of the five LOE provides important information about the health of the aquatic ecosystem. Based on the available data, each of the five LOEs is determined to be either affected or not affected, resulting in 32 possible outcomes. To aid risk assessors and environmental managers, a decision matrix was set up with interpretations and recommended action for each of the 32 possible outcomes.

49 Endocrine Disruption in an Urban Estuary and its Catchment Drains D. Webb, Curtin Univ, Environment and Agriculture. The Swan-Canning Estuary (SCE) is of environmental and cultural importance to the population of Perth, Western Australia. Like all urban estuaries it has become increasingly eutrophic marked by annual algal blooms due to over or incorrect application of fertilisers. Fish, and recent dolphins, deaths have highlighted other water quality issues potentially due to non-nutrient contamination. Furthermore, there has been a decline in the populations of several fish species such as cobbler and Perth herring as well as the almost disappearance of the western school prawn (*Metapenaeus dalli*) from the estuary. A pilot study in catchment drains discharging to the SCE show evidence of endocrine disruption and impaired DNA repair pathways in freshwater shrimp (*Palaemonetes australis*). There was a strong bias towards females in all drains, and intersex was above the normal incidence in crustaceans at several sites. Biomarker and intersex results recorded in this study

have implications for the long term health of all crustacean species within the influence of the types of contaminants measured in the estuary and its tributary drains. Studies using male *Gambusia holbrooki* have identified fish with impaired gonopodial development adding to the evidence of the presence of endocrine disrupting chemicals in drainage to the SCE. Because of the scope of global climate change further stresses will be added to communities already impacted by anthropogenic disturbances. Investigations are planned to study both direct and indirect biological effects to aquatic biota due to changes predicted to occur in the SCE and its surrounding catchment as a result of declining stream flows.

50 Mercury Bioaccumulation in Elasmobranchs N.J. Kutil, Roger Williams Univ, Marine Biology; M. Soto, Roger Williams Univ, Marine Biology, UNAM, Instituto de Ciencias del Mar y Limnologia. Mercury (Hg) is a toxic environmental contaminant that bioaccumulates in fish tissues, including numerous marine species. Cartilaginous fish of the subclass Elasmobranchii are important ecological constituents of marine ecosystems, yet the fate of Hg contaminants in their body tissues is largely unknown. In this study, four species of elasmobranchs: little skate (*Raja erinacea*), winter skate (*R. ocellata*), smooth dogfish (*Mustelus canis*), and spiny dogfish, (*Squalus acanthias*) were collected from the Rhode Island/Block Island Sound, and the Hg content (ppm wet wt) of white muscle tissue was analyzed using automated combustion atomic absorption spectrometry. Diet and feeding habits for each species were also assessed by stomach content and stable nitrogen ($d^{15}N$) and carbon ($d^{13}C$) isotope analyses. Mean Hg concentrations differed significantly among species, with highest levels measured in smooth dogfish (mean Hg = 0.768 ? 0.154 ppm, n = 10), followed by spiny dogfish (mean Hg = 0.324 ? 0.049 ppm, n = 23) and skates (mean Hg = 0.100 ? 0.012 ppm, n = 36 and 0.064 ? 0.005 ppm, n = 23 for little and winter skate, respectively). The Hg concentration of skate muscle tissue did not vary by body weight, suggesting that Hg does not bioaccumulate in these species. Conversely, smooth and spiny dogfish both bioaccumulate Hg with respect to body size, although smooth dogfish have a higher Hg content relative to spiny dogfish. The elevated Hg concentration of smooth dogfish may be explained by their higher trophic level status, as determined from d15N signatures (mean $d^{15}N$ = 13.55 ? 0.81, 11.93 ? 0.58, 12.43 ? 0.59, and 12.71 ? 0.83 for smooth dogfish, spiny dogfish, little skate, and winter skate, respectively). The enriched $d^{13}C$ values of skates and smooth dogfish indicated benthic foraging (range of mean $d^{13}C$ = -16.39 ? 0.35 to -17.69 ? 0.42), which was further confirmed by the dominance of decapod crustaceans in the stomach contents. Conversely, squid and butterfish were the principal prey of spiny dogfish, and the contribution of these pelagic prey was reflected in the depleted $d^{13}C$ signature (mean $d^{13}C$ = -21.98 ± 0.82). In future work, the effect of habitat use and Hg concentrations of principal prey will be examined to better understand bioaccumulation patterns among the elasmobranch species.

51 Exposure of Cutthroat Trout to Carbaryl Following Application to Control Burrowing Shrimp – The Rest of the Story C. Grue, Washington Cooperative Fish and Wildlife Research Unit, Univ of Washington, School of Aquatic and Fishery Sciences; J. Grassley, C. Elfes, A. Troiano, Univ of Washington. Labenia et al. (2007: Marine Ecology Progress Series 329:1-11) suggest the carbaryl exposures they used in laboratory studies with cutthroat trout (*Oncorhynhcus clarki clarki*) and resultant adverse effects are likely to occur in Willapa Bay and Grays Harbor, Washington, following application of the insecticide to control burrowing shrimp thereby threatening local cutthroat trout populations. We captured cutthroat trout within channels adjacent to oyster beds before and after operational applications of the insecticide (8.97 kg of carbaryl [ai]/ha). Trout were captured during daylight high and low tides using gill nets and beach seines, respectively at -48, -24, 6, 24, 30, 54 and 72 h following applications in July 2007 and 2009. Fish were placed in wet ice in the field and frozen (-40 C) prior to brain acetylcholinesterase (AChE) assays. Maximum average enzyme inhibition in 2007 was 16% (n=2 fish) compared to controls (n=7) and occurred at 30 h post application; enzyme activity at other time points post spray was less than + 10% (n=11). Similarly, in 2009 in which two applications separated by 3 days were monitored, maximum inhibition was 18% (n=2) compared to controls (n=23) at 24 h after each of the two applications. Enzyme activity at other time points post spray was also less than + 10% (n=50). Results were similar to those reported previously for juvenile Chinook with maximum inhibition of 10% compared to controls. AChE inhibition in both species was significantly lower than that likely associated with the reductions in swimming endurance and predator avoidance observed by Labenia and her co-workers. We conclude cutthroat trout are unlikely to be exposed to the concentrations and durations of exposure used by the authors in their experiments, and given spatial and ecological contexts, indirect effects of sufficient magnitude to adversely affect cutthroat trout populations in the Bay are unlikely.

52 Vulnerabilities of Atlantic Sturgeon and Shortnose Sturgeon to PCB126 and TCDD Induced Early Life-stage Toxicities I. Wirgin, New York Univ School of Medicine, Dept of Environmental Medicine; N.K. Roy, New York Univ School of Medicine, Environmental Medicine; R.C. Chambers, NOAA, Northeast Fisheries Science Center. Abundances of most sturgeon species worldwide are severely depleted. Overharvest, habitat alteration, and pollution are often cited as the three primary reasons for this decline, however, empirical demonstration of the effects of chemical toxicants are lacking. Shortnose sturgeon was federally listed as endangered in 1973 under the US Endangered Species Act and most populations of Atlantic sturgeon are currently under consideration for a similar designation. Populations of both species from several Atlantic coast estuaries are exposed to high levels of PCBs and PCDDs including those from the Hudson River PCBs Superfund site, however the vulnerabilities of their early life-stages to these AHR agonists have yet to be empirically evaluated. Initially, we partially characterized the cytochrome P4501A (CYP1A) gene and measured its expression in larvae of both species exposed under controlled conditions to graded doses of PCB126 and TCDD. We found that CYP1A expression was significantly inducible in both species at nominal water exposure concentrations as low as 10 ppt and 1 ppt, respectively. We also analyzed survivorship, hatching success and rate, and morphological alterations from these exposures in both species. Survival to hatching declined but days to hatching of survivors was accelerated at the highest doses of TCDD and PCB126. A syndrome of morphological toxic responses was also observed including shorter fish, yolk-sac edema, and retarded eye development at higher contaminant concentrations. However, post-hatching lifespan on yolk reserves alone (i.e., a food-free environment) was not affected by dose of toxicant. Our studies demonstrate that young life-stages of both species are dose sensitive to these two AHR agonists at environmentally relevant concentrations.

53 Identification of Genes Related to Copper Metabolism in the South American Cyprinodontiform Fish *Poecilia vivipara* E.S. Silva, J. Zanette, A. Bianchini, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas. South American cyprinodontiform fish like *Poecilia vivipara* are potential candidates to be used as model species in toxicology. It is well accepted that the copper transporter (Ctr-1) and Cu-ATPase (ATP7) membrane proteins primarily regulate copper uptake and transport in vertebrates. Using Polymerase Chain Reaction (PCR) with degenerated primers, cloning and sequencing approach we sought for *P. vivipara* nucleotide sequences homologous to those key genes involved in copper homeostasis. Ctr-1 is an integral membrane protein composed of three domains and involved in copper uptake. We identified a 139 nucleotides sequence for Ctr-1 in *P. vivipara*. This sequence showed 92% identity when compared to the known corresponding region of the Ctr-1 of the cyprinodontiform *Fundulus heteroclitus*. This allowed us to do the preliminary annotation of this new sequence. Also, a 266 nucleotides sequence was found for ATP7 in *P. vivipara*. This sequence shared 74 and 81% identity with the corresponding region of the ATP7A and ATP7B of the perciform *Sparus aurata*, respectively. Altered levels of environmental copper are assumed to be associated with changes in the transcript levels for the identified genes. RACE methodology is now being used to obtain the full-length sequences for Ctr-1 and ATP7 in *P. vivipara*. Also, copper exposure experiments to characterize the regulation of the new identified genes at the transcriptional level are being performed using RT-qPCR. [Supported by Brazilian CNPq (INCT-TA) and CAPES (Ciências do Mar)].

54 Effects and Adaptations in Estrogen Signaling Pathways in New Bedford Harbor Killifish G.V. Callard, S.R. Greytak, K.A. Cotter, Boston Univ, Biology; D. Nacci, USEPA, ORD, NHEERL, Atlantic Ecology Division. Reproducing the complexities of environmental contamination in a laboratory setting has been a critical barrier to understanding long term effects and adaptations to environmental endocrine disrupting chemicals. The killifish population at a highly contaminated Superfund site (New Bedford Harbor, MA; NBH), in comparison with killifish at a nearby clean

site (Scorton Creek, MA; SC), has proven to be an extremely valuable resource. The history of pollution in NBH indicates exposure to PCBs, heavy metals and other contaminants for ~50 yr (~20 generations). Survival has been ascribed to acquired resistance to dioxin-like chemicals that induce toxicity through AhR signaling pathways but survival alone cannot account for the reproductive success of the NBH population. Molecular markers and standard reproductive parameters indicate that NBH fish are exposed to an estrogenic environment and display evidence of endocrine disruption. To investigate the possibility that chronic exposure to NBH pollutants leads to adaptations in estrogen signaling pathways, we cloned and characterized the two *Cyp19* (aromatase) and three *Esr* (estrogen receptor) genes in killifish. Despite a high degree of polymorphism in sequences of all five genes, no obvious site-related changes were identified. Paradoxically, NBH as compared to SC larvae overexpress ERα mRNA 5-fold; however, they are hyporesponsive to administered estrogen, as measured by inducibility of the ERα gene. One interpretation for this discrepancy is that the ERα mRNA pool in NBH fish has a large fraction of mRNAs that are untranslatable or encode non-functional isoforms. Although our present understanding of endocrine disruption focuses on dysregulation of transcription, advances in molecular endocrinology indicate that transcription and splicing are functionally coordinated and regulated. Currently, we are testing the hypothesis that exposure to environmental chemicals can impact splicing decisions on estrogen responsive genes, and thereby alter the quantity and quality of ERα transcripts. Whether dysregulation of *Esr1* splicing is adaptive in an estrogenic environment and somehow related to the hyporesponsiveness phenotype of NBH fish remains to be investigated. Supported by research grants from NOAA (WHOI) National Sea Grant College Program and NIEHS P42ES07381.

55 Coupling Diffusive Gradient in a Thin Film Probe and IC-ICP-MS for the Simultaneous Determination of CH_3Hg^+ and Hg^{2+} Y. Hong, Johns Hopkins Univ, Geography and Environmental Engineering; E. Rifkin, Nationa Aquarium Baltimore, National Aquarium Conservation Center; E. Bouwer, Johns Hopkins Univ, Geography and Environmental Engineering. Mercury (Hg) is a metal contaminant that is highly toxic, globally ubiquitous, and environmentally persistent. A great need exists for monitoring CH_3Hg^+ and Hg^{2+} concentrations in environments for assessing the risks associated from Hg in ecosystems. However, analysis of Hg is challenging due to lengthy analytical procedures, numerous potential artifacts, and the high cost of the usual techniques that employ USEPA Methods 1630 and 1631 for CH_3Hg^+ and total Hg, respectively. As an alternative to the current Hg monitoring procedures, we combined a diffusive gradient in thin film technique (DGT) and ion chromatography – inductively coupled plasma – mass spectrometry (IC-ICP-MS) for the in situ measurement of labile CH_3Hg^+ and Hg^{2+} in water. Both CH_3Hg^+ and Hg^{2+} diffused through an agarose diffusive layer and accumulated in a resin layer, then the mercury species were extracted using acidic thiourea solution to form stable thiourea-Hg complexes that were separated and detected via a cation exchange column and ICP-MS. The effective diffusion coefficients for the CH_3Hg^+ and Hg^{2+} complexes in the agarose diffusion layer in the presence of chloride and DOC were evaluated from laboratory experiments. The DGT probes were deployed in several different water bodies, such as river, estuarine, and saline environments. The method detection limits are 0.1 and 0.5 ng L-1 for CH_3Hg^+ and Hg^{2+}, respectively, for 4 weeks deployment with 0.5 mm diffusive layer. The DGT coupled to IC-ICP-MS technique can measure time averaged labile CH_3Hg^+ and Hg^{2+} concentrations simultaneously in water and can be used to study the bioavailability of the mercury species, making it useful as an in situ monitoring tool.

56 PAH Analytical Techniques and Impacts on Risk Assessment E.J. Martin, CH2M HILL Canada; C.D. Sandau, TRIUM Environmental Inc. Polycyclic aromatic hydrocarbons (PAHs) constitute a large group of chemicals that are formed during incomplete combustion of organic substances. They can be anthropogenic in origin – burning of coal, oil & gas, tobacco – or form naturally in the environment – volcanoes, forest fires. Due to the numerous sources, PAHs are ubiquitous in the environment. PAHs are often found at contaminated sites. They are a contaminant of concern at approximately 60% of National Priorities List (NPL) sites and are ranked eighth on the 2007 CERCLA priority list of hazardous substances. A number of standard laboratory techniques are available to identify the composition, distribution, and abundance of PAHs in various environmental media including the United States Environmental Protection Agency (USEPA) method 8270C which uses gas chromatography/mass spectrometry (GC/MS). However, more sensitive techniques for measurement of PAHs have also been developed including isotope dilution high-resolution mass spectrometry (ID-HRMS). We have conducted a study to compare a standard analytical method (EPA Method 8270C) to a more sensitive method (ID-HRMS) for monitoring PAHs in soil. Our results indicated that the frequently used standard laboratory methodology (EPA 8270C) consistently overestimated PAH concentrations in soil as compared to the more sensitive ID-HRMS technique which was found to be more accurate and more precise. Using the benzo[*a*]pyrene toxic equivalency (BaP TEQ) scheme, it was found that the BaP TEQ values generated using the standard laboratory technique were much greater that those from the more sensitive technique. These findings may have important implications for contaminated site risk assessment. Risks associated with exposures to PAHs in soil (via inadvertent ingestion, dermal contact and inhalation of soil/dust) are directly proportional to measured PAH concentrations. Any errors/inaccuracies in the determination of PAH concentrations will consequently impact the calculation of risk. Thus, use of more sensitive laboratory techniques for PAH measurements will reduce uncertainty and provide for a more accurate understanding of site conditions and liability.

57 A Sensor Array for Rapid Screening of Dissolved Hydrocarbons in Sea Surface Waters A. Ross, X. Qi, E. Crooke, C. Stalvies, D. Fuentes, S. Armand, A. Revill, A. Taluker, CSIRO. Recent oil release events at Deepwater Horizon in Gulf of Mexico block MC252, and Montara in Australia, have outlined the need to rapidly survey the hydrocarbon content of near surface water over large geographic areas of the ocean surface in order to measure water quality. Conventional oceanographic approaches involve water sampling and measurement at predetermined stations, often through the deployment of conductivity, depth and temperature (CTD) profilers with attached Niskin bottle water sampling apparatus. The analysis of water samples for hydrocarbons can use a number of extraction methods followed by gas chromatography or gas chromatography and mass spectrometry. These methods and analysis permit the detailed determination and quantification of individual gaseous, volatile and higher molecular weight hydrocarbons compounds, however analysis can take several hours. Hydrocarbon sensors have been recently developed for marine applications. These sensors have both low hydrocarbon detection limits in the parts per million to parts per trillion range and rapid measurement cycle times in the order of seconds to minutes. In addition the devices are ruggedized for field deployments. These sensors include fluorimeters tuned for the detection of poly-aromatic hydrocarbons (PAH) and sensors for volatile organic compounds (VOC) tuned for the low molecular weight hydrocarbons. These sensors offer the potential to provide rapid, spatial and temporal sampling and detection; however they do not provide detailed hydrocarbon compositional data. Separate sampling and analytic techniques for hydrocarbon analysis are described in the accompanying poster. In this paper the design and implementation of an arrayed sensor system in an underway configuration combined with onboard complimentary conventional analysis is described. In response to the Deepwater Horizon oil release a hydrocarbon sensor array system comprising Chelsea Aquatracker, Contros and Trios flourimeters was deployed and operated for over 80 days in the in the Gulf of Mexico. Data was acquired covering over 8,998 linear nautical miles (~16,664 line kms) from June 5th to the September 15th 2010 during and after the MC252 spill. This data was mapped and reported to the Unified Area Command daily. During this time the system was successfully operated in various sea states and in environments ranging from riverine to oceanic waters, and from pristine waters through to waters with oil slicks at the surface.

58 Laboratory Processing of Incremental Samples: Options and Data Effects M. Bruce, TestAmerica, Technical Director; M. Heskett, L. Penfold, TestAmerica. The Interstate Technology and Regulatory Council (ITRC) team on Incremental Sampling Methodology (ISM) has been working for nearly three years to assemble guidance to improve the quality of site characterization. The ISM guidance document public release and training sessions are planned for early 2012. This presentation provides an overview of the current status on the near final ISM guidance related to laboratory sample processing options and how analytical data is affected by the various processes. ITRC is a state run organization that develops consensus guidance for environmental issues. Alaska and Hawaii have widely adopted the use of ISM for site characterization. Other states such as Missouri and Ohio have used ISM on limited number of sites. A few states [Texas, Florida, New

Jersey, Michigan, Wisconsin and Iowa] currently have regulations that prohibit the use if composite based sampling techniques such as ISM. The Dept of Defense and US Army Corps of Engineers in particular has devoted many resources to the development of ISM and is also a significant contributor to this ITRC team. In addition to other state and federal regulatory representatives, this guidance is also being developed by engineering firms, consultants and state, Univ, government and commercial laboratories. The overall goal of ISM is to provide an accurate estimate of the mean concentration for each contaminant of concern within each decision unit. SW-845 Method 8330B is the best known guidance for laboratory processing of incremental samples. The ITRC guidance includes other analyte groups such as metals, PCBs, volatile organic compounds and semivolatile organic compounds. The specific laboratory processes used affect the retention of analytes, contamination from sample processing equipment and other samples and subsampling representativeness. These processes have different effects on the final analytical data. This presentation will summarize the low bias, high bias and precision effects of the moisture modification, grinding and subsampling processes. The laboratory processing options include air drying, water addition, field moist options, freeze drying, disaggregation, milling, fractional scoops, riffle splitting, rotary sectorial splitter, 1 and 2-dimensional slabcake. Application of standard quality assurance principles is discussed as well laboratory certification options.

59 Partitioning of PCBs in Neutral Lipids, Polar Lipids and Proteins of a Fish K. Maenpaa, M. Leppanen, Univ of Eastern Finland, Dept of Biology; F. Tigistu-Sahle, Univ of Helsinki, Dept of Biosciences; K. Figueiredo, Univ of Eastern Finland, Dept of Biology; R. Kakela, Univ of Helsinki, Dept of Biosciences. Lipids are the dominant force in determining organic contaminant accumulation in aquatic organisms because hydrophobic organic chemicals (HOCs) partition mainly into lipid phase. Therefore, lipid normalized tissue concentrations have helped to reduce variation in tissue residues between different species and aid in understanding of contaminant toxicity and distribution in food webs. However, partitioning of contaminants between different lipid classes is not very well known. Lipid composition contributes to variation in bioaccumulation potential and neutral storage lipids are thought to be the most important lipid class for HOCs. On the other hand, polar membrane lipids are the target for HOC toxicity and knowing the concentration in membrane lipids would greatly improve the risk assessment of HOCs. We have applied silicone (polydimethylsiloxane) equilibrium approach to estimate silicone in olive oil, phosphatidylcholine and albumin partition ratios for carbon 14 labelled PCB-153 and PCB-77 in purpose to characterize HOC distribution in storage lipid, membrane lipid and protein fractions. PCB distribution was dominated by olive oil (78–82%) while phosphatidylcholine (11–20%) and albumin (2–8%) had lower share. The method is tested with the extracted native PCB contaminated pikeperch oil. Simultaneously, we will determine storage lipid, membrane lipid and protein fractions in fish. If the native and labelled PCBs show the same equilibrium ratios in silicone fish oil system, we can calculate PCB concentrations for all native congeners in these three main sorbing phases. The approach can be applied in dose-response studies of membrane toxicity and bioaccumulation models.

60 Low-cost High-throughput Analytical Method for Polychlorodibenzo-*p*-dioxins, Polychlorodibenzofurans and Polychlorobiphenyls in Fish Tissue B. Subedi, Baylor Univ, Dept of Chemistry and Biochemistry, Dept of Biology, Dept of C; S. Usenko, Baylor Univ, Dept of Environmental Science. To increase the samples throughput, enhanced pressurized liquid solid phase extraction was developed incorporating pressurized liquid extraction and all independent clean-up techniques. USEPA methods of polychlorodibenzo-*p*-dioxins, polychlorodibenzofurans (PCDD/Fs), and polychlorobiphenyls (PCBs) analysis in fish tissue include the independent silica gel, fluorsil, alumina, and celite/carbopak column cleanup techniques following extraction. Under improved method, fish composites (10 g) were extracted and cleaned simultaneously using alumina, fluorsil, silica gel, celite, and carbopak (10:10:5:5:0.5 g/g). Cleaned extracts were concentrated and analyzed through high resolution gas chromatography negative chemical ionization mass spectrometry. Adsorbents and solvents were optimized to separate PCDD/Fs and PCBs. The average recoveries (n=3) of individual PCBs in dichloromethane: hexane (1:1 v/v) extracts were within 90-103 ± 4.7% and individual PCDD/Fs in toluene extracts were within 72-100 ± 7.3%. Samples preparations time and solvents were reduced as much as 80% and 67%, respectively.

61 Buoy-Borne, Real-Time Sensing and Time-Resolved Sampling Of Hydrophobic Organic Chemicals In Onondaga Lake R. Oakes, State Univ of New York, College of Environmental Science and Forestry, Dept of Chemistry; J.P. Hassett, SUNY College of Environmental Science and Forestry, Dept of Chemistry; J.M. Croskrey, SUNY College of Environmental Science and Foresty, Dept of Chemistry; M.M. Giardono, D. Salley, SUNY College of Environmental Science and Forestry, Dept of Chemistry. Traditional methods for extracting and detecting trace organic contaminants in water are limited in many ways. Grab samples only represent one moment in time, limiting their temporal scope, and a large amount of time and effort is needed to collect enough water to achieve the needed low detection limits. This research utilizes a submerged, stirred extraction cell containing small diameter, therefore high surface area to volume ratio, semi-permeable membrane polydimethylsiloxane (PDMS) tubing to extract and concentrate dissolved hydrophobic contaminants in situ. Hydrophobic compounds dissolved in the water diffuse across the membrane into a solvent stream. Diffusion rate is equivalent to 17 L/day of water extracted, achieving a concentration factor of nearly 200. The extract is pumped through an onboard absorbance and fluorescence detector for real-time detection and into 24 hour composite collection vials for retrieval and laboratory analysis. Two solar-powered buoy-borne systems that generated real-time data on the presence and concentrations of trace hydrophobic organic contaminants were deployed in Onondaga Lake, Syracuse, NY, from August to December of 2010. One buoy was located at the southern end of the lake downwind of a chlorobenzene source and above sediments contaminated with PAHs, gasoline components, and coal tar. Data were collected continuously onboard the buoys and transmitted via radio to shore. Absorbance and fluorescence data demonstrated that during high wind events, the wave action disturbed the sediments and increased the dissolved concentrations of these contaminants in Onondaga Lake. This was further confirmed by GC-MS analysis of the composite extracts, which also provided information on individual compounds.

62 Evaluation and Calibration of a Rapidly Equilibrating Polymer Coated Glass (POG) Sampler for Screening Priority Chemicals S. Genualdi, Environment Canada, Science and Technology Branch; T. Harner, Environment Canada, Atmospheric Science and Technology Directorate. Polymer coated glass samplers (POGs) consist of a thin layer of ethylene vinyl acetate (EVA) coated on a glass fiber filter or aluminum foil substrate. Calibration of the sampler was performed through an eight week indoor uptake study using six different film thicknesses ranging from < 0.1 to 20um. Actual air concentrations were measured using weekly lo-volume air samples, polyurethane foam (PUF) disks, and sorbent-impregnanted polyurethane foam disks (SIPs). Depuration compounds were coated onto the POG sampler prior to deployment and used to calculate sampling rates. These consisted of labeled polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs), and perfluorinated compounds (PFCs). The samplers were also evaluated for their use as a rapid screening tool for assessing exposure to PCBs, OCPs, PFCs, and siloxanes in indoor air. Analysis was performed using thermal desorption gas chromatography/mass spectrometry (TDS-GC-MS). The POG shows promise due to its relatively low cost and ease of deployment and it applicability to a range of priority chemicals. The ability to alter the film thickness and hence the sorption capacity of the POG allows for a versatile sampler that can be used under varying sampling conditions and deployment times.

63 Observation-based Distribution, Inventories and Fluxes of PCBs in and Across Key Arctic Ocean Compartments O. Gustafsson, A. Sobek, D. Carrizo, Stockholm Univ. The predictability of future distribution and exposure of PCBs in the Arctic hinges centrally on the quality of our understanding of the present-day distribution and processing of PCBs in the Arctic system. The first part will present pan-Arctic observations of the PCB distribution and inventories in key compartments such as the polar mixed layer, sea ice, shelf sediments and all the major subsurface water masses. Next, observation-derived fluxes across key system boundaries such as surface ocean settling fluxes, pan-Arctic river export and shelf sediment burial will be presented. A synthesis of these results will provide information on their internal geochemical/budget consistency. Finally, the plausible effect of Arctic change scenarios on PCB distribution and fate will be discussed in the context of our present understanding of PCBs in the contemporary Arctic Ocean system.

64 A Global 3-D Model to Simulate Long-range Transport of PAHs: Application to Arctic Contamination C. Friedman, Massachusetts Institute of Technology, Center for Global Change Science; N.E. Selin, Massachusetts Institute of Technology, Engineering Systems Division. We simulate the long-range transport of polycyclic aromatic hydrocarbons (PAHs) to the Arctic under present and future climate using a global 3-D chemical transport model (GEOS-Chem). PAHs reach the Arctic environment by long-range atmospheric transport. We present initial results from model development for the PAHs phenanthrene, pyrene, and benzo[*a*]pyrene, focusing on episodic transport to the Arctic and sensitivity to temperature and other meteorological parameters. This work represents the first effort at modeling PAHs globally taking into account episodic transport events. Results are compared with previous efforts to model atmospheric transport of PAHs, which have either relied on multimedia box models or regional models focusing on specific sources or receptors, or used coarse-scale general circulation models (GCMs) not capable of capturing individual meteorological events that could lead to episodic transport from specific sources. Improved parameterizations of gas-particle partitioning, atmospheric reactivity, and wet and dry deposition are developed. Initial results show that model-predicted annual average concentrations correlate well with land-based measured concentrations for phenanthrene, pyrene, and benzo[*a*] pyrene, but are biased low. We apply these results to identify the importance of various remote source regions to particular Arctic locations compared to local sources, and to calculate the importance of episodic transport to the Arctic. We additionally show results for temperature sensitivity and initial calculations for PAH transport to the Arctic in a changing climate.

65 The Role of Snow and Ice on the Fate of Persistent Organic Pollutants in the Arctic Marine Environment C. Halsall, Lancaster Univ, Lancaster Environment Centre; S. Del Vento, G.P. Codling, Lancaster Univ, Lancaster Environmental Centre; L. Ahrens, Environment Canada, Science and Technology Branch; R. Ebinghaus, GKSS Research Centre. This presentation will explore current knowledge on the behaviour of chemical pollutants in sea-ice and sea-ice snow, placing concentrations in context with other studies and examining the role of ice in delivering pollutants to marine waters. During the International Polar Year there were several field-based programmes that examined persistent chemicals in snow and ice in the Arctic. These studies were undertaken for different purposes, either (1), to construct pollutant time-series to relate accumulation in ice with known chemical use/emissions; or (2), to examine chemical transfer processes in transient seasonal snow and sea-ice. Understanding (2) is particularly important in the context of a 'warming Arctic' as changes to snow and ice systems will in turn affect the timing and loading of pollutants to surface waters. Results from field work conducted in the Canadian Arctic show the presence of PBDEs, PCBs, OC pesticides and C5-C13 perfluorocarboxylates (PFCAs) and PFOS in the remote marine snowpack at levels comparable to other recent studies. Levels of hydrophobic contaminants in wind-blown snow measured from late winter to early melt are, in the main, related to the physical properties of the sampled snow, rather than seasonal changes in air temperature (~-25ºC to 0ºC) with little evidence to support a hypothesis that contaminant levels change markedly in sea-ice snow with increasing air temperatures prior to melt. Concentrations of hydrophobic POPs measured in snow and sea-ice (expressed as melt-water equivalents) show marked enrichment compared to levels measured in beneath-ice seawater (ratio of snow-ice/seawater) although this enrichment declines as melting commences. In contrast, several PFCAs, including PFOA, where found at surprisingly high concentrations in beneath-ice seawater both prior to and during ice-floe breakup, with levels of PFOA up to 300 pg/L in some samples, comparable to or higher than concentrations found in the overlying snowpack and ~3-fold higher than observations in mid-Atlantic surface water. A small number of first-year sea-ice samples also revealed high concentrations of PFCAs, implying a possible enrichment process at the ice-seawater interface. The results of these findings will be extrapolated in the context of ongoing changes to the cryosphere, with the loading of chemicals attributable to marine snow and ice compared to direct deposition to 'ice-free' waters. Areas of uncertainty will be highlighted.

66 Accumulated Contaminants in Ice Cores from Svalbard: Considerations of a Future Source to the Environment M. Hermanson, Univ Center on Svalbard, Arctic Technology; E. Isaksson, Norwegian Polar Institute; C. Teixeira, Environment Canada; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, National Water Research Institute. Since 1998 we have analyzed various persistent organic contaminants in ice cores collected from two ice fields on Svalbard, including Holtedahlfonna (2005) to the west and Austfonna (1998) to the east, about 220 km apart, roughly west-east. The results from Holtedahlfonna, the most comprehensive data set, include analysis of 220 different compounds in four compound classes including PCBs, BFRs, current-use (CUP) and legacy pesticides (LP), and halobenzenes. Compounds from these groups cover vapor pressures (VP) ranging over 8 orders of magnitude (from 2.87 x 10^{-1} kPa to 2.95 x 10^{-9} kPa), and include compounds considered to be too volatile to be deposited (1,3-dichlorobenzene) and others once thought to be too non-volatile for long-range transport (decabromodiphenyl ether, BDE-209). Compounds observed at Holtedahlfonna also have OH. reaction rates suggesting atmospheric lifetimes ranging from one day (Chlorpyrifos) to nearly one year (g-HCH), the former usually considered to be too short for long-range transport. All of these 4 compounds, representing extremes of VPs and atmospheric lifetimes, are present in greater abundance than nearly any other throughout the Holtedahlfonna core (and in greater abundance than ∑PCB), showing that a wide range of organic contaminants needs to be considered when postulates are made of what contaminants will be released if this ice melts, and in what environmental matrix they will be found. Results from Austfonna, which includes only pesticides, suggest variability in net contaminant deposition: in comparison to Holtedahlfonna, where 9 of 47 analyzed CUPs were found, Austfonna shows net deposition of 21 CUPs of 26 analyzed. The most abundant of the CUPs found at Austfonna and not Holtedahlfonna includes a series of neurotoxic organophsophorus (OP) pesticides. Our investigations into sources using long-term (10-year) average air mass trajectories show seasonal and long-term shifts in source regions to these two sampling sites, suggesting a high level of complexity in evaluating the burden of organic contaminants on Svalbard that will be released as these ice masses melt.

67 Bioaccumulation of POPs in a Top Predator, the Osprey, in Alpine Regions of Western Canada J.E. Elliott, Environment Canada, Pacific Wildlife Research Centre, Science and Technology Branch, Canadian Wildlife Service; M. Guigueno, K.H. Elliott, J. Levac, Univ of Manitoba; M. Wayland, Environment Canada; C.A. Morrissey, Univ of Saskatchewan; D.C. Muir, Environment Canada. Due to climate change, chemicals that accumulated in glaciers through evaporation from warm regions and subsequent condensation in cold regions are being released into alpine environments. To examine the role of glacial geography in determining contamination of wildlife in alpine ecosystems, we measured persistent organic pollutants and mercury in apex predators, ospreys (*Pandion haliaetus*) breeding in 16 watersheds in western Canada. Despite living in environments far from point sources of contamination, ospreys in Canadian alpine lakes had significant levels of DDT, PCBs, toxaphene and mercury. After accounting for proximate factors such as trophic level and lipid content, HCB, chlordane, mercury, PCBs decreased with watershed size and toxaphene, DDT, HCB and mercury decreased with watershed size divided by lake size. Once trophic level was factored, ospreys feeding in large watersheds that drain into relatively large, lower elevation lakes with less glacial input had higher levels of contamination. Toxaphene, mercury, HCB, and DDT all decreased with the amount or proportion of glaciation while toxaphene and chlordane decreased with elevation. Thus, foraging ecology (trophic level) and geography explained significant portions of the large variation in osprey contaminant levels in western Canada, but the geographical variation was not consistent with the idea that the patterns in contaminants were determined by current long-range transport or glacial melt. Rather, we suggest that contaminants largely melt out during annual snow pack melt and bioaccumulate at lower elevation lakes, especially lakes with poor drainage. Our study highlights the importance of understanding how biological processes integrate physical patterns when studying the environmental chemistry of wildlife.

68 Empirical Investigation into the Fate of Organic Contaminants During Snowmelt in a Sub-Arctic Snowpack C. Halsall, Lancaster Univ, Lancaster Environment Centre; G.P. Codling, Lancaster Univ, Lancaster Environmental Centre; M. Bergknut, Umea Univ; K. Wiberg, Univ of Umea, Dept of Chemistry; S. Del Vento, Lancaster Univ, Lancaster Environmental Centre; H. Laudon, Swedish Univ of Agricultural Sciences (SLU), Dept of Forest Ecology and Management; M. Tysklind, Univ of Umea, Dept of Chemistry. To understand the role of the seasonal snowpack in providing atmospherically derived organic contaminants to northern catchments a study was undertaken at the Krycklan Catchment Study

(KCS) site in northen Sweden (64°14'N, 19°46'E). For the KCS, snowmelt provides ~66% of the the annual stream flow and is therefore likely to make a signifcant input to contaminant loads to catchment headwaters. The fate of snow-associated contaminants during the melt period is not fully understood, with some chemicals possibly undergoing a first 'flush' during initial melt while others may re-partition back to the air or to particulate matter and hence be retained in the pack until final melt. In this study two approaches were taken: (i) a doping study utilising a group of chemicals of varying physical-chemical properties (PCBs, OC pesticides, PBDEs, organophosphorus insecticides and perfluorosulphonates (PFSAs)) that were artifically introduced into a surface snow layer of an aged snowpack and their movement tracked every 24 hours over a five day period; (ii) a time-series of 'native' contaminant concentrations in snow (PCBs, OC pesticides, PBDEs and PFCAs) achieved over 14 days during the melt period. From the doping study (conducted in semi-enclosed metal tubes sunk vertically into the snow) mass recoveries of the chemicals from the snow and captured meltwater were in the order of PFSAs>PBDEs>PCBs=OCs, indicating that volatile compounds can be lost to the atmosphere. Chemical movement down the snow column was rapid for several of the 24 h periods, with an even distribution of chemicals down the length of the snow column as well as detected in meltwater collected at the base of the snowpack. For the 'native chemicals', PCBs showed a decline from >1 ng/L (in fresh snowfall) to < 0.3 over the 14 day period with most of the decline attributable to the loss of tri- and tetra-chlorinated homologues. Levels of PFOA ranged from < 10 – 200 pg/L and PFOS < 3-~100 pg/L, with concentrations generally higher at the base of the snowpack. Unlike PCBs, concentrations of PFOS, PFOA (and other PFCAs) did not decrease uniformly in the melting snowpack and were retained right up to final melt with implications regarding the extent and timing of chemical release to meltwater runoff.

69 Partitioning of Persistent Organic Pollutants Between Sediments and Benthic Deposit Feeders in Western Antarctic Peninsula L. Zhang, Univeristy of Rhode Island, Graduate School of Oceanography; R. Lohmann, Univ of Rhode Island, Graduate School of Oceanography. Studies have shown that previously deposited persistent organic pollutants (POPs) are being released from glaciers due to global warming. The melting glaciers are believed to be the secondary source of POPs to the Western Antarctic Peninsula (WAP) coastal regions. These POPs have been found to bioaccumulate along the food web into Antarctic penguins which body levels of DDTs have not declined since 1970s. Hydrophobic POPs should not only be present in the pelagic food web, but also be transported downward with sinking particulate organic matter into sediments. Thus, it is important to investigate the concentrations of POPs in the sediments of the WAP and their transfer along the benthic food web. Benthic biota can take up POPs through contact with porewater and/or via ingestion of sediment particles. The uptake pathway is closely related to the animals' feeding strategies. Previous studies have found at certain locations that the partitioning of POPs between filter feeding organisms and porewater were at equilibrium and thus POPs porewater concentration can be used to predict body burdens at that specific site. This might not be true for deposit feeders which not only continuously exchange POPs with surrounding porewater, but also ingest sediment particles indicating a potential for bioaccumulation. As part of an ongoing collaborative research to study the impact of climate change on the transport of POPs in the Antarctic marine food web, surface sediments (0-5 cm depth) and subsurface/ surface deposit feeding holothurians samples were collected at five different locations from north to south along WAP. PCB concentrations (12 congeners) were highest at the tip of WAP at 0.5 ng/g dry weight and decreased towards the interior of Antarctic continent to 0.03 ng/g. However, the PCB concentrations in the lipids of deposit feeders did not reflect this trend. Porewater concentrations were assessed with passive samplers to determine if an equilibrium partitioning model can be used to predict POP concentrations in benthic deposit feeders in WAP. The results provide a better understanding of the transfer of POPs into the Antarctic benthic food web as well as the site-specific risk assessment of sediments.

70 Indoor Dust and the Pet Dog: PBDEs, PCBs, and Pesticides C. Orazio, US Geological Survey, Columbia Environmental Research Center; C. Grimm, Smithsonian National Zoological Park, Center for Species Survival; N. Diggs, Smithsonian Migratory Bird Center, National Zoological Park, Smithsonian Conservation Biology Institute; S. Tan, Smithsonian National Zoological Park, Center for Species Survival; K. Feltz, K. Echols, US Geological Survey, Columbia Environmental Research Center; P. Marra, Smithsonian Migratory Bird Center, National Zoological Park, Smithsonian Conservation Biology Institute; P. Peterman, US Geological Survey, Columbia Environmental Research Center. House dust and blood serum from the family's pet dog were collected from rural and suburban homes near Washington DC to assess levels of polybrominated diphenyl ethers (PBDEs), PCBs, and organochlorine pesticides. Pre-weighed clean dry glass fiber filters were used to swipe dust from high surfaces. Care was taken to prevent dust contamination of the dog blood samples (n=18) during collection and analysis. The breed of dog, sex, age (2–13 years), weight (13–90 lbs), dog food (not analyzed in this study), current medications, daily time spent outdoors (0.25–12 hrs), and dog bedding material were recorded. Dust (0.013–0.055 g) and blood serum (3 g) samples were processed separately, accompanied by appropriate quality control samples, including blank spiked filters and bovine serum blanks. Following extraction, purification and fractionation, the dust and blood extracts were analyzed by GC/MS and isotope dilution GC/high resolution MS for 41 PBDE congeners, 21 pesticides, and PCB congeners. As expected, based on other dust studies, the levels and patterns of PBDE congeners in the house dusts varied. PBDEs were at quantifiable levels in 12 of the 18 dog blood samples, with PBDE-47 and PBDE-209 levels that ranged from 16–80 and 60–300 ng/g lipid-wt, respectively. The predominant PBDEs in the dog bloods were 47, 99, 100, and 209. A linear trend existed for dog blood and dust levels of PBDE 209. The highest level of PBDE-209 in dust of 11,100 ng/g corresponded to 300 ng/g lipid-wt in the dog blood. Dust levels of total-PCBs ranged from 20–3168 ng/g but were less than 2,000 ng/g lipid-wt in the dog blood samples. Three of the 18 dogs had detectable residues of chlordane: The dog from the home with the highest indoor dust level of total-chlordane (22,000 ng/g) had the highest blood level of oxychlordane (219 ng/g lipid-wt). Exposure to PBDEs, PCBs, and pesticides via the diet also can contribute to residue levels in the dog blood; recently Venier and Hites (2011) reported that different brands of dog food do not play an important role in the concentrations of PBDEs. The results of our study indicate that levels of certain contaminants in indoor dust correlate to levels in the family dog.

71 Evaluating Exposure to BDE-47 in Homes: Impact of Couch Construction, Temporal Variability and Variability in Measurement Methods D. Bennett, UC Davis, Public Health Sciences. BDE-47 is used as a flame retardant in furniture foam. Our objectives were to determine 1) if the type of furniture upholstery in a home influences the air concentration of BDE-47 measured in an air sample collected in a home, 2) determine the temporal variability in air and dust concentrations, and 3) determine the differences in measured concentration in dust by measurement method. We quantitatively measured bromine in furniture and determined BDE-47 air and dust concentrations at multiple time points in California homes. First, a portable XRF (X-ray fluorescence analyzer) was used in 68 homes, measuring bromine to a depth of approximately 0.5 cm, representing the foam concentration when placed on the surface. Multiple sub-sections (i.e., seat and back cushions, backing, throw pillows) of both the largest and most frequently used (if different) couch or chair in the main living area were tested, with a preliminary mean bromine concentration of 7030 ppm (SD = 8220). Bromine concentrations, multiplied by the respective section's surface area, were summed to calculate the potential source strength. As an alternative, a small sample of foam from the seat cushion was removed if accessible (i.e., there was a zipper) and the participant agreed (52% of households) and analyzed by a semi-quantitative Elisa method to determine if BDE-47 was present (72% of samples above LOD). A passive air sampler (PUF) was left in the home for 30 days and the PUF was extracted and analyzed for BDE-47 (preliminary mean concentration of 61.4 mg/m^3 (SD=84)). To analyze the data, homes were divided into two groups: (1) those with couches with a thicker resistance layer between the cushion and air, either leather (24% of homes) or an additional upholstery liner (18% of homes), and (2) all others. The slope of the correlation between the bromine source strength and the BDE-47 air concentration was lower for those homes categorized as having a thicker resistance layer, suggesting the potential for less exposure. Further studies should be conducted to determine if XRF combined with couch construction may be a useful, low-cost indicator of exposure and applicable to other flame retardants. Second, air and dust measures were collected approximately 1 year apart in 56 homes to evaluate temporal variability. Third, measured concentrations will be compared between two different investigator collected methods and between an investigator collected method and vacuum cleaner samples.

72 Characterization of Two Chiral Current-use Residential Pesticides in the Indoor Environment E.M. Ulrich, US Environmental Protection Agency, National Exposure Research Laboratory, Methods Development and Applications Branch; Q. Wang, Student Contractor to the USEPA; D. Stout, USEPA. Pesticides are applied to the interior of homes, schools, places of business and employment to control a variety of pests. Residential pest control practices may result in chemical residues located in close proximity to daily activities and potentially serve as a source of exposure. The primary routes of exposure after indoor pesticide application are inhalation, dermal, and ingestion all of which contribute to the aggregate exposure of occupants. Crack and crevice application of several current-use pesticides has allowed evaluation of important exposure routes, fate and transport within the unoccupied USEPA Indoor Air Research House in North Carolina. Two of these pesticides, fipronil and cis-permethrin, were studied to determine temporal and spatial trends of their enantiomers. Many pesticides, including fipronil and permethrin, are typically formulated and applied as a racemic mixture (equal amount of enantiomers). Differences in the pesticidal efficacy of enantiomers may offer an opportunity for "greener" enantiomer enriched formulations which allow for an equally effective but lower concentration of active ingredient. Because enantiomers can have differential toxicity, it is important to thoroughly understand exposure to accurately assess the potential risk from different enantiomers. Chiral pesticides are not frequently studied in indoor settings, creating a data gap for exposure and risk assessments. In this study, selected carpet, surface wipe, indoor air, and deposition coupon samples collected in several rooms of the Research House were analyzed using enantioselective gas-chromatography/mass spectrometry. Preliminary analysis of the enantiomer fraction (EF) data reveals that both pesticides were primarily racemic or near racemic (fipronil EF= 0.47–0.51; cis-permethrin EF= 0.45–0.55). Indoor environments are not thought to have many opportunities for enantioselective degradation or processes, which seems to be confirmed by these findings. However, cis-permethrin had a broader range of EF values, which may indicate some enantioselective degradation, which is usually attributed to biological interactions. Temporal and spatial trends of the EF values will also be discussed.

73 Traditional and Forensic Signatures of Indoor Air S. Emsbo-Mattingly, New Fields Environmental, Forensics Practices, LLC; A. Uhler, NewFields. Environmental scientists recognize the highly variable nature of indoor air. It is greatly affected by the life style of the human inhabitants, the building materials, the quality of the outdoor air, and, occasionally, vapor intrusion. This presentation features a series of case studies that use patterns of TO15 analytes to contrast human activities in residential, recreational, commercial, and industrial environments. The differentiation of source signatures benefits greatly from TO15 methods (GC/MS) designed for traditional and forensic hydrocarbon analytes with trace level detection limits. Of particular interest is the close between outdoor and indoor air. In addition, the case studies help demonstrate how the effects of environmental weathering help identify the dominant sources of indoor air contaminants. The compounds that appear in outdoor and indoor air include benzene, toluene, ethylbenzene, xylenes, styrene, naphthalene, indane, indene, and many other aliphatic, aromatic, and heteroatomic volatile organic compounds (VOCs). These data emphasize the importance of outdoor air sampling and help optimize the sample collection and data interpretation strategies.

74 Relationship Between House Dust and Indoor Air Concentrations: Applying Partitioning Theory to Empirical Data R. Dodson, L. Perovich, J. Brody, R. Rudel, Silent Spring Institute. Individuals encounter a wide range of pollutants in indoor environments, and semivolatile organic compounds (SVOCs), which are found both in the gas and condensed phase, are of particular interest because they can be redistributed over time from their original source to indoor air, dust, and surfaces. House dust and indoor air samples were collected in 50 California homes: 40 homes in Richmond, CA and 10 homes in Bolinas, CA. Seventy-six SVOCs were analyzed in both air and dust: 24 polycyclic aromatic hydrocarbons (PAHs), 3 polychlorinated biphenyls (PCBs), 2 polybrominated diphenyl ethers (PBDEs), 36 pesticides and 11 phthalates. Overall, we detected 40 target analytes in both house dust and indoor air above method reporting limits. Empirical data were used to explore theoretical partitioning relationships between air and dust to evaluate whether gas-phase air concentrations can be used to predict house dust concentrations. Specifically, gas-phase only concentrations were estimated from total air (particulate and gas phase) concentrations, assuming equilibrium and using residence-specific particulate concentrations. Correlation analyses revealed significant associations between gas-phase air and dust concentrations for several phthalates, pesticides and PBDE 47. Predicted dust concentrations, which were estimated using gas-phase air concentrations, fraction of organic matter, octanol-air partition coefficient, and dust density, and measured dust concentrations were strongly correlated ($R^2 \sim 0.7$). Understanding partitioning relationships between air and dust will advance our understanding of exposure pathways in the indoor environment; can be used to prioritize exposure measures in large-scale epidemiological studies; and can be used in conjunction with simple, consistent exposure measurement methods, such as a passive air sampler, to fully characterize the indoor environment.

75 Air-Solid and Solid-Solid Partitioning of Phthalates in the Indoor Environment H. Hwang, Univ of California, Davis, Dept of Civil and Environmental Engineering; H. Kim, Univ of California, Civil and Environmental Engineering. Indoor air and floor dust are severely contaminated by phthalates, which are added to variety of household consumer products such as plastic floor mats, wall papers, carpets, and furniture. Indoor exposure to phthalates has been linked to many adverse health effects such as respiratory disease (e.g., asthma, weezing) and atopic dermatitis. To investigate how phthalates in PVC based plastic floor mats are transferred to indoor air and floor dust, two different chamber studies were conducted. A piece of vinyl flooring mat was placed inside of a metal chamber, which was maintained at 20 °C. Volatilized phthalates were ventilated with continuous flow of nitrogen gas and captured using activated carbon columns, which were replaced regularly for time-series measurement. As expected, gas phase release of diethylphthalate and dibutylphthalate was significantly higher than the release of diethylhexylphthalate. Gas-phase concentrations of diethylphthalate and dibutylphthalate increased quickly so it is recommended to ventilate indoor air more frequently to minimize indoor exposure to these more volatile phthalates through inhalation. To compare the transfer of phthalates from mats to dust through solid-air-solid partitioning and solid-solid partitioning, sieved outdoor soil particles were placed on the top of a piece of mat and a piece of aluminum foil placed in a closed metal chamber 24 hours without ventilation. Almost all diethylhexylphthalate was transferred to soil particles through direct contact and gas phase transfer was negligible. In the case of diethylhexylphthalate, more frequent floor vacuuming is recommended to reduce the exposure through dust ingestion.

76 Impact of Plants on Volatile Organic Compounds (VOCs) in Indoor Environments W.J. Doucette, Utah State Univ, Utah Water Research Laboratory; J. Chard, Utah State Univ. Concerns about the potential build up of volatile organic compounds (VOCs) in indoor air first increased as energy conservation methods minimized the introduction of outdoor air. VOCs including many with documented short- and long-term adverse health effects, are emitted by a wide array of products including: paints, paint strippers, fuels, cleaning supplies, pesticides, building materials, office equipment, and adhesives. These products can release VOCs during use and to lesser extent, when they are stored. Indoor air concentrations of VOCs vary widely, depending on construction materials and specific consumer products within the building but concentrations of most VOCs are consistently higher indoors than outdoors. The use of ornamental plants has been suggested as a simple, unobtrusive, aesthetically pleasing, and cost effective method for sampling and purifying indoor air. The waxy surface of the leaves has the potential to provide a good surface for the passive capture of VOCs. However, the efficiency of capture has not been well characterized and plants themselves give off VOCs. In addition, damp soils can provide an environment for the growth of microorganisms that can impact allergic individuals. By actively drawing air through the root-zone while providing sufficient water and nutrients, a simple bioreactor can be created that can potentially remove VOCs in indoor air through sorption and/or aerobic biodegradation while significantly reducing the potential for allergen production. A flow-through glass and stainless plant growth chamber was constructed to evaluate VOC removal. Potted plants, non-planted controls or plant tissues were placed inside the chamber while one or more representative VOCs found in indoor environments were introduced at environmentally relevant concentrations. Mass balance calculations were performed by comparing the measured concentration of chemical introduced into the chamber to that existing the chamber. In addition, the ability of plants to act as passive samplers was evaluated and compared to conventional passive and active sampling methods.

77 The Measured Relationship Between Aggregate Material Emission Rates and Building Ventilation Characteristics for Indoor Pollutants R. Maddalena, Lawrence Berkeley National Laboratory, Department of Indoor Environment; F. Micallef, Lawrence Berkeley National Laboratory and University of Malta, Department of Physics; N. Aquilina, University of Malta, Department of Physics; T. McKone, University of California, Berkeley, University of California and Lawrence Berkeley National Laboratory. Concerns about the potential build up of volatile organic compounds (VOCs) in indoor air first increased as energy conservation methods minimized the introduction of outdoor air. VOCs including many with documented short- and long-term adverse health effects, are emitted by a wide array of products including: paints, paint strippers, fuels, cleaning supplies, pesticides, building materials, office equipment, and adhesives. These products can release VOCs during use and to lesser extent, when they are stored. Indoor air concentrations of VOCs vary widely, depending on construction materials and specific consumer products within the building but concentrations of most VOCs are consistently higher indoors than outdoors. The use of ornamental plants has been suggested as a simple, unobtrusive, aesthetically pleasing, and cost effective method for sampling and purifying indoor air. The waxy surface of the leaves has the potential to provide a good surface for the passive capture of VOCs. However, the efficiency of capture has not been well characterized and plants themselves give off VOCs. In addition, damp soils can provide an environment for the growth of microorganisms that can impact allergic individuals. By actively drawing air through the root-zone while providing sufficient water and nutrients, a simple bioreactor can be created that can potentially remove VOCs in indoor air through sorption and/or aerobic biodegradation while significantly reducing the potential for allergen production. A flow-through glass and stainless plant growth chamber was constructed to evaluate VOC removal. Potted plants, non-planted controls or plant tissues were placed inside the chamber while one or more representative VOCs found in indoor environments were introduced at environmentally relevant concentrations. Mass balance calculations were performed by comparing the measured concentration of chemical introduced into the chamber to that existing the chamber. In addition, the ability of plants to act as passive samplers was evaluated and compared to conventional passive and active sampling methods.

77.5 Anniston PCB Site: Implications of Field and Laboratory Bioaccumulation Results to an Ecological Risk Assessment B. Anthony, ARCADIS, Blasland Bouck and Lee; J. Meyer, ARCADIS US, Inc.; D. Ludwig, H. Douglas, M. Shivell, A. Fowler, ARCADIS. Choccolocco Creek and the associated floodplain are part of the Anniston PCB Site (the Site) located in portions of Calhoun and Talladega counties, near Anniston, Alabama. The creek and floodplain are part of Operable Unit 4 (OU-4) for the Site and include over 5,000 acres that line a 35-mile long portion of Choccolocco Creek. PCB concentrations were measured in benthic invertebrate tissue and co-located sediment from nine locations within Choccolocco Creek and three reference locations. Additionally, bioaccumulation of PCBs from 12 Site sediments, two reference sediments, and a laboratory control sediment was investigated in the laboratory through 28-day exposures of a freshwater oligochaete worm (*Lumbriculus variegatus*) to whole sediment. The laboratory bioaccumulation tests were performed in two phases by the US Army Corps of Engineers, in basic accordance with American Society for Testing and Materials (ASTM) and US Environmental Protection Agency (USEPA) guidance using sediment collected from various locations in the creek. Relationships between PCB concentration in sediment and tissue were evaluated in both the field-derived biota and sediment data and in the laboratory bioaccumulation studies. The results of the field measurements in benthic invertebrate tissues and laboratory studies will be used to estimate benthic invertebrate tissue concentrations in the ecological risk assessment foodweb models for OU-4. The predicted tissue concentrations from both approaches and the associated uncertainties will be discussed.

78 Anniston PCB Site: Implications of Sediment Toxicity-Testing Results to an Ecological Risk Assessment J. Meyer, ARCADIS US, Inc.; B. Anthony, ARCADIS, Blasland Bouck and Lee; D. Ludwig, H. Douglas, A. Fowler, ARCADIS. Choccolocco Creek and its floodplain are part of the Anniston PCB Site (the Site) located in portions of Calhoun and Talladega counties, near Anniston, Alabama. The creek and floodplain are part of Operable Unit 4 (OU-4) for the Site and includes over 5,000 acres that line a 35-mile long portion of Choccolocco Creek. Chronic toxicity tests were conducted on 26 sediment samples (20 from the Site and 6 from a reference area), together spanning a wide range of combinations of total PCBs and total organic carbon concentrations and a single laboratory control sediment. Test organisms were a freshwater amphipod (*Hyalella azteca*; 42-d tests) and a freshwater midge (*Chironomus dilutus*; life-cycle tests). The tests were performed by the US Geological Survey and the US Army Corps of Engineers, in basic accordance with American Society for Testing and Materials (ASTM) and US Environmental Protective Agency (USEPA) guidance. The sediments were selected to develop a concentration response relationship based on organic carbon normalized PCB concentrations. Threshold-effects concentrations of PCBs were calculated from the concentration-response relationships for survival, growth, and reproduction endpoints, and were compared to threshold effects concentrations (TECs) and probable effect concentrations (PECs) in published "consensus-based" sediment quality guidelines for freshwater systems. Concentrations of other chemicals were also evaluated to help explain observed sediment toxicity. From those results, the most sensitive of the traditional endpoints will be identified and used to evaluate ecological risk associated with OU-4 sediments. Uncertainties associated with using Site-specific sediment toxicity testing results versus published TECs and PECs will also be discussed.

79 Overview of the Anniston PCB Site: History and Remedial Investigation P. Scully, USEPA, Region 4 Superfund; E.g., Macolly, Solutia Inc., Remedial Projects; M. Greenberg, USEPA, Environmental Response Team; A. Fowler, ARCADIS; S. Thoms, USEPA, Region 4 Superfund. The Anniston PCB site (the Site) is located in northeast Alabama. Polychlorinated biphenyls (PCBs) were produced at the Solutia Anniston Facility from 1929 until 1971. The environmental management of the Site is being addressed through a CERCLA Remedial Investigation/Feasibility Study process for three operable units (OUs) that extend over approximately 40 stream miles and 6,000 acres of floodplain. Soil, ground water, and air sampling were conducted to assess risks to human health at the Facility (OU-3). Soil, ground water, sediment, surface water, air and biota data are being used to assess risks to human health and ecological receptors in the residential and non-residential (largely commercial) portions (combined OU-1/OU-2) and less developed, downstream areas (OU-4) of the Site. The floodplain of OU-4 is predominantly comprised of agricultural and forested lands and includes approximately 5,000 acres that surround 35 miles of creek. The range of pathways and the large study area introduce unique challenges within both the human health and ecological risk assessments. The remedial investigation for OU-4 has used a characterization area/exposure unit (CA/EU) approach to streamline the floodplain soil characterization and risk assessment processes. Sediment toxicity and bioaccumulation testing for sediments have been performed to assist in risk management decisions for the Site. This presentation will cover these challenges and will summarize and discuss highlights of the remedial investigation.

80 Results of a One-Year Fish Consumption Survey in Alabama J. Schell, Exponent; E. Ebert, Integral Consulting; J. Loper, The Loper Group; N. Wilson, M. Wacksman, A. Fowler, ARCADIS. To support a human health risk assessment for Operable Unit 4 (OU-4) of the Anniston PCB Site, a one-year intercept survey along Choccolocco and Snow Creeks was conducted. The survey collected site-specific information about the extent of usage of the creeks for fishing, locations fished, species and sizes of fish harvested for consumption, methods used to prepare and cook them, rates at which they were consumed, and demographic characteristics of the user population. The survey used interview and "weighting" approaches demonstrated to be effective at other locales. The survey was conducted on 101 survey days, representing 27% of available days during the one-year period. The sampling days were selected based on a stratified random sample method that accounted for season, time of week, location and time of day. In total, only 72 anglers were observed during the one-year survey period and 52 of those individuals completed interviews. After correcting for avidity bias, it was estimated that a total population of 173 anglers fish the OU-4 portions of the creek each year. The interviewed anglers fished an average of four months during the year and took an average of two fishing trips during a typical four-week period. Estimated trips per year ranged from 1 to 54 with an average rate of seven trips per year. Based on the interviews conducted, anglers were successful at harvesting fish for consumption on 15% of the fishing trips taken and only three of the 52 anglers interviewed at the end of their trip had harvested fish for consumption. Consumption rates, which were estimated for each angler who had harvested fish, were based on the mass of fish harvested by trip end, an edible portion of 30%,

the reported frequency of fishing trips, the average success rate, and the number of persons to share in consumption. Currently, a fish consumption advisory is in effect for the creek. The estimated annualized average fish consumption rates estimated from this study ranged from 0.14 g/day to 7.9 g/day with a mean rate of 2.9 g/day. These estimated consumption rates were consistent with those reported for a similar small water body in Alabama that had no advisory at the time of the survey, indicating that suppression of resource utilization is not occurring.

81 Anniston PCB Site: Human Health Risk Assessment Status T. Woods, F. Sevold, J. Walsh, Avatar Environmental, LLC; K. Koporec, P. Scully, USEPA Region 4. The human health risk assessment for the operable unit 4 (OU-4) area of the Anniston PCB Site in Anniston, AL, is being conducted. OU-4, the largest of the OUs associated with the Site, encompasses the length of Choccolocco Creek and its floodplain from the confluence with Snow Creek, including the backwater area and upstream on Snow Creek to Highway 78, to Lake Logan Martin. PCBs are the primary Site contaminant. Over the years, the Choccolocco Creek and its floodplain have become contaminated as a result of the operations that have occurred at the Solutia, Inc. plant upstream in Anniston, where PCBs were produced from 1929 through 1971. Environmental investigations have been performed at the plant and its' surroundings for the past 30 years. The affected media in OU4 include floodplain soil, creek sediment, fish, and possibly agricultural products grown or raised in the floodplain. The objective of the HHRA is to estimate the health risks as a result of actual or hypothetical contact with the affected media. Likely routes of exposure include incidental soil ingestion, dermal contact with soil and contaminant absorption, ingestion of fish caught from the Choccolocco Creek, and ingestion of agricultural products. The analytical data used in the HHRA were collected in 2007 and 2009 for the purpose of the HHRA and reflect the best estimation of current contaminant concentrations. Based on the current contaminant levels and assumptions on the types of activities that could result in exposure, ingestion of fish caught in the Choccolocco Creek appears to be the exposure pathway that would result in the highest levels of health risk. Even though there has been a 'do not consume' advisory in place for fish in this stream for many years, EPA requires that site HHRAs be conducted without consideration of induced restrictions on human exposures. The contamination levels in the floodplain do not appear to result in elevated risk levels assuming a recreational exposure scenario. Potential consumption of fruits, vegetables, and/or livestock grown/raised in floodplain soils could be a health risk concern pending the implementation of the proposed conservation corridor. The HHRA will be re-visited once the status of the conservation corridor is clearly understood.

82 Anniston PCB Site: Problem Formulation for the Baseline Ecological Risk Assessment along Choccolocco Creek M.S. Greenberg, USEPA, Environmental Response Team; S.R. Thoms, USEPA, Region 4, Superfund Division, Waste Division, Office of Technical Serv, Superfund Support Branch; D. MacDonald, MacDonald Environmental Sciences Ltd.; D. Charters, USEPA, Environmental Response Team; C.G. Ingersoll, USGS, Columbia Environmental Research Center; P.L. Scully, USEPA; W. Lorentz, USACE; M. Huston, USFWS; A. Fowler, D. Ludwig, ARCADIS. The Anniston PCB site is located in northeast Alabama and the CERCLA Remedial Investigation/Feasibility Study is being conducted in multiple phases across three operable units (OUs) including the facility (OU-3), residential and non-residential (predominantly commercial) areas (OU-1/OU-2), and Choccolocco Creek and its floodplains (OU-4). The screening level ecological risk assessments (SLERAs) were completed for OUs-1/2/3 and OU-4 in 2005 and 2006, respectively. Polychlorinated biphenyls (PCBs) were identified as the primary contaminant of potential concern (COPC) for ecological receptors. Several metals were identified as being present above ecological screening thresholds used in the SLERA and other hazardous substances were also identified as potentially contributing to ecological risk. The results of the OU-4 SLERA and Phase 1 OU-4 investigations were used to develop the problem formulation of the baseline ecological risk assessment (BERA) and an adaptive management process for COPCs in the OU-4 portion of the Site. The baseline problem formulation (BPF) covers the terrestrial, riparian, and aquatic habitats of OU-4. Key ecological receptors were identified from these habitats to develop assessment and measurement endpoints for decision making at the site (including the in-creek portions of OU-1/OU-2). The assessment endpoints include terrestrial and aquatic plant communities, terrestrial and benthic invertebrate communities, fish communities, birds, mammals, amphibians, and reptiles. Measurement endpoints include environmental sampling, toxicity testing, and exposure modeling to evaluate effects on survival, growth, and reproduction. This presentation will summarize the environmental data from completed investigations on OU-1/OU-2 and OU-3, Phase 1 OU-4 sampling, the results of the SLERAs, and how this information was collectively used to develop the BPF for Choccolocco Creek. A status update for the nearly completed Phase 2 investigations will also be provided.

83 Childhood Exposure to PCBs from Dietary Supplements Containing Fish Oils J. Ashley, Philadelphia Univ, Institute for Textile and Apparel Product Safety; J. Ward, ICQ – USA; C. Anderson, Philadelphia Univ, School of Science and Health; M. Schafer, L. Zaoudeh, D. Velinsky, Academy of Natural Sciences. Children's dietary supplements containing fish oils have become a popular means of increasing children's intake of polyunsaturated fatty acids (PUFAs). However, there is growing concern that the levels and potential health effects of lipophilic organic contaminants such as polychlorinated biphenyls (PCBs) may diminish some of the health benefits associated with daily consumption of fish oil supplements. In this study, thirteen over-the-counter children's fish oil supplements were analyzed for PCBs and daily exposures were calculated. Concentrations of t-PCBs ranged from 0.4 to 20.0 ng/g wet wgt and were low compared to our recent study of adult fish oil supplements (3.1 to 264 ng/g wet wgt). Based on manufacturers' recommended dosages, a child's daily intake of PCBs would range from 2.8 to 50.3 ng/day. Daily consumption of fish oil supplements expose children to PCBs, albeit at low levels. In comparison to ingestion of fresh or frozen fish to gain equivalent amounts of PUFAs contained in supplements, children's fish oil dietary products may decrease daily PCB exposure.

84 Choccolocco Creek Conservation Corridor – Watershed Protection Through Proactive and Permanent Institutional Controls E.G. Macolly, Solutia Inc., Remedial Projects; J. Loper, The Loper Group; M. Shivell, A. Fowler, ARCADIS. Choccolocco Creek and its floodplain are part of Operable Unit 4 (OU-4) of the Anniston PCB Site located in Calhoun and Talladega counties in Alabama. The floodplain includes over 5,000 acres adjacent to 35 miles of Choccolocco Creek. This presentation describes the development and implementation of a Conservation Corridor including planning and design activities, challenges associated with implementation, current status and the benefits of a watershed-based protection project in the long-term remedial resolution of a complex floodplain site. The Conservation Corridor was designed using a GIS database including tax parcel information and years of investigation data. The GIS was used to evaluate the extent of the Corridor, identify land parcels essential to the success of the program, and prioritize the parcels to maximize watershed protection in the shortest timeframe. Tax parcels were ranked based on distance downstream from the Anniston/Oxford area, Creek frontage and acreage within the Corridor footprint. The resulting Conservation Corridor is implementable, protective of the undeveloped nature of the Creek and floodplain, protective of the existing land uses and landowner rights in perpetuity. The Conservation Corridor is being implemented in a phased approach through a non-profit land trust that manages over 150,000 acres of conservation land in Georgia and Alabama. The initial phase focuses on a 10 mile section of the floodplain downstream of the urbanized portions of Anniston and Oxford. Much of this first phase (842 of ~1,500 planned acres) is under easement or ownership by the land trust. The land trust hopes to extend the Corridor downstream to the Coosa River and upstream into the Talladega National Forest. While the Conservation Corridor is a standalone project implemented to protect the Creek and its riparian floodplain, there are many additional benefits. These include increased educational and recreational opportunities and a role in the selection of a remedial solution. The Corridor also acts as a focal point for local land owners and other stakeholders to drive a range of watershed improvement projects. By limiting future development adjacent to the Creek and keeping farm animals from entering the Creek, the Corridor is a direct mechanism for improving habitat and water quality. The Conservation Corridor is also a long-term land-use institutional control that will be an integral part of the selected remedy for OU-4.

85 Assessing the Bioavailability of Parent and Alkylated-PAHs Using Passive Samplers in Petroleum Oil-Impacted Sediment Treated by Activated Carbon Y. Choi, Y. Cho, R.G. Luthy, Stanford Univ, Dept of Civil and Environmental Engineering. Alkylated-polycyclic aromatic

hydrocarbons (PAHs) are known to constitute about 90% of total PAHs in petroleum oil. Yet they are seldom studied in petroleum oil-impacted sites because of the difficulty in characterizing the large number of compounds that fall in this category. In this study, we have developed a rigorous analytical technique to characterize 20 different groups of alkylated-PAHs, ranging from C1- to C4-PAHs, as well as 18 individual parent-PAHs, using gas chromatography-mass spectrometry (GC-MS) in a selective ion monitoring (SIM) mode. Polyethylene (PE) passive samplers were employed to enhance the measurability of aqueous concentrations, which is indicative of the bioavailable fraction of the compounds. The analytical procedure we developed has been used to study the reduction in aqueous concentrations of PAHs by activated carbon amendment in a petroleum oil-impacted sediment. The sediment sample had a concentration of 11.6 mg/kg as parent-PAHs and 114 mg/kg as alkylated-PAHs. The amendment of 5% (sediment dry weight basis) activated carbon, 75-300 um in grain size, reduced the uptake in PE samplers by 82% and 74%, respectively, for parent- and alkylated-PAHs after 8 weeks of thorough mixing. The effect of activated carbon amendment was greatly enhanced by using a finer activated carbon particles. Using an activated carbon grain size of < 32 um, the reduction of PE uptake increased up to 98.9% for both parent- and alkylated-PAHs. Additional experiments are underway to study the activated carbon performance in long-term tests and to measure the PE-water partitioning coefficients of PAHs that will be used to correlate the PE uptake with aqueous concentrations.

86 Reducing Bioavailability at the Sediment Water Interface by Active and Passive Thin Capping – Field Testing in Norway E. Eek, Norwegian Geotechnical Institute, Environmental Technology; A. Oen, Norwegian Geotechnical Institute, Dept Environmental Engineering; G.D. Breedveld, Norwegian Geotechnical Institute, Univ of Oslo, Institute for Geosciences; M. Schaanning, Norwegian Institute for Water Research; G. Cornelissen, Norwegian Geotechnical Institute. In order to study the effectiveness of thin layer capping with active and passive materials in reducing the bioavailability persistent organic pollutants (POP) at the sediment surface, six different test plots have been constructed and subsequently monitored in contaminated Norwegian fjords. As a part of this study both placement success chemical availability (as sediment to water flux) and benthic fauna health where monitored. Here we focus on flux of freely dissolved PAHs, dioxins and TBT from capped and uncapped seabed sediments. Outside the TBT contaminated Fiskerstrand ship yard on the west coast two test plots where constructed: 7 cm thick cap of fine grained limestone slurry and 7 cm thick cap of fine grained limestone slurry mixed with activated carbon (AC). In the dioxin contaminated Grenlandfjords on the south east coast of Norway four different test plots where constructed; 5 cm thick crushed limestone cap, 5 cm clean clay cap, 2 cm cap with clean clay mixed with AC at two different water depths 30 m and 100 m. On each of these plots three infinite sink benthic flux chambers where deployed to monitor the release of POPs from the seabed to the overlying water. The infinite sink benthic flux chambers work by enclosing a volume of water and an area of the seabed and collects POPs on an infinite sink material (triolin filled Polyethylene membranes or silicon rubber sheets) inside the chamber. By extracting and measuring the amount of POPs collected on the infinite sink the flux can be calculated from the enclosed seabed area and the deployment time (Eek et al. 2010 ES&T Vol. 44). The measured flux, within a year after capping, was lower on all capped test plots compared to flux from the test plots before capping or from adjacent uncapped reference fields, and showed that the flux was reduced by 75 – 99 % by a passive capping layer of 5 cm or more. However, at the fields with 2 cm AC containing cap, only a 55 – 63 % reduction was found. The greater influence of bioturbation in the thinner capping layers and the slow mass transferee of POPs from sediment particles to AC particles is a likely explanation to these observations.

87 Bioaccumulation of Highly Hydrophobic Organohalogen Flame Retardants in Sediment to the Oligochaete, *Lumbriculus variegatus* B. Zhang, State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences; J. You, State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy Sciences, State Key Laboratory of Organic Geochemistry. Recent studies reported that highly hydrophobic organohalogen flame retardants, such as decabromodiphenyl ether, decabromodiphenyl ethane, and dechlorane plus, which had log Kow values greater than 9, were ubiquitous in the environment. Due to their hydrophobicity, organohalogen flame retardants tended to be associated to sediment and high concentrations of these contaminants have been widely detected in sediment in the Pearl River Delta (PRD), South China. However, studies on their bioavailability to benthic organisms were limited. In the current study, bioavailability of the three target halogenated flame retardants was assessed by exposing the oligochaete, *Lumbriculus variegatus* to both spiked and field-contaminated sediments. The spiked sediment was dosed in two different concentrations of the target compound while the field sediment was collected from an electronic waste recycling site in the PRD. Meanwhile, the freely dissolved chemical concentrations in sediment porewater were also measured using matrix solid-phase microextraction. The uptake and depuration curves in the bioaccumulation tests showed that these highly hydrophobic contaminants were bioavailable to the worms. On the other hand, the freely dissolved concentrations of the contaminants in porewater were very low indicating ingestion of sediment particles may be the major uptake routes for these highly hydrophobic organohalogen flame retardants.

88 Use of SPME Fiber and Tenax Methods to Predict the Toxicity of Pyrethroids in Field Sediments A.D. Harwood, Southern Illinois Univ, Zoology; M. Lydy, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology; D. Weston, Univ of California, Dept of Integrative Biology. The presence of pyrethroids in both urban and agricultural sediments at levels lethal to invertebrates has been well documented. However, variations in bioavailability among sediments make accurate predictions of toxicity based on whole sediment concentrations difficult. A proposed solution to this problem is the use of bioavailability-based estimates such as SPME fibers and Tenax beads. Previous research has demonstrated that both methods serve as accurate predictors of bioavailability and mortality. This study compared three methods to predict bioavailability and ultimately toxicity: field-deployed SPME fibers, laboratory-exposed SPME fibers, and a 24 hour Tenax extraction. The objective was to compare the ability of these methods to predict the toxicity of pyrethroid contaminated field sediment to three benthic species *Hyalella azteca*, *Chironomus dilutus*, and *Hexagenia* sp. Six sites in central California with known pyrethroid contamination were chosen. At each site, six Plexiglas holders containing SPME fibers encased in copper mesh were deployed and approximately 4 liters of sediment was collected. Standard 10 day toxicity evaluations were conducted on the six sediments for the three species in concurrent separate exposures. In addition, SPME fibers were exposed to sediments, a 24 hour Tenax extraction was performed, and pyrethroid sediment concentrations were determined using standardized laboratory methods. All SPME fibers were exposed for 42 days to ensure they had reached equilibrium. All six sediments were toxic to at least one species. Typically, *H. azteca* were the most sensitive followed by *Hexagenia* and *C. dilutus*. For both Tenax and SPME extracted concentrations a bioavailable toxic unit was calculated (SPME or Tenax concentration/sediment LC50). This value was then correlated to mortality for each method, including standard toxic units for the bulk sediment concentrations. The study demonstrates the applicability of bioavailability-based toxicity estimates versus standard methods.

89 Bringing (Bio)accessibility Extractions to the Next Level – Combining Mobilisation Medium and Infinite Absorption Sink V. Gouliarmou, Aarhus Univ, National Environmental Research Institute, Environmental Chemistry and Microbiology; E. Edelmann, A.P. Loibner, Univ of Natural Resources and Applied Life Sciences, Agrobiotechnology – IFA Tulln; C. Collins, Reading Univ, Soil Research Center; P. Mayer, Aarhus Univ, National Environmental Research Institute. Soil bioaccessibility extraction techniques are generally simple dissolution experiments, where the fraction of compounds that is transferred to the medium is measured and considered to be bioaccessible. However, such techniques can lead to an underestimation of bioaccessibility, since they do not account for the consumption of contaminants by either degradation or absorption. It is therefore crucial to develop practical bioaccessibility extraction approaches that combine both mobilisation and consumption processes. The mobilisation medium can be chosen to either maximize desorption without attacking the matrix or even to simulate the relevant organism conditions. A sorbent can act as an infinite diffusion sink for continuously removing the mobilized contaminants from the medium. Initially, we combined cyclodextrin extraction with a polymer of poly(dimethylsiloxane) and activated carbon which lead to the contaminant trap method1. This contaminant trap is a practical and simple approach for the isolation and quantification of the desorption resistant contaminants in soils, its main limitation being that it is not possible to

back extract from the polymer. The next step was to find a polymer material and format that can act as infinite sink and allow simple back extraction. Silicone rods were chosen, which are already used in silicone rod extraction and passive sampling. This resulted in a better and more relevant bioaccessibility extraction approach and simplified the analytical procedures. The silicone rods were applied to both cyclodextrin solutions and artificial digestive fluids, using PAHs as model compounds. Passive dosing2 was applied to determine the free fraction and partitioning of PAHs in cyclodextrin and digestive fluids, which in turn was used for sink dimensioning. Validation experiments with spiked cyclodextrin and digestive fluids confirmed an efficient trapping of PAHs by the silicone rod. References (1) Mayer, P.; Olsen, J. 90 Sediment Quality Guidelines in British Columbia, Canada J. Arblaster, Simon Fraser Univ, Resource and Environmental Management; F.A. Gobas, Simon Fraser Univ, School of Resource and Environmental Management (Faculty of Environment); M.G. Ikonomou, Institute of Ocean Sciences. Current methods used to derive Sediment Quality Guidelines (SQG) in Canada do not account for the biomagnification of chemicals in marine food chains, resulting in SQGs that are insufficiently protective of upper trophic level organisms such as marine mammals, birds and humans. The Biota-Sediment Accumulation Factor ($BSAF=C_{biota}/C_{sediment}$) quantifies the relationship between concentrations in organisms and the sediment and can be applied in risk assessment or to derive SQGs that by accounting for biomagnification of chemicals are more protective of ecosystems. Here, we investigate the use of BSAF for guideline development in B.C. using empirical data and bioaccumulation modeling. PCB data for four sites on the B.C. coast was used to derive BSAFs, assess how protective of upper trophic level populations current guidelines are and to derive new SQG. A west coast bioaccumulation model was developed for additional species and human health risk assessment. Empirical BSAF values are highest for Dungeness Crabs and Harbor Seals, but are highly variable both within and between sites. Species with similar trophic position show similar BSAF values indicating that species-specific traits do not play a significant role in BSAFs. The model shows good agreement with empirical data in Vancouver and the Strait of Georgia, but less so in Victoria and the Central Coast where BSAFs are lower. Applying empirical and model derived BSAF values for risk assessment shows that current guidelines fail to protect the majority of Orca whale, Stellar sea lion and harbor seal populations based on toxicological reference values. Current guidelines also do not ensure fish and shellfish populations are below Tissue Residue Guidelines for human consumption. SQGs back-calculated from relevant endpoints for human health, marine mammal population health and to meet Chinook salmon tissue residue guidelines ranged from 0.002 µg/kg dw to 2.7 µg/kg dw – substantially lower than the current B.C. SQG of 20 µg/kg dw.

91 Improving Predictability of Sediment-Porewater Partitioning Models using Trends Observed with PCB-Contaminated Field Sediments S.B. Hawthorne, Univ of North Dakota, Energy and Environmental Research Ctr; D.J. Miller, C.G. Grabanski, Univ of North Dakota, Energy and Environmental Research Center; H.H. Arp, Norweigen Geotechnical Institute, Environmental Engineering. More than 1900 sediment-water partitioning coefficients were measured for 58 polychlorinated biphenyl (PCB) congeners in 53 historically-contaminated sediments collected from 10 urban and rural waterways in the United States and Canada. Freely-dissolved porewater concentrations were determined using passive sampling with polyoxymethylene. Measured total organic carbon (TOC)/water partitioning coefficients, KTOC, ranged from one to nearly three orders-of-magnitude higher than typical literature values based on spiking experiments and model predictions. Although total PCB concentrations ranged from 0.08 to 194 mg/kg, the more highly-contaminated sediments showed only slightly lower KTOC values than less-contaminated sediments. No correlation was observed between log KTOC values and sediment TOC, black carbon (BC), or BC/TOC fractions (r^2 typically < 0.1). Utilizing a two-carbon model incorporating anthropogenic BC did not improve predictions over a one-carbon TOC model. A comparison of models recently validated for historically contaminated sediments showed that a coal-tar poly-parameter linear-free energy relationship (PP-LFER) and the Raoult's Law model were successful at predicting average log KTOC values, without the need for any calibration or fitting (within a factor of 10 more than 90 % of the time, and within a factor of 30 more than 99 % of the time). Predictions were further improved by the introduction of a Weathering Factor (WF) that accounts for the relative depletion of lower molecular weight congeners due to weathering processes (e.g., desorption, degradation). Highly weathered sediments (with a WF near 1) tended to follow the coal-tar PP-LFER and Raoult's Law model the closest. Fresher sediments (with WF

92 Modeling trade-offs between pollutant sorption and biodegradation in biochar-amended soils D. Werner, Newcastle Univ, Civil Eng. and Geosciences; K.M. Bushnaf, Newcastle Univ; S. Puricelli, S. Saponaro, Politecnico di Milano. Biochar addition to soil is being investigated as a novel technology to remediate polluted sites. A critical consideration is the impact of biochar on the intrinsic microbial pollutant degradation, in particular at sites polluted with a mixture of readily biodegradable and more persistent organic pollutants. Pollutants bound in the micropores of carbonaceous sorbents such as biochar or activated carbon become less accessible for bio-uptake by soil organisms, bacteria or plants, and the addition of activated carbons or biochars thereby reduces the transfer of these pollutants from soil into the terrestrial food-chain. This occlusion may, however, also reduce the pollutant's availability for microbial break-down and increase persistence. On the other hand, biochar addition to degraded soil has been shown to improve the soil structure and fertility and microbial cell numbers. Because of these antagonistic effects, the effect of biochar on the microbial degradation of soil pollutants cannot be readily anticipated. We therefore studied the impact of biochar (2% on dry weight basis) on the volatile petroleum hydrocarbon intrinsic biodegradation in an aerobic sandy soil with batch and column studies. The soil-water partitioning was enhanced in the biochar-amended soil and petroleum hydrocarbon vapour migration was retarded accordingly. The Kd value of toluene increased 36 times, because of the ability of this compound to interact via π-π electron forces with the aromatic surface of the biochar. Additional methyl-groups on the aromatic ring appear to interfere with these interatomic interactions, since m-xylene and 1,2,4-TMB did not show a comparable enhancement in their Kd value in the biochar-amended soil. We employed a numerical pollutant fate model to interpret measured VOC concentration profiles in soil with and without biochar amendments at various distances from a NAPL source. The column study indicated similar total petroleum hydrocarbon degradation in soil with and without biochar, greater volatilisation of all petroleum hydrocarbons from soil without biochar and greater biodegradation of linear, branched and cyclic alkanes in soil with biochar. We conclude that the total petroleum hydrocarbon degradation rate was controlled by a factor other than substrate availability in the soil we investigated, and the reduced availability of monoaromatic hydrocarbons in biochar amended soil led to greater biodegradation of the other petroleum compounds.

93 Relationship Between the BCF, BAF and the TMF F.A. Gobas, Simon Fraser Univ, School of Resource and Environmental Management (Faculty of Environment); A.R. Brisebois, Simon Fraser Univ, Resource and Environmental Management; H.A. Leslie, Institute for Environmental Studies, VU Univ; P. Leonards, Institute for Environmental Studies, VU Univ, Chemistry and Biology, VU Univ, Institute for Environmental Studies. There is a reasonable degree of consensus among bioaccumulation scientists on the use of Trophic Magnification Factors (TMF) as "conclusive" evidence of the bioaccumulative nature of chemicals in the environment. However, regulatory criteria for the determination of whether a substance is bioaccumulative mostly rely on the use of the Bioconcentration Factors (BCF), measured in laboratory tests. In this paper, we present the results from laboratory, field and modeling studies aimed at testing the hypothesis whether the BCF is a good predictor of the TMF. Our studies involved (i) the compilation of BCFs for a range of potentially bioaccumulative substances through literature studies; (ii) a field study of the food-web bioaccumulation of the same substances in Western Scheldt Estuarine food-web aimed at determining the TMF in food-webs containing both water and air-breathing organisms; (iii) a modeling study aimed at formulating and exploring the relationship between the BCF and the TMF. We conclude that the BCF can be a useful predictor of the TMF for a range of chemicals with specific chemicals characteristics and under specific ecological conditions. We also conclude that there are two major types of "exceptions" where the BCF does not provide accurate information about the bioaccumulative nature of chemicals in the environment. The first exception deals with substances that show a relatively low BCF but have a high TMF. The second exception is for chemicals that

exhibit a high BCF in laboratory tests, but which do not show biomagnification in food-webs and have a low TMF. Supported by model calculations, we propose a set of simple rules that may be useful in the interpretation of laboratory based bioconcentration factors in terms of their bioaccumulative nature in the environment. These rules may be helpful to regulators involved in bioaccumulation assessments and to scientists that apply bioconcentration studies to study the bioaccumulative nature of chemicals in the environment.

95 In Situ Mercury Uptake by Aquatic Invertebrates in the South River, Virginia J.R. Flanders, W.J. Reese, G. Murphy, URS Corporation; R.G. Stahl, DuPont Company, Corporate Remediation Dept, Principal Consultant. The relative importance of mercury uptake through aqueous and dietary pathways is critical to understanding the movement and biomagnification of mercury from physical media and primary producers to aquatic consumers. Aqueous and dietary uptake of inorganic mercury (IHg) and methylmercury (MeHg) by aquatic invertebrates were assessed along a gradient of mercury concentrations in physical media (surface water and sediment) in the South River, Virginia. The study design included a seven-day uptake period for mayfly nymphs (i.e., *Maccaffertium* sp.) and crayfish (i.e., *Orconectes* sp.) transplanted from a reference river and deployed in microcosm chambers containing cobble, pebble, and gravel substrates. The dietary treatment contained substrates colonized with native epiphytic communities to provide food resources for study organisms, while the aqueous treatment contained uncolonized substrates. The microcosm chambers were designed to facilitate surface water and pore water exchange. Co-located measurements of IHg and MeHg in physical media and primary producers were collected on day-0 and day-7 of the study period. In addition, resident mayfly nymphs and crayfish were collected on day-0. The experiment was performed in spring and summer to determine seasonal effects on uptake. Preliminary results indicate that uptake of both IHg and MeHg by mayfly nymphs were significantly greater than by crayfish for both seasons, treatments, and study sites. Furthermore, uptake of IHg and MeHg by mayfly nymphs did not differ consistently among seasons or uptake pathways. However there were significant differences between study sites.

96 TVA Kingston Ash Spill: A Preliminary Weight-of-Evidence for Aerial Insectivores Exposed to Selenium and Other Metals S. Young, T. Schlekat, D. Jones, A.R. Stojak, ARCADIS; T.H. Henry, Tennessee Valley Authority; N.E. Carriker, TVA Kingston Ash Recovery Project, Kingston Fly Ash Recovery Project. The December 2008 Kingston ash spill spawned predictions of dire effects on the aquatic ecology in the region as a result of bioaccumulation of ash-related constituents. Tennessee Valley Authority (TVA) proactively developed a comprehensive and integrated research program to evaluate the potential for adverse environmental effects of the spill. One aspect of that work focused on accumulation and effects of ash-related constituents on aerial-feeding insectivores consuming emergent aquatic insects from the Kingston river system. This consisted of assessing potential risks to aerial-feeding insectivorous birds and mammals, as represented by the tree swallow (*Tachycineta bicolor*) and gray bat (*Myotis grisescens*). This talk focuses on the assessment for tree swallows, which have been shown to be a useful indicator of bioaccumulative constituent exposures. Tree swallows feed on emergent aquatic insects whose larval forms may accumulate constituents from submerged sediments. Thus, tree swallows may exhibit adverse effects of constituents transferred from the sediment to terrestrial systems. Three types of data are available for tree swallows: dietary exposure models, measured body burdens, and population survey results. The food web model used a combination of standard and site-specific factors to estimate conservative and realistic dietary exposures. Notable is the use of measured metal concentrations in adult mayflies (*Hexagenia bilineata*). Body burden samples and field survey data were obtained from nest boxes in the vicinity of the spill and at reference reservoirs. Several tree swallow colonies were established in 2009 and 2010 and evaluated for exposure and reproductive productivity. Nests were monitored regularly and accessed multiple times to obtain egg and nestling samples. Metal and metalloid concentrations were evaluated relative to spill proximity and sediment data as measures of exposure to ash-related constituents. Selenium tissue concentrations were compared with literature data to estimate potential effects. Parameters such as clutch size and hatchling success are direct measures of potential population-level effects. The preliminary weight-of-evidence suggests that although exposure to some ash-related constituents is elevated in the river system, potential adverse effects are not clearly evident. This presentation highlights key findings and discusses the relative strengths and weaknesses of the various lines of evidence.

97 Bioaccumulation of PCBs and PBDEs in Marine Zooplankton from the Strait of Georgia, British Columbia, Canada H. Frouin, N. Dangerfield, Fisheries and Oceans Canada, Institute of Ocean Sciences; R. MacDonald, Fisheries and Oceans Canada, Institute of Ocean Sciences; P. Shaw, Environment Canada, Science Division; P. Ross, Fisheries and Oceans Canada, Institute of Ocean Sciences. The accumulation of polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs) in plankton plays a significant role in the transport and fate of these compounds in aquatic food webs. We collected water samples at three stations in the Strait of Georgia to measure concentrations of 204 PCB and 61 PBDE congeners. Samples were collected at both near surface and near bottom in each of four seasons over a one year period. In an effort to capture movement in and out of the system, a minimum of one tidal cycle was sampled with InfiltrexTM in situ samplers. Zooplankton samples were collected vertically from the water column using a SCOR plankton net with 255 µm cod end. PCBs and PBDEs in water samples were analyzed in two fractions, representing dissolved (XAD) and particle-bound (0.7 µm; GF/F). The spring phytoplankton bloom may explain higher plankton PCB and PBDE concentrations in the June samples. The PCB/PBDE ratios were higher in dissolved phase than in particle-bound phase, this partitioning being partly related to chemical properties of the PCBs and PBDEs. This was particularly evident for the "heavier" BDE-209, which partitioned preferentially onto particles. The PCB pattern was dominated by tri- and tetra-PCB compounds in both dissolved and particle-bound fractions and by penta- and hexa-PCB compounds in zooplankton. BDE-47, -99, -100 and -209 dominated in environmental matrices and zooplankton. Principal components analysis (PCA) further revealed a congener-related pattern difference between zooplankton, dissolved and particle-bound fractions, highlighting the importance of particles in driving fate of organic contaminants in both environmental and biological matrices. The logBAFLWs (Bioaccumulation factor on a lipid weight basis) for PCBs and PBDEs versus octanol-water partition coefficient (logKow) relationship was near 1:1 for POPs within the log Kow range of 5 to 7. A curvilinear model provided a better relationship between these two variables when POP compounds with log Kow > 7 were included, suggesting that POPs ~ log Kow 5 to 7 in zooplankton are at equilibrium with water and that physical partitioning, rather than biotransformation, is the major factor governing POP profiles in marine zooplankton. Given increasing PBDE concentrations over recent decades, and the persistence of PCBs in the environment, this uptake by zooplankton represents an important prelude to further food web-based biomagnification.

98 Spider Mediated Trophic Transfer of PCBs from Aquatic to Terrestrial Food Webs D. Delach, Clemson Univ, Environmental Toxicology; C.M. Lee, Clemson Univ, Environmental Engineering and Earth Sciences Dept; D. Walters, USGS, Fort Collins Science Center, Ecologist. Trophic transfer within the Lake Hartwell, Twelve Mile Creek watershed has been documented from the sediment to biofilms to fish, resulting in concentrations above 2ppm, which is the limit established by the FDA for sale of commercial seafood in the US. There is also transfer from the aquatic to the terrestrial components of the ecosystem. Emergent insects that develop in the sediment function as biovectors of contamination when they are captured by riparian spiders. This directs the PCB contamination to predators such as lizards, amphibians and birds. Risk of potentially harmful PCB levels to such predators increases as the spiders constitute higher percentages of the diet and as PCB concentrations increase. Sampling from a variety of spider families has indicated that the enantiomeric fraction of chiral congeners as measured by GC-ECD differs for families and over the contamination gradient. Sediment concentrations of 15ng/g have been measured, resulting in a bioaccumulated concentration of up to 2400ng/g in spiders with enantiomeric fractions (EFs) that differ from their prey sources. For example, *Chironomus dilutus* have racemic EFs (0.50) for PCB congeners 91 and 95, whereas *Tetragnathidae* spiders have significantly nonracemic EFs at 0.28 for PCB 91 and 0.25 for PCB 95. Spiders have yet to be included in trophic transfer studies despite their important role mediating the transfer from aquatic to terrestrial food webs. With a global distribution, terrestrial and aquatic insect prey sources, and unique trophic placement, their potential use in toxicological studies can create opportunities to assess spatial and temporal differences in biotransformation.

99 Trophic Transfer of Decamethylcyclopentasiloxane (D5) in Aquatic Food Webs in Comparison to Polychlorinated Biphenyl Materials (PCB-153 and PCB-180) D.E. Powell, Dow Corning Corporation, Health & Environmental Sciences, Dow Corning Corporation, Health & Environmental Sciences (C03101); R.M. Seston, J.A. Durham, K.B. Woodburn, Dow Corning Corporation, Health & Environmental Sciences. The potential of a chemical substance to accumulate in aquatic organisms and to increase in concentration with increasing trophic level are criteria used to classify substances as being persistent, bioaccumulative, and toxic (PBT). Bioaccumulation is the accumulation of a substance in the tissues a living organism through any route. Biomagnification is the increase in concentration of a substance in living organisms that are separated by a single trophic level step on a food chain. Trophic magnification, which describes the increase in concentration of a substance in living organisms that occupy successively higher trophic levels within a food web, is used to assess bioaccumulation and biomagnification of chemicals in the environment. Sediments and aquatic organisms were analyzed to evaluate trophic magnification of decamethylcyclopentasiloxane (D5; CAS No. 541-02-6) in the freshwater food web of Lake Pepin (Minnesota, USA) and in the marine food web of Oslofjord (Norway). Isotopic signatures for the stable isotope of nitrogen (^{15}N) and carbon (^{13}C) were used to identify trophic level positions occupied by the organisms and to evaluate the flow of carbon in the food webs. Additional samples from Lake Pepin were also analyzed for the polychlorinated biphenyl materials 2,2',4,4',5,5'-hexachloro-1,1'-biphenyl (PCB-153; CAS No. 35065-27-1) and 2,2',3,4,4',5,5'-heptachloro-1,1'-biphenyl (PCB-180; CAS No. 35065-29-3), which are "legacy" chemicals that are both known to bioaccumulate in aquatic organisms and biomagnify in aquatic food webs. Concentrations of D5 in Lake Pepin and Oslofjord were greatest in the lowest trophic levels and significantly decreased up the food web, with the lowest concentrations being observed in the highest trophic levels. In contrast, concentrations of PCB-153 and PCB-180 in Lake Pepin were lowest in the lowest trophic levels and highest in the highest trophic levels. These results indicated that trophic dilution of D5, not biomagnification, was occurring across the aquatic food webs. The high level of agreement for results between Lake Pepin and Oslofjord demonstrated that trophic dilution of D5 was not related to differences in the environment (freshwater vs marine) or to exposure.

100 Trophodynamics of Polychlorinated Biphenyls and Polybrominated Diphenyl Ethers in Coastal Waters Food Web from Surabaya City, Indonesia M. Ilyas, Ehime Univ, Center for Marine Environmental Studies (CMES), Environmental Chemistry; A. Sudaryanto, I.E. Setiawan, Agency for the Assessment & Application of Technology, Technology Center for Marine Survey; A.S. Riady, Ehime Univ, Center for Marine Environmental Studies (CMES), Environmental Chemistry; C.K. Hyeon, Kyung Hee Univ, Environmental Science and Engineering; T. Isobe, Ehime Univ, Senior Research Fellow Center; S. Takahashi, Ehime Univ; S. Tanabe, Ehime Univ, CMES, Environmental Chemistry. Biomagnification of polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs) was studied in the coastal waters food web from the highly industrialized city of Surabaya, Indonesia. We measured the concentrations of PCBs (62 congeners) and PBDEs (42 congeners) as well as carbon and nitrogen stable isotope ratios in wild fish and shellfish (n=33) from Surabaya coastal waters to elucidate the contamination status, trophic positions in food web and trophic magnification factors (TMFs) of the contaminants. Concentration ranges and median of PCBs and PBDEs were 84–1600 (410) ng g^{-1} lw and ND–43 (5.6) ng g^{-1} lw, respectively. BDE-47 and -209 were the predominant PBDE congeners in most of the samples. BDE-209 was particularly detected in benthic species, indicating the bioaccumulation of BDE-209 associated with sediment. On the other hand, CB-153, -138 and -180 were the predominant congeners of PCBs in fish tissues. Concentrations of PCBs and PBDEs in biota were significantly correlated with lipid contents ($p < 0.001$). The TMFs of PCBs and PBDEs indicated that most of PCBs and PBDEs were not biomagnified in the biota of the present study, including total PCBs, CB-153, -138; total PBDEs, BDE-47, -153 and -209, for which the TMFs values were 0.95, 0.97, 0.91; 0.69, 0.86, 0.89 and 0.65, respectively. However, CB-180 and -170 have TMFs > 1 (1.4 and 1.3), suggesting that these congeners are biomagnified in the coastal water food web of Surabaya. This study reported for the first time the biomagnification characteristics of organic contaminants in coastal ecosystem from Surabaya City, Indonesia.

101 A Case Study of Regional Ecological Risk Assessment Based on Land Use Analysis in Beijing G. Xiurui, Beijing Univ of Technology, College of Environmental and Energy Engineering; C. Dongsheng, H. Hongwei, C. Shuiyuan, Beijing Univ of Technology. Ecological Risk Assessment (ERA) has been focused by researchers recently. Regional Ecological Risk Assessment (RERA) could be an effective way to describe and assess the adverse effect to ecosystems from environment pollutions, human activities or nature disasters on regional scale. Its objective is to providing the support for the regional risk management. Generally, RERA can be divided into 4 parts: risk receptor analysis, risk source analysis, exposure and hazard analysis and risk characterization, etc. This paper conducted a RERE study in Beijing. It can be reclassified into 5 categories of representative ecosystems for the 16 kinds of land-use in Beijing as risk receptors, which are forest, lawn, cultivated field, water and urban area. By screening and identifying all the risk sources in Beijing it was determined that drought, air pollution and dust were the main risk sources, for which the spatial distribution, intensity and probability were analyzed. For the exposure and hazard analysis, this paper chose the ecological loss index to reflect the ability of receptors to resist the disturbance. AHP (Analytic Hierarchy Process) was employed to assess the weights of main risk sources. Risk characterization can get the comprehensive ecological risk value for each county in Beijing, according to which 5 levels of ecological risk were divided by ArcGIS software. The results showed that the value of ecological risk ranged from 0.0027-0.0535, with Miyun, Huaishou and Yanqing being of highest risk, downtown area being of lowest risk, and Fangshan, Tongzhou and Shunyi being of middle risk. It can be concluded that the risk assessment results lied in the 95% confidence interval by the uncertainty analysis. Finally, some policy suggestions for the ecological management measures for local government were presented.

102 An Integrated Risk Assessment Framework to Advance Environmental Quality and Species Recovery Initiatives at the Watershed Scale R. Johnston, US Navy, Marine Environmental Support Office-NW; J. Brandenberger, Battelle Pacific NW Division-MSL. Integrated ecosystem assessments for large ecosystems have a critical need to identify and rank risk drivers to ensure that recovery actions are focused on the most urgent and important problems. Effective ecosystem management and recovery will require a rigorous and holistic assessment of the relative risks by relating sources of stress like toxic loadings, hypoxia/anoxia events, nuisance species, and loss of habitat to the structure and function of the food web and the critical provisioning and sustaining ecological processes needed to obtain ecosystem recovery. To address this need, an integrated risk assessment conceptual model framework is proposed that links the sources of stress (threats and drivers) to secondary stressors (environmental media and structures) and identifies the pathways (pressures and processes) by which primary and food web receptors can be impacted. The framework allows identification of assessment endpoints, measurement endpoints, and available data sources that can be used to assess relative ecological and human health risks. Application of a numerical modeling framework linking watershed scale processes to the food web and cumulative net ecosystem benefit will improve the risk assessment by increasing the capacity to assess risks to higher levels of ecological organization (population and community) and allow spatially explicit characterizations of risk to be developed. Regional or watershed scale approaches are necessary to properly bound and address the complexity of the problem and develop meaningful management actions. The framework encompasses and harmonizes requirements for three of the major regulatory drivers for ecosystem recovery – restoration (ESA), cleanup (CERCLA), and water quality improvement (CWA). By providing an effective feedback between what is causing risk and actions to manage risk, the framework also supports adaptive learning and improves the understanding needed for effective ecosystem management.

103 Assessing Ecological Risk Over Large Geographic Scales with Spatial Applications of Eco-Epidemiology K. Kapo, Montani Run, LLC; S. Dyer, The Procter & Gamble Company, Central Product Safety, The Procter & Gamble Company, Miami Valley Innovation Center. Integration of existing data resources (e.g., local, state, and federal agencies, trade associations, etc.) for the identification and prioritization of ecosystem stressors over large geographic scales is a practical first-tier strategy for meeting the challenge of regional watershed management. Spatial applications of eco-epidemiology, in which geographic patterns of biological and diverse environmental parameters (e.g., percent effluent, habitat, river size, landcover, etc.) are related and expressed in quantitative terms of relative ecological risk, provide a desktop

approach for integrating and utilizing multiple agency data products and modeling resources. This presentation provides an overview of recent applications of a spatial analysis approach using weights-of-evidence and logistic regression, focusing on a statewide eco-epidemiological assessment of fish and invertebrate communities of Ohio. A 2000–2008 database of biological, habitat, chemical, toxicological, demographic, and other landscape factors from multiple agency resources linked to hydrologic features was analyzed to delineate stressor-response associations and ecological risk models at statewide and ecoregional geographic scales. The assessment of ecological risk from a holistic, large-scale perspective allowed for the evaluation of risk of specific chemicals within the realistic context of multiple ecosystem stressors, such as physical habitat stress. Variation in analysis design by predominant land use, stream size, and biological endpoints (species, traits, and community indicies) provided a spatially explicit, comprehensive screening-level assessment of ecological risk that can serve as guidance for targeted assessment at the site-specific level. Such an analysis was found useful for determining experimental design requirements for investigating causal relationships of chemicals emanating from municipal wastewater treatment plants, such as those from consumer products.

104 Integrated Multiple Stressor Regional Risk Assessment for the South River and Upper Shenandoah River, VA W.G. Landis, Western Washington Univ, Institute of Environmental Toxicology, Western Washington Univ, Institute of Environmental Tox. & Chem.; K. Kolb Ayre, Western Washington Univ, Institute of Environmental Toxicology; A.J. Markiewicz, Western Washington Univ, Institute of Environmental Toxicology; J. Stinson, H.M. Summers, Western Washington Univ, Institute of Environmental Toxicology. An integrated risk assessment has been performed for the South River from the area just upstream of Waynesboro VA to the uppermost part of the Shenandoah River. Six risk regions have been delineated. The area is a site of historic mercury contamination from synthetic fiber production in Waynesboro. Other sources of other stressors include urban and agricultural run-off, channelization, erosion, and contaminated sediments and biota. The current iteration of the relative risk model (RRM) incorporating the hierarchical patch dynamics paradigm was used to construct a conceptual model, designate risk regions, create a ranking system and calculating risks to the stakeholder derived endpoints and impacts. In concert with this effort a Bayesian network was constructed based upon the framework of the RRM and using the same risk regions, sources, stressors, habitats and impacts. The use of the Bayesian network allows a straightforward calculation of management requirements to reduce risk in each of the six risk regions. Atypically, the current source of the Hg contamination is the environment itself. The warm water fish species have been found to have consistently high tissue concentrations downstream of the original source. Temperature may also be a risk factor affecting fish reproduction. Nutrients from upstream of Waynesboro also may be contributing to risk to a variety of endpoints. Although intensively studied for a number of years, the lack of data from upstream and from within the watershed are contributing to the uncertainties in the risk estimates. Much of the information regarding non-point sources has to be inferred from remote sensing estimates of the various types of land-cover for the risk regions. This research program identifies risks and demonstrates the benefits of an integrated risk, research and management program in the restoration of watersheds at a regional scale.

105 Perfluorinated Compounds in Surface Waters from Northern China: Comparison to Level of Industrialization T. Wang, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing 100085, China, State Key Lab of Urban and Regional Ecology; C. Chen, Chinese Academy of Science, Research Center for Eco-Environmental Sciences; J.E. Naile, Univ of Saskatchewan, Dept of Veterinary Biomedical Sciences and Toxicology Centre; J. Khim, Korea Univ; Y. Lu, Chinese Academy of Sciences; J.P. Giesy, Univ of Saskatchewan. Inclusion of Perfluorooctane Sulfonate (PFOS) into the Stockholm Convention has, because of its exemptions, has resulted in increased annual production of PFOS-containing chemicals in China to accommodate domestic and overseas demands. Accordingly, concern about environmental contamination with perfluorinated compounds (PFCs), such as PFOS, has been arisen. However, little information is available on the status and trends in the distribution, sources and risk of PFCs in aquatic environments of China. In the present study, forty two surface water samples collected from five regions with different levels of industrialization were monitored for concentrations of PFCs by use of solid phase extraction and LC/MS/MS. Mean concentrations (maximum concentration) of PFOA and PFOS, which were the dominant PFCs, were 1.2 (2.3) and 0.16 (0.52) ng/l for Guanting, 1.2 (1.8) and 0.32 (1.1) ng/l for Hohhot, 2.7 (15) and 0.93 (5.7) ng/l for Shanxi, 6.8 (12) and 2.6 (11) ng/l for Tianjin, 27 (82) and 4.7 (31) ng/l for Liaoning, respectively. The greatest concentrations of PFCs (121 ng/l), PFOA (82 ng/l) and PFOS (31 ng/l) were observed in Liaoning, which might originate from tributaries of the Liaohe River, the most polluted watershed in Northeast China. While, concentrations of PFCs in the Guanting and Hohhot regions were 3 to 20 fold less than those from Tianjin and Liaoning. This result is consistent with little contribution of PFCs being released from agricultural and non-industrial activities. The magnitudes of mass flow for PFOA and PFOS in decreasing order were: Guanting < Hohhot < Tianjin < Liaoning < Shanxi and Guanting < Hohhot < Shanxi < Tianjin < Liaoning. The larger mass flows of PFOS were accompanied by relative larger magnitudes of PFOA. Concentrations of both PFOA and PFOS in waters from all regions were less than suggested allowable concentrations. However, the relatively greater concentrations of PFCs in Tianjin and Liaoning suggest that further studies characterizing their sources and potential risk to both humans and wildlife are needed.

106 Application of Multiple Index Development Approaches to Benthic Invertebrate Data from the Virginian Biogeographic Province, USA M. Pelletier, National Health and Environmental Effects Research Laboratory, USEPA, Dept: ORD NHEERL AED; A. Gold, Univ of Rhode Island, Natural Resource Science; L. Gonzalez, Univ of Rhode Island, Computer Science and Statistics; C. Oviatt, Univ of Rhode Island, Graduate School of Oceanography. Benthic invertebrate indices have commonly been utilized to assess benthic invertebrate communities. These indices have been constructed using different techniques, but have shown different levels of application success. For example, the EMAP Virginian Province Index did not perform well in a smaller estuarine complex. Similarly, the Chesapeake Bay Benthic Index of Biotic Integrity did not perform well outside of Chesapeake Bay, despite multiple metric and good habitat separation. In this study, we assembled multiple variables (metrics) from the literature and applied different methods of index compilation to explore the relative strengths and weaknesses of the indices. Three different approaches were utilized -- two multimetric indices (Chesapeake Bay approach and the Mebane approach) and a logistic regression technique. The data were subdivided by habitat (salinity and grain size) and indices compiled using the same initial group of benthic metrics. Each approach was examined for its classification accuracy for both reference and impaired sites for the entire Virginian Province. The Chesapeake Bay approach did not perform well in this study. In contrast, another multimetric approach, the Mebane approach, performed well, as did the logistic regression approach. Both techniques have promise for index development and could be useful in applying a biological condition gradient to estuaries.

107 Integrated Assessment of Sediment Contamination by Anthropogenic Pollutants in a Semi-enclosed Bay in Korea S. Hong, Korea Ocean Research & Development Institute, Oil and POPs research group; W. Shim, U. Yim, Korea Ocean Research and Development Institute, Oil and POPs research group; S. Ha, Korea Ocean Research and Development Institute; U. Yim, Korea Ocean Research and Development Institute, Oil and POPs research group; D. Lim, J. An, N. Kim, Korea Ocean Research and Development Institute. Marine environment is the ultimate sink for land based anthropogenic pollutants. After the adsorption to the suspended particles, the contaminants sink and stay remained at the bottom sediment for a long time. Benthic biota will eventually pickup these residues and biomagnify through the food web. In order to assess the contamination status and identify the priority substances in Masan Bay, intensive sediment sampling was conducted and organic and inorganic contaminants were analyzed. Additionally, benthic amphipod toxicity test was conducted as well. The spatial distribution of contaminants clearly revealed the fact that sewage treatment plant outfall and industrial waste output from the inner bay are major pollution sources. After the implementation of 'Total Pollution Loads Management System (TPLMS)' to this bay in 2008, the overall trend in sediment contamination decreased except for PBDE. In order to assess the pollution status of this bay in an integrative way, sediment quality index (SQI) was prepared from the chemical data. The SQI was calculated using two functions viz. 'scope' (the number of variables that do not meet guideline objective) and 'amplitude' (the magnitude by which variables exceed guideline objective) based on sediment quality guideline

(SQG) values from Canada, USA and Australia/New Zealand. The overall status of this bay is 'fair' or 'good'. Among the targeted chemicals, TBT and heavy metals were identified as the priority chemicals influencing the SQI values in Masan Bay. The SQI values were strongly influenced by the target variables (compounds) and their sediment quality guideline values. High copepod toxicity was also observed near the STP outfall and inner most part of the bay, which matched well with the spatial distribution pattern of toxic chemicals. However, some samples with high copepod toxicity didn't show high exceedance of SQG, implying co-contaminants, other than the target chemicals influence the motility.

108 The Use of a Bayesian Network to Model the Risks of Mercury Contamination to Fish and Other Vertebrates in the South River, Virginia H. Summers, W. Landis, Western Washington Univ, Institute of Environmental Toxicology and Chemistry. The South River watershed in western Virginia has had a history of mercury contamination from past industrial practices. An environmental risk assessment of the effects of the mercury contamination was conducted using Bayesian networks. A conceptual model has been created for the effect pathways connecting the sources of mercury to the potential environmental impacts by examining the exposure through various habitats. From this conceptual model, a three-tiered Bayesian network was created for mercury impacts, which included sources of mercury contamination, habitats and direct/indirect toxicological effects on fish, amphibians, mammals and birds. Each parameter in this model consisted of four different risk levels: zero, low, medium and high. A method for evaluating data quality was created that characterizes their applicability to the stakeholder defined endpoints and potential uncertainties in order to categorize the potential for risk within each parameter. A series of distributions of data specific to the South River study area were used to create cumulative probability tables that were linked within the Bayesian network to calculate overall risk to stakeholder endpoints. The method was initially applied to a single endpoint, the risk to smallmouth bass (*Micropterus dolomieu*), for which the largest amount of sampling data exists. The model was expanded to other fish, amphibians and birds. A sensitivity analysis was conducted to identify the effect pathways with the greatest influence on smallmouth bass survival. The results of the analysis will inform future decisions for the restoration and management of the South River watershed.

109 SETAC Gulf of Mexico Oil Spill Focused Topic Meeting: I. Summary on Ecosystem and Risk Assessment W.L. Goodfellow, EA Engineering Science & Technology, Inc.; M.S. Greenberg, USEPA, Environmental Response Team; B. Vigon, SETAC North America; G. Schiefer, SETAC North America. The SETAC Gulf of Mexico Oil Spill Focused Topic Meeting was held April 26–28, 2011 in Pensacola, FL, USA, attracting more than 250 participants. The meeting provided a multi-stakeholder forum for exchange of current and developing knowledge on key aspects of the spill and attracted a diverse group of oil spill assessors and responders with expertise in ecology, toxicology, chemistry, modeling and tracking of oil, technology development, emergency response, environmental management and risk communication. The assessment of the environmental impacts from the oil spill were presented in several sessions including the ecosystem effects of oil spills; risk and damage assessment; and seafood contamination, safety and human health issues. This first of two talks will summarize the discussions from these sessions related to the ecosystem assessment, risk and damage assessment and seafood safety and human health sessions. Included in this presentation will be a summary of the discussions on the assumption of the use of dispersants and the net environmental benefit analysis. These discussions indicated that the participants felt that a rigorous analysis of the risks and benefits of dispersant use in spill response is warranted, given the myriad of receptors and habitats, exposure regimes, and modes of effect. Developing better information to support decisions on the use of oil dispersants will require a holistic and integrated approach. Regarding seafood safety, the results presented indicated that seafood samples were 100-1000 times below levels of concern for PAHs and dispersant markers. A segment of one panel discussed the adequacy of the equivalency approach used, in that the number and relative toxicity of the individual PAH compounds taken into account results in a lower margin of safety than was claimed/presented in public forums (still below thresholds but less than the reported 100 to 1000 times). It was also asserted during the meeting that even though health agencies have determined based on extensive data that Gulf seafood is safe to eat, many people don't accept that. This presentation will highlight these and other key findings, data gaps and future research needs identified within meeting sessions and panel discussions that focused on ecosystem impacts, ecological and human health risk associated with the Gulf of Mexico oil spill.

110 SETAC Gulf of Mexico Oil Spill Focused Topic Meeting: II. Summary on Current Response Technology and Capabilities M.S. Greenberg, USEPA, Environmental Response Team; W.L. Goodfellow, EA Engineering Science & Technology, Inc.; B. Vigon, SETAC North America; G. Schiefer, SETAC North America. The SETAC Gulf of Mexico Oil Spill Focused Topic Meeting was held April 26-28, 2011 in Pensacola, FL, USA. The meeting provided a multi-stakeholder forum for exchange of current and developing knowledge on key aspects of the spill and attracted a diverse group of oil spill assessors and responders with expertise in toxicology, chemistry, modeling and tracking of oil, technology development, emergency response, environmental management and risk communication. Successful oil spill response relies on a multi-disciplinary approach and the application of numerous response techniques that may include subsea containment, remote sensing, mechanical recovery, surface and subsea use of dispersants, in situ burning, and natural attenuation. These techniques are each most efficient under a different conditions (e.g., oil properties, release scenarios, environmental conditions) and should all be evaluated for their applicability in dynamic spill response situations. An understanding of oil fate and transport is a key input factor needed for this evaluation. Current knowledge on oil transport indicated that this occurred in the Gulf within two main regimes: a subsea plume of dispersed particles (< 100 um) and associated dissolved compounds; and a surface plume (>1 mm). The fate of the oil within these regimes (e.g., degree of weathering, bioavailability, oiling of shorelines and the sea bottom) was different as evidenced by the monitoring, chemistry, and environmental forensics data that were presented during the meeting. Several panel discussions centered on improving or increasing the effectiveness of the response toolbox, and how to better choose among response actions. Other discussions identified a combination of needs from higher resolution data on particle size distributions to a variety of fate and effects modeling issues. Some modeling conversations focused on environmental compartments that are not well understood, while others discussed overall improvements to the multi-media integrated models themselves. There was consensus that a better understanding of oil fate will also improve our ability to predict ecosystem-level effects of the spill. This presentation will highlight these and other key findings, data gaps and future research needs identified within meeting sessions and panel discussions that focused on control and abatement techniques, oil fate and transport measurement and modeling, oil tracking technology, and response technology effectiveness.

114 Species Composition, Distribution and Abundance of Megafauna in the Vicinity of MC252 During August 2010 and March 2011 M. Benfield, Louisiana State Univ, Oceanography and Coastal Sciences; R. Putt, Environmental Consultant; M. Valentine, Louisiana State Univ. This presentation will provide data from two independent surveys conducted in close proximity to the Macondo well BOP. From Aug–Sep 2010, two ROVs were used to survey the distribution and abundance of megafauna at 5 sites around the MC252 well. Five sites were located 2000 m due N,W,S, E of the well and 500 m N of the well. Two of these sites (2000 m N, W) were resurveyed during March 2011. A series of radial 250m transects on bearings separated by 15° (Aug 2010) or 30° (Mar 2011) were conducted. Densities of benthic and demersal megafauna were quantified at each site. The sites were dominated by seastars, sea pens, crustaceans (shrimp, crabs, and squat lobsters), and a variety of fish species. Comparisons with independent, qualitative, pre-spill ROV surveys conducted during Feb/Mar 2010 at MC252 suggest similar species dominated before and after the spill. Statistical comparisons among sites will be summarized to compare mean densities for dominant taxa.

116 Modifications to Diets Greatly Affect Outcomes in the Amphibian Metamorphosis and the Fish Short Term Reproduction Assays H. Krueger, Wildlife International, LTD, Aquatic Toxicology; J. Claude, Wildlife Internaitonal, LTD, Aquatic Toxicology; T. Ross, S. Gallagher, Wildlife International, LTD; S. Schneider, S. Palmer, E.M. Burgess, Wildlife International, LTD, Aquatic Toxicology; T. Springer, Wildlife International Ltd; A. Leopold, Leopold Ecotox Services, Wildlife International Ltd.; M. Jaber, Wildlife International, LTD. Slight modifications to the diets specified in the new test guidelines for both the Fish Short Term Reproduction and

Amphibian Metamorphosis Assays improved our ability to meet the performance and validity criteria of the tests. In our laboratory, we found that strict adherence to the feeding regimes of both guidelines was too restrictive. For the fish assay, we could not consistently meet the fecundity requirements using the feeding regime from the guideline. Feeding trials were performed comparing the fish guideline diet of frozen adult brine shrimp to a modified diet that combined newly hatched brine shrimp with commercial flake food. Fish were better able to sustain reproductive output under the modified diet, which has allowed us to more consistently meet guideline acceptance criteria. Feeding trials with tadpoles compared the guideline rates of Sera Micron diet to ½ those amounts. Use of the guideline rates for amphibians resulted in accelerated growth and development with more frogs being pushed into later stages of development (greater than NF Stage 60) at test termination. A high incidence of tail curvature or scoliosis in tadpoles also was observed at the guideline rate. By reducing the feeding rate to approximately ½ the guideline rate, the amount of tail curvature or scoliosis was greatly reduced and tadpoles were at developmental stages that better fit the acceptance criteria of the guideline.

117 Summation of Historical Control Data for Both the Amphibian Metamorphosis Assay and the Fish Short Term Reproduction Assay K. Coady, The Dow Chemical Company, Toxicology & Environmental Research and Consulting, Michigan State Univ, Zoology Dept; R.J. Currie, The Dow Chemical Company, Toxicology, Environmental Research and Consulting; T. Marino, C. Lehman, The Dow Chemical Company; V.J. Kramer, Dow AgroSciences, LLC; J. Thomas, L. McFadden, The Dow Chemical Company; G.M. Klecka, The Dow Chemical Company, Toxicology and Environmental Research Dept. The amphibian metamorphosis assay (AMA) and the fish short term reproduction assay (FSTRA) are both Tier 1 tests in USEPA's Endocrine Disruptor Screening Program. In the Tier 1 battery of tests, the AMA is intended to assess the potential activity of test chemicals on the hypothalamus-pituitary-thyroid (HPT) axis of developing African clawed frogs (*Xenopus laevis*), while the FSTRA is intended to assess both (anti-)estrogenic and (anti-)androgenic activity as well as potential activity in the hypothalamus-pituitary-gonad (HPG) axis of fathead minnows (*Pimephales promelas*). Our lab has run eleven AMA and eleven FSTRA tests over the last several years, and historical control data from these tests are summarized and compared to the USEPA and the Organisation for Economic Co-operation and Development validation data sets. Variability in the measured endpoints is assessed and the ramifications for the study designs, test performance criteria, and interpretations of findings are considered for each assay.

118 EDSP Implementation: Impact of OSRI Acceptance and Path Forward for Ecotoxicology Assays W. Jones, M. Leggett, CropLife America; M. Kern, Bayer CropScience; C.J. Borgert, Applied Pharmacology and Toxicology. In response to congressional mandates in 1996, EPA developed the endocrine disruptor screening program (EDSP) with the intent to identify chemicals with the potential to interact with the estrogen, androgen, or thyroid systems. EDSP is a tiered approach with Tier I providing the screening battery and Tier II providing more definitive multi-generational studies. In late 2009, EDSP was officially implemented with the receipt of testing orders for the chemicals on the first screening list, the majority being pesticide active ingredients. Chemicals selected for screening are subjected to a battery of 11 assays. Test order recipients could choose to utilize existing information- also called Other Scientifically Relevant Information (OSRI) – in lieu of generating new data for a sub-set or the entire Tier I battery. Of the 50+ pesticide registrants, 61% provided OSRI for the in vivo EDSP Tier I studies. Of those that cited OSRI for the Amphibian Metamorphosis assay and the Fish Short Term Reproduction Assay, the USEPA rationale for acceptance and rejection of the OSRI will be discussed; only 4% of the Fish Short Term Reproduction Assay waivers and 13% of the Amphibian Metamorphosis Assay waivers were accepted. Understanding the agency's rationale for accepting or rejecting data submitted as OSRI will be increasingly important as this rationale directly affects animal use and the overall resource burden of the EDSP program. Of emphasis will be how consistently the OSRI was evaluated, what were the missing endpoints within the OSRI submitted and to what extent would other assays in the Tier I battery address those endpoints (or other Part 158 studies). The discussion will include challenges associated with the Amphibian Metamorphosis Assay and the Fish Short Term Reproduction Assay according to the prescribed Series 890 Test Guidelines (including performance criteria). With the focus of this first phase of EDSP on data-rich pesticides, learning's from this listing of chemicals can help industry, USEPA and other stakeholders on the path forward.

119 Comparative Sensitivity of Fish to EDSP Testing and Standard USEPA Pesticide Testing C. Habig, Exponent, Inc., Compliance Services, Inc., Principal Scientist; P. Whatling, Cheminova, Inc., Senior Manager of Regulatory Science. EPA has recently initiated endocrine disruptor screening testing on chemicals to determine whether the test chemicals display effects on selected endocrine systems. A key tenant of the new requirement for endocrine testing is that organisms are highly sensitive to endocrine-active substances, and thus, effects due to these types of substances may be missed in USEPA's standard pesticide guideline testing. Tier I endocrine testing consists of a battery of in vitro and in vivo assays designed to determine whether the test compounds interact with either the reproductive system or thyroid-mediated processes. These assays include two assays involving non-target organisms, the fish short-term reproduction test and the amphibian metamorphosis test. USEPA's initial list of compounds required to undergo endocrine disruptor (EDSP) testing primarily consisted of pesticides. Relatively full data sets were already available for the majority of these pesticides, including mammalian and avian reproduction testing, fish early life stage testing, daphnid and mysid lifecycle testing, and, in some cases, fish full lifecycle testing and/or field testing (mesocosms). While some of the EDSP test endpoints differ from those evaluated in these standard guideline tests, some of the endpoints are either the same, or essentially similar. This presentation reviews the results of EDSP testing on an OP insecticide using fathead compared to previous results from a fish early life stage study with rainbow trout, and results from preliminary fathead minnow full lifecycle testing. The current chronic toxicity risk assessment endpoint for this compound is based on the results of a trout early life stage (ELS) test. The preliminary fathead minnow full life stage testing indicated that fathead minnows are substantially less sensitive to this OP than trout. Results of the trout ELS indicated that the most sensitive endpoint was fish growth (length and weight). Results of the EDSP testing confirmed that fathead minnows are less sensitive than trout to this OP. Moreover, the fathead EDSP results indicated that length and weight were still the most sensitive endpoints, but at concentrations substantially higher than in trout. There were no effects on the reproductive endpoints assayed in the EDSP study at test concentrations that did not elicit observable toxicity in the test organisms.

120 Results of Tier 1 Screening of the USEPA Endocrine Disruptor Screening Program Compared to Data Generated for Pesticide Registration A. Blacker, C. Banman, M. Dobbs, Bayer CropScience; L.S. Ortego, Bayer CropScience, Ecotoxicology; L. Sheets, Bayer CropScience. Pesticides are among the first compounds undergoing Tier 1 testing in USEPA's Endocrine Disruptor Screening Program (EDSP). The Tier 1 testing battery consists of 11 assays designed to identify whether a chemical has the potential to interact with the estrogen, androgen or thyroid pathways of the endocrine system. Under the Federal Insecticide, Fungicide and Rodenticide Act and subsequent amendments, comprehensive toxicology and ecotoxicology testing is required for registration of a pesticide. The data generated in the registration process includes sub-chronic and chronic testing evaluating growth, development and reproduction in multiple species and provides valuable information on whether a compound has potential endocrine activity. However, Tier 1 assays do include endpoints, e.g., receptor binding, vitellogenin, which are not measured in the current data requirements for a pesticide registration. Comparisons of Tier 1 results to toxicity data for registration purposes will be provided using specific examples, and utility of the 11 Tier 1 screens will be discussed in relation to existing datasets for pesticides.

121 Application of an Integrated Testing Strategy to the USEPA Endocrine Disruptor Screening Program Could Reduce Aquatic and Other Animal Testing C. Willett, P. Bishop, People for the Ethical Treatment of Animals, Regulatory Testing; K. Sullivan, Physicians Committee for Responsible Medicine. To maximize efficiency and reduce the number of animals used in testing, new approaches to generating and evaluating toxicity data for chemicals are needed to cope with the ever-increasing demands of new programs like the US Environmental Protection Agency's (USEPA) Endocrine Disruptor Screening Program (EDSP). One such approach involves the use of an integrated testing and evaluation strategy based on the specific properties and activities of a chemical. In this approach, testing

is organized according to the type of information generated. At each step, the information is then reviewed and used to target any potential further testing, until the information necessary for hazard or risk assessment has been generated. Such an integrated strategy, whether applied to existing or future programs, can promote efficient use of resources and save animals. We compare the numbers of tests that will be performed and animals used in the first phase of the current EDSP with what the outcome could have been if the proposed strategy had been used for three randomly selected chemicals.

122 Cross-Species Extrapolation of EDC Toxicity: Consequences for Screening Programs G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; L.E. Gray, USEPA. Many structural and functional aspects of the vertebrate hypothalamic-pituitary-gonadal (HPG) axis are known to be highly conserved, but the full significance of this from a toxicological perspective has received comparatively little attention. High-quality data generated through development and validation of different Tier 1 tests for the USEPA Endocrine Disruptor Screening Program (EDSP) offer a unique opportunity to compare responses of mammals versus fish to chemicals that affect shared pathways within the HPG axis. This analysis used data from 12 different chemicals that act (primarily) as estrogen receptor agonists (17α-ethynylestradiol, methoxychlor, Bisphenol A), androgen receptor agonists (methyltestosterone, 17β-trenbolone), androgen receptor antagonists (flutamide, vincolozolin, *p,p'*-DDE) or inhibitors of different steroidogenic enzymes (ketoconazole, fadrozole, fenarimol, prochloraz) that had been tested in the 21-d fathead minnow assay and in one or more of the other four in vivo (rat) Tier 1 screens (Uterorophic, Hershberger, male and female pubertal assays). Each of the 12 chemicals was identified as endocrine-active by two or more of the five Tier 1 assays, indicating excellent coverage of the HPG pathways of concern. The fathead minnow assay was positive for all the test chemicals. The consequences of these observations in terms of screening efforts like the USEPA EDSP will be discussed. The contents of this abstract do not reflect USEPA policy.

123 The Development of Quantitative Weighting Factors for Use in a Weight of Evidence Framework for the Evaluation of Endocrine Activity C. Borgert, Applied Pharmacology & Toxicology, Inc.; E. Mihaich, Environmental and Regulatory Resources, LLC; L. Ortego, Bayer CropScience; K. Bentley, DuPont Crop Protection; C. Holmes, BASF Corporation; S. Levine, Monsanto Company; S. Marty, Dow Chemical Company; B. Neal, Exponent; R. Becker, American Chemistry Council. We previously developed a conceptual framework for conducting weight of evidence (WoE) evaluations of endocrine screening and testing data (Borgert et al., in press). The framework was designed to be broadly applicable, but with an emphasis on data emerging from the USEPA's Endocrine Disruptor Screening Program (EDSP), and specifically tailored to accommodate endpoints measured in the eleven Tier 1 Endocrine Screening Battery (ESB) assays. The framework calls for a transparent process whereby specific hypotheses are formulated and data quality is evaluated with respect to overarching scientific principles, including primary validity of the measurements, reliability of data reporting, and probative capability of the study design to evaluate causation. The framework also calls for assigning quantitative weighting factors to assay endpoints (WREL) that reflect their relevance for deciding specific hypotheses. This is an important step in the WoE framework as it explicitly recognizes the fact that some assays are very specific and sensitive for evaluating certain hypotheses related to endocrine activity but may be irrelevant for evaluating others. For example, an increase in thyroid follicular hyperplasia as assessed in the amphibian metamorphosis assay would be expected to have a very high WREL for evaluating the hypothesis that a chemical has potential thyroid antagonist activity, but would have a very low WREL for evaluating the hypothesis that a substance has potential estrogen or androgen agonist or antagonist activity. The framework recommends that WREL values be derived as numerical weighting factors based on the predictive value of the endpoint for actual endocrine activity in vivo, which would typically be determined in chronic reproductive and developmental toxicity tests, i.e., EDSP Tier 2 tests. This predictive value, however, may be difficult to evaluate until results for a test set of chemicals are available from the ESB and can be compared to results of Tier 2 tests. As an interim step, however, provisional WREL values can be derived based on a rank ordering of relevance for each hypothesis. This rank ordering should also be based on data, but will necessarily involve considerable scientific judgment. An example derivation of rank ordered WREL values for evaluating Tier 1 EDSP hypotheses is presented, with particular emphasis on endpoints measured in the fish screening and frog metamorphosis assays.

124 A Comparison of Fish BCFs Obtained for Pharmaceuticals as per OECD 305 and Estimated BCFs Obtained Using the Reduced Sampling Method L.A. Constantine, Pfizer, Inc., Pharmacokinetics, Dynamics and Metabolism. Understanding whether an active pharmaceutical ingredient is likely to be taken up from the aquatic environment by fish and bioaccumulate has triggered the need to conduct bioconcentration studies in fish. Such studies are typically considered appropriate for pharmaceuticals having a logD value > 3 and required, as per the EMA Guideline, for pharmaceuticals having logD values > 4.5. The standard OECD Guideline 305 includes an exposure (uptake) phase followed by a post-exposure (depuration) phase typically equal to ½ the duration of the uptake phase. During the uptake phase, ranging between 14 and 60 days, water and fish samples are analyzed periodically until steady state has been established and the depuration phase may be initiated. During the depuration phase, analysis of water and fish samples continues until a plateau has been reached. Based on the sampling schedule outlined in the guideline, >100 fish per study may be required to determine a kinetic bioconcentration factor (BCF). In a effort to reduce the number of fish required to obtain a BCF, an approach to estimating the aquatic bioconcentration factor using reduced sampling has been developed (Springer, et al.2008). This reduced sampling approach aims to estimate BCFs using a minimum number of sampling time points and therefore a reduced number of fish. The goal of this project is compare the BCFs of several active pharmaceuticals obtained through standard OECD 305 test methods with those BCFs determined using the approach of estimating aquatic bioconcentration factors using the reduced sampling method.

125 Derivation of Screening Values for Ecological Risk Assessment of PPCP Releases from CSOs into the Gowanus Canal, Brooklyn, NY S.D. Baker, GEI Consultants, Inc., Ecotoxicologist/Wildlife Biologist; N.E. Paden, GEI Consultants, Inc., Ecological Division; N. Love, C. Claytor, S.M. Pargee, GEI Consultants, Inc; R.W. Gensemer, GEI Consultants, Inc, Ecological Division. Screening values were derived for pharmaceutical and personal care products (PPCPs) as part of a Screening Level Ecological Risk Assessment (SLERA) to evaluate the potential for ecological risks in the Gowanus Canal due to loadings from combined sewer overflow (CSO) discharges. For each media sampled (i.e., water and sediment), conservative screening values for PPCPs detected at least once were derived. When available, previously-generated, risk-based thresholds from national or international government documents (e.g., US Environmental Protection Agency [EPA] and Canadian Council of Ministers of the Environment) which have undergone peer- and public-review were used; however, very few such efforts have been conducted for PPCPs. For PPCPs without existing thresholds, the primary literature was searched for relevant toxicity data. The approach used to derive screening values depended on the amount of relevant toxicity data available for a given PPCP. Several PPCPs had limited available toxicity data, but in a few cases, many data for several species were available. If data were not available from the literature, thresholds of toxicity as predicted by EPA's ECOSAR model (EPA 2003) were used as screening values. In general, sediment toxicity data were less available than those for surface water, so sediment screening values could be derived from available toxicity data for only a few chemicals. Therefore, sediment screening values were generally estimated from surface water screening values using organic carbon partition coefficients (Koc) and the fraction of organic carbon (foc) to predict equilibrium partitioning between sediment and overlying water. The detailed processes and decision-making criteria used to derive surface water and sediment screening values for almost 30 PPCPs will be presented.

126 Environmental Impact Analysis of 10 Active Pharmaceutical Ingredients with QSARs L. Geerts, Flemish Institute for Technological Research NV ("VITO"); I. Van Ginneken, B. Mertens, Janssen Pharmaceutical Companies of Johnson & Johnson; D.J. Caldwell, Johnson & Johnson. An environmental risk assessment is required for all new marketing authorisation applications of medicinal products. The risk assessment follows a stepwise approach. As a start a base set on aquatic toxicology and fate of the active pharmaceutical ingredient (API) has to be generated. This base set can be generated by tests performed according to the standard OECD guidelines, but before doing so the potential effects on aquatic organisms and the environmental fate can be calculated to screen for possible alerts. Structure activity relationships (SAR) are methods for estimating properties

which provide information on intrinsic hazards of chemicals, while reducing time, monetary cost and animal testing. Ten APIs from multiple therapeutic categories were evaluated using EpiSuite. Model results were compared to measured values. QSARs are shown to be a reliable tool for screening environmental properties of APIs. All the test result on (non) ready biodegradability were confirmed by the predictions of the Biowin model. All the ecotoxic substances were identified by Ecosar. The acute toxicity is in line with the measured values (74%) or overestimated (26%) by the model. For the chronic toxicity, the lowest chronic value determines the PNEC and hence the outcome of the risk characterisation. The calculated lowest chronic value for each API is in line with the measured value or lower. For the Ecosar classes considered for these 10 APIs, the main parameter in the algorithm is the log Kow: the higher the log Kow, the lower the ecotoxicity value. It could be argued for the salts to provisionally use the measured log Kow in order to refine the overestimation and avoid underestimation of the ecotoxicity by the model. For the APIs with only covalent bonds the results with measured and calculated ecotoxicity are in the same order of magnitude. As part of an intelligent testing strategy within risk assessment, QSAR predictions can deliver added value to other non-test methods such as in vitro tests, read across and a weight of evidence approach in order to replace animal testing where justified and to secure a high level of safety for man and the environment.

127 Pharmaceuticals at Sites Affected by Contamination: A UK Approach to Assessing Risk to Human Health K. Baker, J. White, B. Magee, ARCADIS. The UK has a well developed framework for the assessment of risks to human health and the environment from land contamination. This includes good practice guidance on deriving Health Criteria Values (HCV), or acceptable daily intakes, for use in quantitative risk assessment and to generate clean-up criteria. However, limited guidance is provided within the framework to assist in developing HCVs where suitable toxicological studies are not readily available. For facilities involved in the production of pharmaceuticals, the absence of data required to derive HCVs in line with the good practice guidance has resulted in poor, or even no, assessment of the potential risks from these compounds where present in soil or groundwater following leaks or spills. A case study for a site in the UK is presented, which overcame these difficulties by calculating HCV utilizing Minimum Therapeutic Doses, an approach initially proposed by the UK Drinking Water Inspectorate. The use of the methodology enabled assessment of risk to human health from 11 pharmaceutical compounds, including phenobarbital, chlorpromazine and molindone, and the derivation of clean-up goals to assist in the remediation process.

129 Environmental Risk Assessment of Ionisable Organics T. Gouin, Unilever, Safety and Environmental Assurance Centre; V. Coombe, Astra Zeneca; J.F. Ericson, Pfizer Inc, Environmental Sciences, PDM; B. Hidding, BASF; J. Ryan, GlaxoSmithKline; K. Silverman, Merck & Co., Inc., Global Safety & the Environment; B. Simon-Hettich, Merck KGaA. The environmental release of ionisable organic compounds (where behaviour depends on pH, ionic strength, etc.) represents a number of challenges for risk assessors who must select relevant and appropriate test endpoints using methods that have historically been used with more neutral lipophilic compounds. ECETOC have thus established a Task Force to review the current understanding and available literature on partitioning property data of ionisable organic compounds at environmentally relevant pHs, including estimation methods for these properties. It is anticipated that the output of the task force will lead to suggestions and recommendations for improved methods for predicting the environmental concentration of ionisable organic compounds in aquatic environments. To date, the work of the Task Force has emphasised the need for better generic environmental fate models, with appropriate soil and water properties, and other parameters required for effective environmental risk assessment of ionisable compounds. Preliminary findings include identification of the key parameters needed to better predict the bioavailability of ionisable organic compounds, which are shown to be strongly influenced by the physical-chemical properties of the substance, for instance, pK_a and log K_{ow}, as well environmental properties such as pH. Modelling activity is supported from data assembled for a physical-chemical property database for ionisable organic compounds used as pharmaceuticals. Using the best available property data a sensitivity analysis has been performed using a number of environmental fate models to determine how variability in environmental input parameters influence the predicted environmental concentration and ultimately the bioavailabilty of a substance. Recommendations on where future research priorities should be targeted are summarized.

130 Magnifying Perceived Risk: Trace Concentrations of Pharmaceuticals in Surface and Drinking Water Have No Demonstrated Human Health Impact D.J. Caldwell, Johnson & Johnson; F. Mastrocco, Pfizer, Inc.; P. Anderson, ARCADIS. Media reports have indicated the presence of pharmaceuticals in surface and drinking water with no details given on actual concentration. For some pharmaceuticals, such as steroid hormones, inaccurate field measurements reported in scientific journals have led to reports of "high concentrations" that are called 'environmentally-relevant' when they are not. Speculation about potential adverse effects from such exposures has produced undue concern and the potential risk from surface and drinking water exposure to pharmaceuticals is exaggerated. With the media frequently focusing on contraceptives use when discussing the endocrine issue, public perception is being swayed and the regulatory community is considering unwarranted risk management actions to address the presence of trace concentrations of pharmaceuticals with potentially costly consequences. While not as extensively evaluated as the steroid hormones, reports of detection of other pharmaceuticals in surface and drinking water and the selective reporting of these studies have contributed to the misconception that pharmaceutical exposure is of great consequence to humans. A detailed review of monitoring and effects data demonstrates human exposures to pharmaceuticals in surface and drinking water are minor and well below available acceptable daily intake values. We conclude that there is negligible impact on human health from exposure to trace concentrations of pharmaceuticals in surface and drinking water.

131 Unique Challenges in the Health Risk Assessment of Antibiotic Resistance Genes in the Environment A. Pruden, Virginia Tech, Via Dept of Civil and Environmental Engineering. Recent research has clearly revealed that human activities have a profound impact on the levels of antibiotic resistance in the environment. Wastewater treatment plants and animal feeding operations have been identified as two major contributors of elevated antibiotic resistance genes observed in impacted water bodies. However, the risks to human health imposed by environmental sources of antibiotic resistance remain elusive. Clearly, the rates of resistance among critical pathogens have been increasing at a global level, and antibiotic resistance remains as one of the most critical human health threats of our time. Unfortunately, current risk models are not adequate to assess the human health risks posed by antibiotic resistance genes. Typical risk assessments are based on fundamental dose-response relationships, which are not directly applicable to antibiotic resistance genes. Antibiotic resistance genes can persist independent of a host and transform new bacterial hosts. They may also establish among the natural gastrointestinal flora of humans and livestock, thus resulting in a latent risk of onset of an antibiotic resistant infection. Furthermore, within environmental reservoirs, the elevated background of resistance elements increases the probability that pathogens will acquire resistance and contribute to an overall higher background resistant pathogen exposure rate. Some exposure routes to consider include: ingestion of drinking water and dermal and respiratory contact during bathing or recreational water activites. The purpose of this presentation will thus be to outline the critical steps needed to move forward in the development of a risk assessment for antibiotic resistance genes in the environment.

132 Cytochrome P450 CYP2- and CYP17-like Genes in the Mangrove Oyster *Crassostrea brasiliana*: Insights on Mechanism of Phenanthrene Toxicity in Bivalves K.H. Luchmann, T. Dorrington, UFSC, Bioquimica; A.C. Bainy, Universidade Federal de Santa Catarina, Bioquimica. Polycyclic aromatic hydrocarbons (PAHs) have been recognized as typical inducers of cytochrome P450 (*CYP*) superfamily in vertebrates, which has become a common biomarker of PAH exposure. A limited number of studies are available on *CYP* modulation in bivalve. We show the presence of three new putative *CYP* genes from the mangrove oyster *Crassostrea brasiliana* and changes in their expression following short-term exposure to phenanthrene. *CYP* homologues were searched against the *C. brasiliana* EST database and sequences with identity >40% were annotated using blastx algorithm. Sequences corresponding to *CYP2*, *CYP3* and *CYP17* families were identified and transcript levels were evaluated by qPCR in the gill and digestive gland of oysters exposed for 24 h to 100µg and 1000µg of phenanthrene. Phenanthrene (1000µg) induced expression of *CYP2-like* gene in both tissues, while *CYP17-like* was induced in the gill. The largest change in response

to 1000µg phenanthrene were the induction of *CYP2-like* (~11-fold) and *CYP17-like* (~9-fold) in gill. Although also induced in digestive gland, *CYP2-like* mRNA levels were much less responsive (~2-fold induction) to 1000µg phenanthrene. In contrast to the other genes, *CYP3-like* was not induced by phenanthrene in any of the tissues or concentration. The tissue-specific response of *CYP17-like* and the higher transcripts of *CYP2-like* in gill suggest an important function of this tissue in PAH biotransformation for bivalve mollusks. These results represent the first insight into *CYP* transcript responses of *C. brasiliana* with potential applicability in field surveys. Further studies are necessary to address roles for *CYP*s providing a better understanding of the biotransformation process in bivalve mollusks. Support: CNPq INCT-TA,FAPESC

133 DNA Damage from Aflatoxin B1 but not Benzo[*a*]pyrene in *Caenorhabditis elegans*: A Case Study of Evolution of Genotoxicity M.C. Leung, Duke Univ, Nicholas School of the Environment , Duke Univ, graduate student; J.V. Goldstone, Woods Hole Oceanographic Institution; W.A. Boyd, National Toxicology Program, Biomolecular Screening Branch; J.H. Freedman, National Institute of Environmental Health Sciences, Laboratory of Toxicology and Pharmacology; J.N. Meyer, Duke Univ, Nicholas School of the Environment. The nematode *Caenorhabditis elegans* is emerging as a useful model in toxicology, but there is little information on how it responds to different promutagenic compounds. We carried out experiments to elucidate the capacity of *C. elegans* to metabolically activate two important human promutagens via CYPs – aflatoxin B_1 (AFB_1), a naturally occurring mycotoxin found in foods such as corn, peanuts, various other nuts, and cottonseed and metabolized in mammals by CYP1, CYP2, and CYP3 family enzymes; and benzo[*a*]pyrene (BaP), an environmental pollutant produced by incomplete fossil fuel combustion and metabolized in mammals by CYP1 family enzymes. Phylogenetic comparisons identified CYP2 and CYP3 family enzymes in *C. elegans*, but not CYP1 family enzymes. While exposure to AFB_1 resulted in significant DNA damage in *C. elegans*, exposure to BaP produced no detectable damage. To further test whether BaP exposure generates bulky DNA adducts, the toxicities of AFB_1 and BaP were compared in nucleotide excision repair (NER)–deficient (xpa-1) and NER-proficient (N2) strains of *C. elegans*. Exposure to AFB_1 inhibited growth more in xpa-1 than N2 nematodes, but the growth-inhibitory effects of BaP were indistinguishable in the two strains. In addition, a CYP-nicotinamide adenine dinucleotide phosphate reductase–deficient strain (emb-8) of *C. elegans* was found to be more resistant to the growth-inhibitory effect of AFB_1 exposure than N2, showing that the AFB_1-mediated growth inhibition resulted from CYP-mediated metabolism. Together, these results indicate that *C. elegans* lacks biologically significant CYP1 family–mediated enzymatic metabolism of xenobiotics. Finally, AFB_1 was found to selectively target mitochondrial DNA in *C. elegans*, which suggests a conserved mechanism of intracellular partitioning in nematode and mammalian species. The results also suggest a broader cross-species genotoxicity of the naturally-occurring AFB_1 as compared to the man-made BaP, possibly due to the selective pressure on the detrivoric, AFB_1-producing mold species.

134 Identification and Expression of Genes in Response to Anthropogenic Stressors from the Estuarine Sea Anemone *Nematostella Vectensis* A.M. Reitzel, Woods Hole Oceanographic Institution, Biology; J.V. Goldstone, Woods Hole Oceanographic Institution; M.J. Jenny, Univ of Alabama; A.M. Tarrant, Woods Hole Oceanographic Institution. Estuaries are heavily impacted by a broad range of anthropogenic contaminants including metals, aromatic hydrocarbons, pesticides, and pharmaceuticals. The fate of estuarine communities depends upon the ability of resident organisms to deploy molecular and physiological responses to a combination of anthropogenic and natural stressors. Previous research has provided a wealth of data describing these mechanisms in fish and crustaceans, but we currently lack sufficient data on what mechanisms a majority of resident organisms, particular infaunal species, deploy to combat environmental stressors. We conducted bioinformatic surveys to identify the suite of genes from the estuarine sea anemone *Nematostella vectensis* that are potentially involved in stress responses ("defensome"). Broadly, these studies support a hypothesis that many genes are ancient and were present in the Cnidarian-Bilaterian ancestor. Secondly, we studied the relative toxicity of diverse chemicals to *Nematostella*. Thirdly, we employed molecular techniques, including transcriptional profiling and quantitative PCR, to determine the effects of toxic metals and hydrocarbon pollutants on gene expression for further insight into gene function. We have identified several genes that may be useful bioindicators of environmental stressors. Together, these data provide an integrated view of the molecular mechanisms deployed by an infaunal invertebrate and provide an informative reference for studies of related species of conservation concern, particularly hard corals.

135 Mitochondrial Fitness, Gene Expression, and Hypoxic Stress in a Hybrid Population of the Killifish, *Fundulus heteroclitus* P.A. Flight, Brown Univ, Ecology and Evolutionary Biology; D. Nacci, USEPA, ORD, NHEERL, Atlantic Ecology Division; D. Champlin, USEPA; A. Whitehead, Louisiana State Univ, Dept of Biological Sciences; D.M. Rand, Brown Univ, Ecology and Evolutionary Biology. The physiological link between oxygen availability and mitochondrial function is well established. However, whether or not fitness variation is associated with mitochondrial genotypes in the field remains a contested topic in evolutionary biology. In this study we draw on a population of the teleost fish, *Fundulus heteroclitus*, where functionally distinct subspecies hybridize, likely as a result of past glacial events. We had three specific aims: 1) to infer the age of the split between the subspecies using mtDNA sequences; 2) to determine the effect of mtDNA genotype on survivorship of male and female fish under hypoxic stress; 3) to determine the effect of hypoxic stress, sex and mtDNA genotype on gene expression. Our results are consistent with previous studies suggesting the split between *F. heteroclitus* is more than an order of magnitude older than the last glacial maximum (~700 kya). We found a highly significant effect of sex on survivorship under hypoxic conditions (P=0.0022), but no significant effect of mtDNA genotype. Gene expression analyses revealed hundreds of transcripts differentially regulated by sex and hypoxia. Mitochondrial transcripts were among those influenced by hypoxic stress, and the mtDNA control region was the most highly suppressed transcript under conditions of hypoxia (P=9.40x10^{-8}). Effects of mtDNA sequence variation on expression were limited, however a potentially important epistasis between mtDNA and a nuclear-encoded mitochondrial translation protein was discovered. Overall, these results confirm that mitochondrial regulation is a major component of hypoxia tolerance and further suggest that purifying selection has been the predominant selective force on mitochondrial genomes in these two subspecies.

136 Molecular and Biochemical Response in the UV-B Damaged Copepod, *Tigriopus japonicus* J. Lee, Hanyang Univ Graduate School, Dept of Chemistry; J. Rhee, Hanyang Univ, Dept of Molecular and Environmental Bioscience; Y. Lee, Sangmyung Univ, Dept of Green Life Science. The copepod mitochondrial genome showed a high divergence between biogeographically-isolated conspecific strains, indicating that there might be low DNA repair ability, resulting in accumulating mutation on the genome. To examine DNA repair ability and damage response, we measured photoreaction and dark repair ability after UV-B irradiation, and found that the intertidal copepod, *Tigriopus japonicus* has significantly poor activity for DNA repairs. To examine the ability of molecular chaperoning protein, heat shock proteins upon DNA damage, we performed acute toxicity test for UV-B radiation and measured ROS level and antioxidant enzyme (GR, GPx, SOD, GSH, and GST) activity after exposure to UV-B (12 and 24 kJ m-2) for 48 h in the copepod *T. japonicus*. Subsequently, transcriptional changes in hsp families (hsp10, 20, 20.7, 40, 60, 70, 70p, 90α, and 105) were further investigated in stress-exposed groups. As results, the LD50 value for UV-B radiation was measured at 23.12 and 26.42 kJ m-2 in the male and female copepod for 48 h. ROS level was significantly increased at UV-B-exposed copepod. Activities of antioxidant enzymes were also highly elevated at both stressors-exposed copepods, indicating that UV-B can induce oxidative stress by generating ROS and stimulate the involvement of antioxidant enzymes as defense mechanisms against their toxicity. In experiment with UV-B radiation, the expression of hsp20 mRNA was firstly appeared at 6 kJ m-2 and followed by hsp70 and hsp90α at 9 kJ m-2. Most of hsps mRNA expression was significantly increased in dose-dependent manners. The expression of hsp10, hsp40 and hsp60 mRNA was not modulated until 15 kJ m-2, but rather down-regulated at 18 kJ m-2 and more, indicating that high dose of UV-B may cause cellular damage in this species. This study will be helpful to obtain a better understanding on molecular mechanisms of protective action against UV-B stress in this species.

137 Multiple Stressors: The Impact of Fasting and 17β-estradiol on Organ Mass and Gene Expression in Fathead Minnows (*Pimephales promelas*) A.M. Jessick, Univ of Nebraska Medical Center, Dept of Biology; A.S. Kolok, Univ of Nebraska Medical Center, Environmental,

Agricultural and Occupational Health. The central aim of this study was to examine the levels of expression of estrogen responsive genes in fed and fasting fathead minnows, (*Pimephales promelas*). Two different experiments were conducted in this study. In the first, adult females were either fed or fasted for 7 days. Fasted fish experienced significant reductions in liver and kidney mass, but not in the relative mass of the ovary or the brain. Furthermore, fasting did not significantly influence the hepatic expression of the estrogen-responsive gene vitellogenin. In the second study, male minnows were exposed to fasting, 17β-estradiol (E2) and to both treatments simultaneously. Adult males fasted for 7 days demonstrated significant reductions in liver mass, but gonad and kidney mass remained proportional to body mass, while relative brain mass actually increased during fasting. When exposed to E2, fed males significantly over-express the estrogen-responsive gene VTG, but fasted males exposed to E2 are not significantly different from that in unexposed males. No significant difference was observed in ER-α expression between E2 exposed fed and fasted males compared to unexposed males, but the fed and fasted controls were significantly different. Based upon the results, the interaction between the expression of estrogen responsive genes and fasting differs between males and females. Females maintain normal expression levels of these genes in the face of fasting, whereas the estrogen-induced males demonstrate inappropriate expression of these genes, which appear to be compromised when the fish are fasting.

138 Population Genetic Monitoring for Toxicant Effect Based on Tolerance Evolution Y. Tanaka, H. Mano, National Institute for Environmental Studies, Research Center of Environmental Risk; H. Tatsuta, Univ of the Ryukyus, Dept of Ecology and Environmental Science. Evolution of tolerance to a pollutant chemical in a natural population of organisms gives direct evidence of the examined population to have suffered adverse effect by the chemical because the tolerance evolution of a population is solely brought about by selection pressure that removes sensitive individuals or genotypes from the population. Despite the advantage in using the tolerance evolution as a monitoring tool of chemical pollution in the field, such approach is not relevant for a quantitative impact evaluation because observed differences in the tolerance between a contaminated and an uncontaminated site are rarely connected to the ecological risk that burdens the population. Applying the theory of evolutionary ecology and quantitative genetics into the tolerance evolution, we attempted to estimate the selective force that is needed to maintain the observed difference in the tolerance between populations. For this aim, we made a heuristic assumption for the evolutionary analysis of tolerance: the strength of tolerance induced by a genotype to a particular compound is positively associated with fitness cost of the tolerance, and the joint action of selection induced by the cost and selection favoring higher tolerance achieves the optimization of the total fitness that takes into account the fitness gain by the tolerance and the fitness cost due to the tolerance. The fitness gain by the tolerance means reduced toxicity of a specific exposure concentration in comparison to sensitive individuals, and can be quantified by the life table toxicity data. As a case study of such an approach, we detected inter-population differences of the fenvalerate tolerance among natural populations of a water flea (*Daphnia galeata*) in Kasumigaura Lake (Japan) and an agricultural reservoir near to this lake. There was a statistically-significant negative association, among isofemale clones, between tolerance values and intrinsic population growth rates under the null exposure. With the fitness optimization, we derived an estimate of stationary exposure level of the chemical (all compounds that exhibited co-tolerance with this chemical) as 15 ppb, and concluded that the examined population of this species had been suffering the population-level effect that corresponded to 1/4 reduction of the intrinsic population growth rate. The indicated level of the population-level effect may have considerably reduced the probability of persistence of the population.

139 UV-B Modulates DNA Damage Responses in the Monogonont Rotifer, *Brachionus orientalis* J. Lee, Hanyang Univ, Dept of Chemistry, Hanyang Univ Graduate School, Dept of Chemistry; J. Rhee, Hanyang Univ; E. Won, Hanyang Univ, Dept of Environ Mar Science; B. Kim, Hanyang Univ, Dept of Chemistry. To understand the effect of UV-B radiation on the rotifer, *Brachionus orientalis*, several parameters including 24-h survival rate, population growth rate, and ROS level were measured after exposure to a wide range of UV-B doses. To check the expression of other important inducible genes such as replication protein A (*RPA*), DNA-dependent protein kinase (*DNA-PK*), *Ku70*, *Ku80*, and heat shock proteins (*hsps*) after UV-B radiation, we observed dose- and time-dependency at 2 kJ/m^2.We also examined 13 *hsp* genes for their roles in the UV-B damaged rotifer. Results showed that UV-B remarkably inhibited the population growth of *B. orientalis*. The level of intracellular reactive oxygen species (ROS) was high at 2 kJ/m^2, suggesting that 2 kJ/m^2 would already be toxic. This result was supported by other enzymatic activities, such as GSH levels, glutathione peroxidase, glutathione S-transferase, and glutathione reductase. For dose dependency, low doses of UV-B radiation (2, 4, and 6 kJ/m^2) significantly up-regulated the examined genes (e.g., *RPA*, *DNA-PK*, *Ku70*, and *Ku80*). For the time course study, *RPA* genes showed immediate up-regulation but returned to basal or lower expression levels compared to the control 3 h after UV-B exposure. The *DNA-PK* and *Ku70/80* genes significantly increased, indicating that they may be involved in repairing processes against a low dose of UV-B exposure (2 kJ/m^2). At the basal level, the *hsp90α1* gene showed the highest expression, and followed by *hsp10*, *hsp30*, *hsp60*, and *hsc70*, and *hsp90*β in adults (w/o egg). In eggs, the *hsp10* gene was expressed the highest, and followed by *hsp30*, *hsp27*, *hsp90α1*, and *hsp60* genes. In real-time RT-PCR array on rotifer *hsp* genes, low doses of UV-B radiation (2 and 4 kJ/m^2) showed up-regulation of several hsp genes but most of the hsp genes showed down-regulation at 8 kJ/m^2 and higher, indicating that significant *Hsp*-mediated cellular damage already occurred at low doses. For the time course study of four hsp genes (*hsp20*, *hsp27*, *hsp70*, *hsp90α1*), they showed a significant correlation for UV-B radiation (2 kJ/m^2). In this paper, we demonstrated that UV-B radiation would affect growth retardation with up- or down-regulation of some important genes in DNA replication, repair process, and chaperoning. This finding provides a better understanding of molecular mechanisms involved in UV-B-mediated cellular damage in the rotifer, *B. orientalis.*

140 The pH Dependence of Natural Organic Matter Sorption to Nanoparticles and Its Ability to Disperse Particles in Aqueous Solutions P. Mwaanga, Clemson Univ, Environmental Toxicology; E. Carraway, Clemson Univ, Environmental Engineering & Earth Sciences, Clemson Institute of Environmental Toxicology. Several studies have demonstrated that natural organic matter (NOM) can reduce toxicity of most toxic chemicals through sorption /complexation processes. In the area of nanoecotoxicolgy, this has also been demonstrated. The sorption of NOM on to the nanoparticles has further been lauded for particle dispersion and hence lessening the effect of particle aggregation. In this study, the particle dispersion of NOM on both sonicated and nonsonicated TiO_2 nanoparticles at different pH values was examined. The study further examined the sorption of NOM to TiO_2 at the same pH values. The dynamic light scattering (DLS) technique was used to characterize the aggregates. The PALS Zeta potential analyzer was used to estimate surface charge. The total organic carbon was measured by the Total Organic Carbon Analyzer- Shimadzu (TOC-VCPH). The results indicated that the particle dispersion by NOM is pH dependent and is more pronounced at higher pH, but least at pH values close to the point of zero charge (PZC) for the TiO_2 particles. The ability of NOM to disperse nonsonicated particles was found to be mild. As expected, the sorption results showed that the least amount of NOM is sorbed at higher pH, despite the observation that the highest dispersion occurred at higher pH.

141 Impact of ZnO Nanoparticles on the Dynamic Energy Budgets of the Marine Mussel *Mytilus galloprovincialis* E.B. Muller, Univ of California, Marine Science Institute; R.M. Nisbet, Univ of California, Ecology, Evolution and Marine Biology; S.K. Hanna, H.S. Lenihan, Univ of California, Bren School of Environmental Science and Management; R.J. Miller, Univ of California, Marine Science Institute. Traditional methods for the analysis of toxicity data are limited in scope, as conclusions drawn from such analyses typically depend on the choice of endpoint, exposure duration and/or laboratory conditions, such as feeding regime. These limitations are overcome with Dynamic Energy Budget (DEB) theory, a powerful tool to integrate the impact of environmental conditions and toxic effects on the production of individual organisms. The results of a DEB based analysis are independent of endpoint and exposure duration. We use DEB theory to analyze the sublethal effects of ZnO nanoparticles on the marine mussel *Mytilus galloprovincialis*. We exposed individuals of different sizes to ZnO nanoparticles (nominal concentrations in the range of 0–2 mg/l) in laboratory-controlled conditions for 3 months. To fully specify the dynamics of toxicant exchange and energy budgets, we measured Zn tissue concentrations, Zn clearance rates, increase in shell length, production of somatic and reproductive biomass, respiration and feeding rates. Because mortality was only significant at the highest exposure level, mussels were exposed to the

full range of sublethal concentrations of ZnO nanoparticles. Biomass production and increase in shell length declined and tissue Zn levels increased with increasing ZnO exposure levels, indicating that our data are amenable to DEB analysis. We will show how the results of this analysis can be used to project the impact of toxicants on the long-term population growth rate.

142 Investigating the Mechanisms Underlying the Effects of Titanium Dioxide Nanoparticles on Two Species of Freshwater Phytoplankton K. Kulacki, Univ of California – Santa Barbara, Ecology, Evolution, and Marine Biology, Univ of California Santa Barbara, Earth Research Institute; S. Bennett, Univ of California Santa Barbara, Bren School of Environmental Science and Management; B. Cardinale, Univ of Michigan, School of Natural Resources & Environment. Titanium dioxide (n-TiO_2) is one of the most widely produced and well-studied types of nanomaterial. Despite this, we lack a basic understanding of how this material impacts the structure and function of natural ecosystems. Here we report the results of a laboratory experiment in which we exposed two of the more common species of freshwater phytoplankton – *Chlamydomonas moewusii* and *Scenedesmus quadricauda* – to increasing concentrations of n-TiO_2 (0, 1, and 100 mg L^{-1}) to examine how n-TiO_2 influences algal growth. n-TiO_2 reduced the growth of *C. moewusii* at 100 mg L^{-1}, in part because n-TiO_2 decreased rates of primary production. There were also signs of physiological stress in this alga, as higher intra-cellular chlorophyll content suggested cells were limited by light. In contrast to the effects of n-TiO_2 on *C. moewusii*, high concentrations of n-TiO_2 (100 mg L^{-1}) enhanced the growth of *S. quadricauda*. We could not find clear evidence of a mechanism to explain this growth stimulation, as there were no signs of altered metabolism or physiology that might indicate photo-stimulation. There was no evidence that n-TiO_2 was degrading organic matter in a way that might release limiting nutrients, nor was there evidence that n-TiO_2 reduced bacterial metabolism in a way that might release algae from competition. Our study reveals the potential for contrasting effects of n-TiO_2 on different species of algae. We were able to identify several mechanisms that might underlie the impacts of n-TiO_2 to *C. moewusii,* and we were able to eliminate several potential mechanisms to explain the stimulatory effects on S. *quadricauda*.

143 Acute and Chronic Toxicity of Nanoparticle and Ionic Forms of Silver to *Daphnia pulex* E. Costa, Wilfrid Laurier Univ; J. McGeer, Wilfrid Laurier Univ, Dept of Biology. The objective of this research is to compare the effect of ionic (Ag^+) and nanoparticle silver (nAg) on acute and chronic uptake and toxicity in *Daphnia pulex*. Exposure solutions were prepared and characterized by solution ultrafiltration (e.g., Ag content in < 450nm, < 100nm, < 10nm, and < 1nm fractions) and dissolution techniques to assess the content of Ag^+ and nAg. Acute toxicity tests were standard 48 h exposures to determine lowest observed effect concentrations (LOECs) and 50% effect concentrations (EC50s). The time-course of bioaccumulation was measured (whole organism dry weight basis) at the LOEC concentration for either Ag^+ or nAg LOECs to assess uptake (48 h) and depuration (48 h). *Daphnia* (n = 12) were sampled at time 0, 1, 3, 6, 12, 24, and 48 h in both phases to measure whole-body Ag, Na, and Cl. As well, short-term (3 h) uptake kinetics were also measured via exposure to concentrations ranging from 0 to 1 ug/L Ag^+ or nAg. Chronic toxicity tests were standard 21 d exposures to determine survival (LC50) and reproductive (EC50) effects. The acute EC50 for Ag^+ (0.78 ug/L ± 0.1 95% CI) and nAg (0.83 ug/L ± 0.27 95% CI) were similar but uptake kinetics differed. Short-term nAg accumulation was linear (r^2 = 0.95), indicating a non-carrier (diffusion) uptake and Ag^+ accumulation was hyperbolic following Michaelis-Menton kinetics (r^2 = 0.95), indicating carrier-mediated transport. For the uptake and depuration studies (48 h), *Daphnia* accumulated nAg at a faster rate than Ag^+ but depurated Ag^+ faster than nAg. Therefore, the results show different uptake processes for the two forms of silver even though the effect endpoints are similar. Exposure solution characterization by ultrafiltration supported the finding that dissolution of nanoparticles to form ionic silver in solution does not play a significant role in nAg toxicity. This research was supported by the NSERC-NRC-BDC Nanotechnology Initiative.

144 Reproductive Effects and Bioaccumulation in an Estuarine Crustacean, *Americamysis bahia*, Following Chronic Exposure to Multi-walled Carbon Nanotubes E.R. Roberts, Univ of Georgia, Environmental Health Science; M.C. Black, Univ of Georgia, Dept of Environmental Health Science; M.E. DeLorenzo, NOAA, National Ocean Service, Dept of Marine Ecotoxicology. Large amounts of carbon nanotubes are currently being manufactured, which will lead to an increase of nanomaterials into the environment through accidental spills or known releases. Previous research has used acute toxicity tests to assess the potential toxicity of CNTs to invertebrates and fish. However, little information is available on the toxicity of nanomaterials following chronic exposures of aquatic organisms, particularly in marine and estuarine environments. Here, we report the adverse chronic effects of multi-walled carbon nanotubes (MWCNTs) on 7 day old *Americamysis bahia* (formally *Mysidopsis bahia*), an estuarine crustacean, in a water-only system. Four concentrations were tested (0.1 mg/L to 10 mg/L), assessing mortality, maturation stage, and bioaccumulation of ^{14}C-MWCNTs as endpoints. Within 24 hours, MWCNTs were visible in the gut tracks of individuals exposed to the 10 mg/L concentration, which was confirmed as bioaccumulation through liquid scintillation counting. No significant mortality was noted at any concentration; however, a decrease in sexually mature individuals was present at the higher exposure concentrations. The percentage of sexually immature individuals increased from 20% of the total population in controls to 60% in organisms exposed to 10 mg/L MWCNTs. The experiment will be repeated to test the sensitivities of *A. bahia* at an earlier (0 day old) and later life stage (14 day old). Although the concentrations used in this experiment were high relative to expected environmental concentrations, continuous exposure of MWCNTs could result in a delayed maturation time of *A. bahia* over time, potentially causing population declines.

145 Using Radiolabels for Investigating the Bioaccumulation and Interaction Effects of 14C-SWNT and 3H-Ponasterone A in *Leptocheirus plumulosus* A.N. Parks, Duke Univ, Nicholas School of the Environment; P. Schierz, Duke Univ, Dept of Civil and Environmental Engineering, Duke Univ, Pratt School of Engineering; R.M. Burgess, USEPA, Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, USEPA; K.T. Ho, L.M. Portis, USEPA, Atlantic Ecology Division; M. Perron, Brown Univ, School of Engineering; M. Pelletier, National Health and Environmental Effects Research Laboratory, USEPA, Dept: ORD NHEERL AED; K. Washburn, Univ of South Carolina, Arnold School of Public Health; G.T. Chandler, Univ of South Carolina, Dept of Environmental Health Sciences; L. Ferguson, Duke Univ, Dept of Civil and Environmental Engineering, Duke Univ, Nicholas School of the Environment, Pratt School of Engineering. The development of single-walled carbon nanotube (SWNT) technologies and products continues to increase, and with this comes greater risk of environmental release through waste discharge and product use. During waste treatment, released SWNT will co-occur with other molecular contaminants such as endocrine disruptors, which may adsorb to the surface of SWNT due to its black carbon like behavior. Therefore, it is important to study the interactions of SWNT with microcontaminants. We have previously assessed the bioaccumulation of pristine SWNT in two benthic estuarine invertebrates (*Ampelisca abdita* and *Americamysis bahia*) via ingestion of sediment and food (algae *Cyclotella sp*. and brine shrimp *Artemia salina*) amended with SWNT. Near infrared fluorescence (NIRF) spectroscopy was used as a sensitive and specific detection method to quantify and characterize SWNT. This study showed uptake of SWNT from amended algae in non-depurated amphipods (35-50 µg/g dry tissue), but the depurated amphipod body burdens were below the detection limit (< 1.4 µg/g dry tissue). Although NIRF spectroscopy provides more detailed SWNT characterization and can be used to analyze environmental samples, radiolabels offer a lower detection limit (0.044 µg/g) for laboratory-based bioaccumulation studies. To capture this greater sensitivity, a parallel study was performed exposing *Leptocheirus plumulosus* to sediment and food (*Isochrysis galbana*) amended with ^{14}C-SWNT at nominal concentrations of 10 µg/g and 100 µg/g. After a 28-day exposure, depurated and non-depurated amphipods exposed to 100 µg/g sediment, displayed body burdens (0.3-0.65 µg/g dry tissue and 3-7 µg/g dry tissue, respectively) significantly different from controls. The dual-label, mixed-contaminant system was tested using ^{14}C-SWNT (100 µg/g) and the ecdysteroid ^{3}H-Ponasterone A (1 ng/g), each individually and in a mixture. A second form of black carbon (coconut charcoal) was used as a positive control. After a 28-day sediment exposure, the bioaccumulation of each contaminant in *Leptocheirus plumulosus* was determined. Results of these experiments will be presented in the context of the relative effects on the bioavailability and bioaccumulation by benthic deposit-feeding organisms of SWNT and microcontaminants present in the environment as mixtures.

146 Bioaccumulation and Trophic Transfer of Nanoparticles to *Leptocheirus plumulosus* B. Jackson, Dartmouth College, Dept of Earth Sciences; C. Chen, Dartmouth College, Dept of Biological Sciences. The bioaccumulation and trophic transfer of CDSe quantum dots (QDs) and Ag nanoparticles (AgNPs) to *L. plumulosus* was assessed in a series of exposure and toxicity tests conducted in waters of varying salinity. Trophic transfer was investigated by exposing the amphipods to nanoparticles in the presence or absence of the algae, *Isochrysis galbana*. The relative particle size distribution of the nanoparticle in the water column; aggregated, dispersed, dissolved, was assessed by filtration at 0.45 and 0.2 µm and ultra-centrifugation at 3KDa. Animals were exposed to nanoparticles for 96 hrs and allowed to depurate for 24 hrs. Body burden of nanoparticles were assessed by digestion and ICP-MS analysis. Exposures were compared with an equivalent concentration of dissolved metal ion (Cd for the QDs). Ag-NPs aggregated readily at salinities of 5, 10 and 20‰. Bioaccumulation of AgNPs was greater for 10nm particles than 50nm particles but less than an equivalent concentration of dissolved Ag. No differences in bioaccumulation were observed at higher salinities. Mortality was only observed for dissolved Ag at 5‰. No differences were observed in the presence or absence of algae. QDs remained dispersed (or < 0.45 µm) at 20‰ salinity. Bioaccumulation of QDs was greater than equivalent dissolved Cd both in the presence and absence of algae. However, mortality was much greater in the presence of algae. Laser ablation ICP-MS was used investigate qualitative differences in QD assimilation between exposure routes.

147 Multi-generational Impacts of Carbon Nanomaterial Exposure on the Model Organism *Daphnia magna* D. Arndt, Univ of Wisconsin-Milwaukee, School of Freshwater Sciences, Great Lakes Water Institute; R. Klaper, Univ of Wisconsin-Milwaukee, School of Freshwater Sciences, Great Lakes Water Institute. We examined how carbon nanomaterial core structure and surface chemistry influence the toxicity of these materials to the progeny of an exposed F_0 generation of *Daphnia magna*. F_0 daphnids were exposed to various types of carbon nanomaterials with different core structures and functionalizations. Chronic toxicity was measured on the parent population by evaluating mortality and reproductive parameters over a 21-day period. The neonates produced by the F_0 generation were raised for an additional 21-day period and mortality and reproduction were assessed. This was repeated for the next 3 generations of *Daphnia*. Data indicate that some carbon nanomaterials can have an impact on the reproductive capacity of future generations of daphnids from exposed parents. These results indicate that a single generation exposure may have an impact on future generations of organisms. Future experiments will look at the mechanism by which nanomaterial exposure may impact these subsequent generations of daphnids after a parental exposure, including methylation of DNA in the promoter regions of relevant genes.

148 Dyes, Old Contaminants that Still Need Toxicological Evaluation G.A. Umbuzeiro, UNICAMP, FT; H. Freeman, North Carolina State Univ, College of Textiles. Colours are part of our life. Everything that surrounds us are naturally or artificially colored. Dyes have been used all around the world in textiles, food, hair, plastics, houses, vehicles, cosmetics and other products. In the past they were metal based products. Because of the high toxicity and persistence of metals in the environment they were substituted by organic compounds, that are biodegradable. Thousands of different dyes are produced and in use these days. Because they are visible in very low concentrations, we believed that they would not be present in hazardous amounts. But when dyes from different colours are mixed a brownish to grey colour is obtained, sometimes difficult to be noticed when reaching a water body. In general dyes are very complex organic molecules. The most abundant group are the azodyes, that are produced from aromatic amines. Several aromatic amines has proven to be carcinogenic and are now prohibited. We thought that dyes would be degraded in the biological treatment and only the detection of their former aromatic amines would be enough to evaluate their possible hazard. But recently this paradigm was proved to be wrong, different dye transformation products, such as the PBTAs were found in rivers. They were even more mutagenic than the parental dyes and are colorless. Different dyes as well their transformation products have been found in rivers, sediments, treated effluents, sludges and even in drinking water. Thin layer chromatography, although an old and not sophisticated technique was key for their detection. HPLC methods are now under development to quantify dyes and their transformation products that are present in the environment in ppb to ppt concentrations. The majority of the detected compounds were not yet tested for ecotoxicity or genotoxicity and other important endpoints. It is now impossible to estimate the risks regarding the exposure of those compounds because no consistent hazard evaluation is available in the literature. Another key information is that the commercial dye products can contain more than 50% of impurities, other dyes and aromatic amines, and are usually sold in unknown surfactants, also not properly evaluated. Dyes, although old contaminants can be considered emergent compounds and should be properly tested before being released into the environment.

149 First Stages in the Ecological and Human Health Assessment of Aromatic Azo and Benzidine-based Compounds on Canada's Domestic Substances List J.R. Hill, A. Okonski, Environment Canada, Government of Canada, Ecological Assessment Division; B. Aikawa, S. Blechinger, M. Gagne, K. Hughes, Health Canada, Government of Canada, Existing Substances Risk Assessment Bureau. In June 2010, the Government of Canada published a Notice of intent to assess the potential health and ecological risks of approximately 350 aromatic azo- and benzidine-based substances on Canada's Domestic Substances List. Substances included in this assessment are among those identified as priorities for action through the Domestic Substances List Categorization process. The aromatic azo- and benzidine-based substances are those which may break down to certain aromatic amines of concern (including benzidines). Some substances within this class or substances similar to those included in this class have been identified by other jurisdictions as a concern due to the potential cleavage of the azo bonds that can lead to the release of aromatic amines that are known or possible carcinogens or genotoxicants. In addition, recent data gathering initiatives have confirmed some of these substances are found in imported consumer products (e.g., clothing, leather products) in Canada. The Government of Canada will apply weight-of-evidence and precaution in decision making. Accordingly, where data are limited and where considered appropriate, assumptions with a reasonable level of conservatism will be applied in the risk assessment. For example, assumptions may be applied regarding the potential for these substances to degrade or metabolize to simple aromatic amines, to migrate or leach from finished products, or to be dermally absorbed from products in contact with the skin. A general scope of the approach will be outlined with focus on chemical clustering based on structural similarities, common functional uses, and physical-chemical properties of these substances. Potential data gaps will be identified and discussed.

150 Assessing the Bioaccumulation Potential of Substances with Low Bioavailability: Benchmarking a Dispersible Colorant M. Bonnell, Environment Canada, New Substances Division, Science and Risk Assessment Directorate; J. Hill, Environment Canada. A general lack of empirical data at the time of categorization of the Canadian DSL (2006) required that, from an ecological standpoint, evidence from quantitative structure-activity relationship (QSAR) models be used to fill data gaps. While this approach was a practical means to accomplishing the prioritization of thousands of chemicals, key ecological hazard properties (i.e., bioaccumulation and ecotoxicity) may be incorrectly predicted for substances with a potentially low to very low bioavailability. We will demonstrate this potential for error using a dispersible colorant and illustrate how its bioavailability and reactivity compares with a benchmark PCB and a solvent dye and how it contrasts with an acid dye. Data from molecular dimensions, physical-chemical properties, metabolism potential, dietary assimilation efficiency, bioconcentration factor (BCF), biomagnification factor (BMF), biota-soil accumulation factor (BSAF) and ecotoxicity are compared and contrasted with the benchmark chemicals. When these lines of reasoning are considered, it can be shown that internally consistent evidence point towards a low bioaccumulation potential of this disperse dye governed principally by low bioavailability to aquatic organisms.

151 Effect of Photoelectrochemical Chlorination and Conventional Chlorination on Mutagenicity Reduction of CI Disperse Blue 291 Dye M.B. Zanoni, UNESP, Analytical Chemistry; G.A. Umbuzeiro, UNICAMP, FT; R.L. Oliveira, G.J. Zucollo, UNESP, Analytical Chemistry. Guilherme Julião Zocolo[1], Rafael Leite de Oliveira[1], Gisela de Aragão Umbuzeiro[2], and Maria Valnice Boldrin Zanoni[1] [1]Electroanalytical Chemistry Laboratory – Dept of Analytical Chemistry – UNESP – Univ of São Paulo State, Brazil [2] Environmental Ecotoxicology and Microbiology Laboratory – LEAL, Faculty of Technology, Univ of Campinas, Limeira, SP, Brazil

Abstract The CI disperse Blue 291 dye, 2-[(2-Bromo-4,6-dinitrophenyl) azo]-5-(diethylamino)-4-methoxyacetanilide) is a commercial azo dye highly used in textile industry for dyeing of polyester. The present work evaluates the chlorination process effect on dye treatment using photoelectrocatalytic process and conventional chlorination. The removal of CI Disperse Blue 291 dye from wastewater of textile industry was investigated and the generated by products were monitored by using spectrophotometry, chromatographic, organic carbon, mass spectra analysis and mutagenicity assays. The process efficiency was compared with conventional chlorination process commonly adopted in DWTP. CI Disperse Blue 291 dye was almost completely mineralized and is mutagenicity was removed under optimized conditions of photoelectrocatalysis using Ti/TiO_2, using both NaCl as sodium sulfate as supporting electrolytic solution in a short time scale treatment (120 min). The results indicate that byproduts generated by photoelectrocatalytic chlorination are free of amine substituent, which seems to be the key for its mutagenicity.

152 The Toxicity of Commercial Dye Disperse Red 1 and His Main Fraction Dye to Estuarine Copepod M. Artal, Univ of Campinas; A. Albuquerque, Univ of Campinas, Av. Conego Manuel Alves, 220; G. Lotufo, US Army Engineer Research and Development Center; G. Umbuzeiro, Univ of Campinas. Azo dyes are the most abundant and representative class of dyes. Commercial forms of these compounds are mostly a mixture of the main dye, surfactant and other dyes. Components of the commercial dye Disperse Red 1 were separated by TLC (thin-layer chromatography) and the main fraction, corresponding to CI Disperse Red 1 were about 60% of the mixture. We compared the acute toxicity of the main fraction and the commercial dye using the estuarine copepod *Nitokra* sp. Both the commercial dye and the fraction were dispersed with ultrasound sonication for 8 min because they are poorly soluble in salt water. The acute toxicity tests were performed in quadruplicate, 10 organisms per replicate, with marine reconstituted water (salinity 20), photo-period 12-12h at 23ºC for 96 hours with adults. We tested 6 concentrations ranging from 0.03 to 30 $mg.L^{-1}$, and a negative control, for both samples. After exposure the immobility of organisms was recorded with the aid of a dissecting microscope and the EC50 was calculated by Trimmed Spearman-Karber method. Sensitivity tests were performed monthly with zinc sulfate as a reference toxicant and the average value is 3.3 $mg.L^{-1}$ (N=8). Acute median-effect concentrations (EC50, 96h) for Commercial dye Disperse Red 1 and its main dye were virtually identical, 0.13 $mg.L^{-1}$ and 0.14 $mg.L^{-1}$, respectively. If only the main dye was responsible for the toxicity effect of the commercial product, the EC50 for the commercial product would be lower than that observed for the main dye. Therefore we suggest that the toxicity of commercial dye Disperse Red 1 is caused by CI Disperse Red 1 as well as other components in the mixture. The isolated surfactant and the other dyes present in the commercial product are being tested under the same conditions. These results highlight the importance of testing the commercial product and not only the main substance before approving the products for use.

153 Application of Organic Dye Measurements in Airport Stormwater Runoff as Tracers for Assessing Runoff of Aircraft Deicing/Anti-icing Fluids L. Ferguson, Duke Univ, Dept of Civil and Environmental Engineering, Duke Univ, Nicholas School of the Environment, Pratt School of Engineering, Dept of Civil & Envionmental Engineering; S.R. Corsi, US Geological Survey, Water Resources Division. Aircraft deicing and anti-icing fluids are used extensively during winter weather events at airports to minimize risks of ice/snow-related safety incidents. The widespread use of these fluids, which contain a number of potentially hazardous organic contaminants (including glycols, benzotriazloles, surfactants, and colorants) has led to significant concern over their impacts on surface waters and groundwaters in proximity to airports. To date, it has been difficult to trace the contribution of deicers vs. anti-icing fluids (which are more toxic) to stormwater loads of BOD and other markers of organic contaminant concentrations. We have taken advantage of the unique and relatively class-specific dyes used in deicer/anti-icer fluids in order to trace inputs of these two major types of deicing fluids to surface waters. Results indicate that dye identity and concentration are unique between anti-icing and deicing fluids. Tartrazine was a commonly observed "yellow" dye in Type IV anti-icing fluids, while Orange II and Sunset Yellow FCF were the most prevalent dye type in Type I deicing fluids. Measurement of these dyes in surface waters and runoff samples indicates that they can be used as a reliable tracer for deicing and anti-icing fluid inputs to stormwater.

154 Biodegradation and Toxicity of the Reactive Azo-dye Remazol Red by Brevibacterium sp Strain Isolated from Activated Sludge of the Textile Industry E. Franciscon, Faculty of Technology, State Univ of Campinas, Laboratório de Ecotoxicologia e Microbiologia Ambiental "Prof. Dr. Abílio Lopes"; L.R. Durrant, Faculty of Food Engineering, State University of Campinas, Department of Food Science; Gisela Umbuzeiro, UNICAMP, FT. Azo dyes account for the majority of all dyes produced and have been the most commonly used synthetic dyes in the textile, food, paper making, color paper printing, leather and cosmetic industries. The main azo dye possess the function azo as group chromophoric, are characterized by the presence of one or more azo bond -N=N - on the aromatical systems. Under usual dyeing conditions these dyes don't bind to fibers what results in colored effluents. Dyes removal is desired, not only by esthetic reasons, but also because many azo dyes and their derived products are toxics to aquatic life and mutagenic to humans. Although activated sludge has been extensively used on industries this treatment has not been effective and dyes are adsorbed in the biomass, being later disposed in landfills, contaminating these wide areas. Trying to solve these problems, *Brevibacterium* sp., a bacterial strain isolated from activated sludge of textile industries near Campinas (SP, Brazil) was cultivated with growth medium plus Reactive azo-dye Remazol Red RR (RBN 198) in static conditions. The dye degradation was determined by UV-visible spectrophotometer and confirmed by Total Organic Carbon (TOC) reduction. The degradation products were also characterized by HPLC- MS techniques, and their toxicity measured using *Daphnia similis*. *Brevibacterium* sp. strain degraded completely the dye present in the medium in 24 hs and after 7 days the reduction in TOC was ~70%. The *Daphnia similis* tests were carried out in a 1:4 dilution of the original supernatant concentration, because 100% mortality occurred in the undiluted and 1:2 diluted dye media. Untreated dye showed immobility of 47% at a dilution of 1:4. Samples take from static culture was less toxic, immobility ? 13%. The HPLC- MS reveleted possible compounds of the RR198 azo dyes biodegradation, in the sample: 4-chloro-N-o-tolyl-1,3,5-triazin-2-amine; sodium 4-aminonaphthalene-2-sulfonate and 3,6-dimethyl-7-(o-tolyldiazenyl) naphthalen-1-amine. The results demonstrate that the static process using a *Brevibacterium* sp. was successful in achieving a complete decolourization and partial degradation of azo dyes. The acute toxicity for *Daphnia similis* after treatment revealed to be lower than untreated dye, indicating the high potential of the bacterium for the use in azo dyes removal.

155 The Carcinogenic Potential of a Black Dye Commercial Product (BDCP) in Rats Subcutaneously Exposed R.O. de Lima, Universidade Estadual de Maringá – UEM; G.E. Fontes, Unesp; G.A. Umbuzeiro, UNICAMP, FT; D.F. Salvadori, UNESP. Azo dyes are used and sold as commercial products. They contain, besides surfactants, impurities such as other dyes and aromatic amines. Water contamination by dyes is a matter of concern because they have been found in river waters, sediments, sludges and drinking waters. The components of a black dye commercial product (BDCP), Disperse orange 37, Disperse blue 373 and Disperse violet 93 were tested positive for mutagenicity in the Salmonella microsome assay and were detected in Cristais river in Brazil. The source of the dyes in the river was identified as a textile plant upstream the intake of a Water Treatment Plant. The textile plant effluent showed a high mutagenic effect in the Salmonella assay; potentially carcinogenic activity was also detected in the aberrant crypt foci assay in rats orally treated. Herein, we investigated the carcinogenic potential of the BDCP in distal colon of male Wistar rats. Aberrant crypt foci assay was used to estimate the frequency of preneoplastic lesions. The animals were subcutaneously exposed at doses of 25, 40 or 60 mg/kg b.w. After 6 weeks no significant effects on animal body weight gain and water and food consumption ($p > 0.05$) were observed. However, significant increase of aberrant crypt foci and aberrant crypts (AC) were found in those rats subcutaneously treated with the highest dose of BDCP. In conclusion, the results demonstrated the carcinogenic potential of BDCP and also highlight that actions must be taken to prevent human exposure to this compound. Toxicokinetics of those compounds are still poorly understood and further studies are required to understand how the dyes can be activated in mammals. Supported by CNPq.

156 Detection and Spatial Imaging of Heavy Metals in Feathers Using an Electron Probe Microanalyzer F.R. Wolter, Fayetteville State Univ, Biological Sciences. Using birds as environmental indicator species and analyzing their feathers for accumulated toxic elements is a well-established protocol (Burger 1994). A number of studies have attempted to address

the distribution of external versus internal metal contamination of feathers (Dauwe, et al. 2003; Ek, et al. 2004; Jaspers, et al. 2007). However, traditional chemical assays, such as atomic spectroscopy, condense and consume the entire sample during analysis; thereby, creating two fundamental issues: (1) it is difficult to differentiate findings between bioaccumulation inside and atmospheric deposition on the outside of a feather, and (2) these methods destroy the sample; thus, they are not available for subsequent analyses or for imaging spatial detection. Consequently, this proof of concept study explores the applications of novel avian ecotoxicology research techniques and procedures by using an electron probe microanalyzer (EPMA) to detect, spatially describe, and quantify both the internal and external variation of heavy metals in a single feather. An extensive literature review indicates that this research approach has not been investigated previously. The objectives for the presented portion of this study are two-fold: (1) to determine if and how feathers could be mounted for electron probe microanalyses; (2) to determine if heavy metals may be both detected in a feather sample using wavelength dispersive spectroscopy (WDS) and displayed in detailed images. Primary flight feathers of an adult Carolina Wren (*Thryothorus ludovicianus*) and an adult Red-eyed Vireo (*Vireo olivaceus*) were obtained through the mist netting of live birds known to be nesting and foraging in habitats found within an EPA listed Superfund site in North Carolina. Findings showed that feather samples mounted in an epoxy resin and appropriately polished could be EPMA analyzed. Additionally, using WDS allows for spatial detection imaging of arsenic, mercury, lead, and cadmium. To address challenges related to quantifying amounts of detected elemental x-rays, continued exploration of applying this analytical method applied to feathers is necessary.

157 Optimization of Stirbar Sorptive Extraction for the Study of Water Accommodated Fractions of Diesel/Biodiesel via Gas Chromatography Mass Spectrometry R. McCreary, Univ of Texas at El Paso, Dept of Chemistry; W. Lee, Univ of Texas-El Paso. Accidental release of diesel and biodiesel from handling, processing, and consumption is a continued threat for the aquatic environment. Studies have shown that the presence of these fuels can have adverse health effects on a variety of organisms. Due to the continuing demand for diesel and increasing demand for biodiesel, it is imperative that an efficient, effective, and environmentally conscious method be developed to extract and analyze the presence of these compounds in fresh water and sea water accommodated fractions (FWAF & SWAF) so that toxicity of such constituents and concentrations can be addressed. The objective of this study is to implement green chemistry in an analytical method by using stir bar sorptive extraction-thermal desorption-gas chromatography/ mass spectrometry (SBSE-TD-GCMS). Using practically no solvent, SBSE offers great sensitivity for a variety of organic compound at found at very low concentration in aqueous matrices, potentially applicable in monitoring as well as identifying different suppliers and types of oil. Organic compounds–fatty acid methyl esters (in biodiesel) and alkanes (in diesel)–that remain in fresh and sea water will be analyzed. Optimization of this method involved using different methanol concentration and varying stirring time in SBSE process. The results of the optimized conditions and the profiles of water accommodated fractions of these fuels will be presented.

158 A Gas Chromatography/Triple Quadrupole Mass Spectrometry Based Method for Determination of Hydrophobic Organic Contaminants in Freshwater and Seawater H. Zhang, National Univ of Singapore, Dept of Civil and Environmental Engineering; S. Bayen, B.C. Kelly, National Univ of Singapore, Dept of Civil and Environmental Engineering. The occurrence of hydrophobic organic contaminants (HOCs) such as polychlorinated biphenyls (PCBs), DDTs and chlordanes in aquatic environments is an important ecological and public health issue due to their capabilities of bioaccumulation and adverse biological effects. Conventional analytical methods using gas chromatography single quadrupole mass spectrometry (GC-MS) is often limited due to high matrix interfaces and relative low selectivity. A potentially more robust approach is to employ gas chromatography triple quadrupole tandem mass spectrometry (GC-MS/MS). Detailed information regarding GC-MS/MS based methods for the analysis of HOCs is scarce. The purpose of this study was to develop GC-MS/MS method for quantifying individual PCBs, organochlorine pesticideds (OCPs) and synthetic musk fragrances (SMFs) in freshwater and seawater following solid phase extraction. Target analytes included PCBs with 2-10 chlorine atoms, OCPs such as endosulfan, hexachlorocyclohexanes (HCHs), chlordanes and aldrin, and synthetic nitro and polycyclic musks such as musk ketone and musk xylene, galaxolide (HHCB) and tonalide (AHTN). Precursor and product ions were chosen according to the results of MS1 full scan and Product Ion scan, respectively. MRM results using different collision energies were compared to obtain optimal collision energy for each MRM transition. Dwell time was optimized using system software. Performance characteristics including linearity, limit of detection (LOD) and limit of quantification (LOQ) were calculated and evaluated. Freshwater and seawater samples, collected at various locations around Singapore were filtered through 1 μm glass fiber filters. Filtrates and filters were spiked with ^{13}C or deuterated mass-labeled surrogate internal standards. Solid phase extraction with C_{18} Empore Disks and sonication extraction were applied to filtrate and filter, respectively, to determine freely dissolved and particulate bound chemical concentrations. A series of spiking experiments were conducted to validate the developed GC-MS/MS method and determine method detection limits (MDLs) of individual target analytes. Observed concentrations and patterns of PCBs, OCPs and SMFs in Singapore's freshwater and marine environments are reported and discussed.

159 Improved Affinity Extraction of Emerging Contaminants from Water E. Papastavros, D. Hage, Univ of Nebraska-Lincoln, Dept of Chemistry; D. Snow, Univ of Nebraska-Lincoln, Water Sciences Laboratory, School of Natural Resources; D. Cassada, Univ of Nebraska-Lincoln, Water Sciences Laboratory, School of Natural Resources. Emerging contaminants are chemical compounds that have not traditionally been thought of as pollutants. They comprise a wide range of compounds, including pharmaceuticals, hormones and endocrine disrupting compounds. Emerging contaminants are typically found in surface and groundwater in trace amounts and have agricultural, municipal and industrial sources. They are of concern because their effects on the environment and on human health are not fully understood. A novel, affinity-based extraction method for these compounds is being developed and preliminary results indicate the potential for its use with environmental samples. In this method, a serum protein is immobilized onto a chromatographic support and placed in a column used to selectively bind desired analytes. Liquid chromatography-tandem mass spectrometry (LC/MS/MS) is commonly used for the analysis of environmental samples with solid phase extraction (SPE) being used for the extraction and concentration of analytes. However, more efficient and selective methods of extraction are sought because of the complexity of wastewater matrices. Immunosorbents are other affinity-based extraction methods that have been successful in such applications but require expensive antibodies. Serum proteins such as bovine serum albumin (BSA), which were used in the majority of this work, offer a lower cost alternative that can still bind strongly to various emerging contaminants. The BSA extraction column used in these experiments had only a slightly lower binding capacity than a C_{18} column of the same dimensions but had much higher retention for certain pharmaceuticals, hormones and pesticides and could bind to a wide range of such compounds.

160 A Comparison of Three Sediment Extraction Procedures: Accelerated Solvent Extraction, Microscale Solvent Extraction, and Shaker Extraction J.R. Thorn, E.S. Barrows, K.P. Cushing, D.M. Schumitz, K.M. McInerney, Battelle, Applied Research and Laboratory Operations; E. Webb, Astrix; C. Cooper, Battelle, Statistics and Information Analysis. Green chemistry or sustainable chemistry involves the use of chemical products and processes that reduce or eliminate the use or generation of hazardous substances. In the analysis of environmental sample matrices for organic contaminants, the benefits of using green chemistry technologies--reduced waste and use of energy and resources--translate into less solvents, reagents, and prep time. EPA and many scientific organizations promote green chemistry through their projects and programs including educational activities and research and development. But how do the results of sample analyses by green chemistry extraction methods compare to results of samples processed using the traditional sample extraction techniques? Four samples of riverine sediment having varying levels of contamination were extracted using three extraction techniques: accelerated solvent extraction (ASE®), EPA Method 3545A; microscale solvent extraction (MSE), EPA Method 3570; and an orbital shaker table procedure. Final extracts from these sediment samples were analyzed by gas chromatography-mass spectroscopy operated in selected ion monitoring mode (GC/MS-SIM) for polynuclear aromatic hydrocarbons (PAHs), both parent PAHs and alkylated compounds, and by GC/MS-SIM for polychlorinated biphenyl (PCB) congeners. Each sample was analyzed in triplicate allowing for evaluation of replicate analyses. Sample analytical results generated by each of the three procedures were used to

assess reproducibility, comparability, sensitivity, and cost. Reproducibility was determined by the relative standard deviation (RSD) of the triplicate analyses using each procedure. Comparability was determined by a statistical comparison of the triplicate analyses using all of the procedures. The impact of differing sample masses employed by each procedure on analytical sensitivity was determined using the achieved laboratory detection limits. To compare sample preparation costs of each procedure, consumption of laboratory solvents and reagents, as well as labor hours were also considered. Our investigation summarizes these factors to present a comparison of ASE and MSE green chemistry methods to traditional sample extraction.

161 Tracking Hypoxic Conditions via Mo Accumulation: The Influence of N Loading and Local Residence Time W.S. Boothman, US Environmental Protection Agency, Office of Research and Development, National Health and Environmental Effects Research Laboratory; L. Coiro, M. Abdelrhman, W.G. Nelson, US Environmental Protection Agency. One approach to developing nitrogen (N) criteria for coastal waters is to determine quantitative relationships between N loading and ecological effects, such as hypoxia. Hypoxia may vary significantly within estuaries, making it difficult to document over large spatial and temporal scales. Accumulation of molybdenum (Mo) in surface sediments has been proposed as an indicator of the duration of hypoxia in overlying waters, providing a metric to evaluate the relationship between varying N loads and the occurrence and duration of hypoxic conditions in more than a dozen southeastern New England (USA) estuaries. Nitrogen loads were calculated for each estuary based on watershed land use. Because effects of nitrogen are expected to vary with residence time of the nitrogen within estuaries, N loads were normalized in each estuary for volume and local residence times (LRT) derived from hydrodynamic modeling to account for tidal flushing. Multiple sampling sites were selected within each estuary to span a range of normalized N loading, and surface sediments collected at each site for Mo analysis. A linear relationship between the concentration of Mo in surface sediments and the annual duration of hypoxia (defined as dissolved oxygen concentrations below 2.8 mg/L) was derived for southeastern New England estuaries and used to convert Mo concentrations to average annual duration of hypoxia. This presentation will illustrate the spatial distribution of hypoxia derived from the Mo data and the quantitative relationships between N load, residence time and extent/frequency of hypoxia. By combining these relationships with knowledge of hypoxia tolerance in local or critical species, this approach may be useful to evaluate criteria for nitrogen loading in coastal waters.

162 A Comparison of Total Nitrogen Measurement Techniques in Surface Fresh Water A. Jones, Clemson Univ, Institute of Environmental Toxicology; E. Carraway, Clemson Univ, Environmental Engineering & Earth Sciences, Clemson Institute of Environmental Toxicology. Total nitrogen (TN) concentrations are of great importance in surface waters because TN is a controlling factor in the total productivity of the system. A major goal has been the replacement of the Kjeldahl nitrogen analysis, which is laborious and generates toxic wastes. The work presented here compares the Kjeldahl method to the alkaline persulfate digestion method, with three different detection methods, and to nitrogen combustion with a silicon diode detector. The three alkaline persulfate digestion methods presented are ion chromatography (IC) with conductivity detection, cadmium reduction with colorimetric detection, and cadmium reduction with IC-conductivity detection. The nitrogen combustion method requires very little sample treatment prior to analysis and is not labor intensive, however the alkaline persulfate digestion methods require some sample treatment prior to analysis. Surface water samples from small, wadeable streams in South Carolina comprise the majority of the analyses and range from 0.1 mg/l TN to 5 mg/l TN (n≈200). Regression analysis, analysis of variance, and error analysis are used to assess the performance of the different methods. Results indicate that the alkaline persulfate digestion method yields better recoveries of total nitrogen in surface water samples than nitrogen combustion, but may not be a complete replacement for the Kjeldahl method.

163 Using Whale Earwax Plugs as a Matrix for Reconstructing Contaminant Profiles in a Marine Ecosystem E. Robinson, Baylor Univ, The Institute of Earth, Ecological, and Environmental Sciences; S. Trumble, Baylor Univ, Dept of Biology; S. Usenko, Baylor Univ, Dept of Environmental Science. Chemical trends and profiles that have been reconstructed from matrices, such as sediment and ice cores, have provided a wealth of information regarding contaminant behavior and environmental fate, periods of stress, and climate change. Like all mammals, whales excrete wax into their ear canals; however, whales accumulate their earwax over their lifetime (~20 to 100 yrs) and form layered earwax plugs similar to a sediment core. Therefore, whale earwax plugs may represent a marine matrix capable of recording and archiving a whale's lifetime contaminant profile. An analytical method for identifying historic and current-use pesticides, polychlorinated biphenyls (PCBs), and polybrominated diphenyl ethers (PBDEs) in lipophilic whale earwax was developed. A method was developed using pressurized liquid extraction, an accelerator solvent extractor (ASE), to extract contaminants from ~0.5 g of each layer of sectioned earwax. In-cell ASE cleanup sorbents, silica gel, alumina oxide basic and acidic, florisil, and celite, were optimized. The contaminants were analyzed using gas chromatography-mass spectrometry with electron capture negative ionization. Results indicated a gray whale's earwax plugs were a viable matrix since pesticide and PCB contaminant profiles were identified in its chronologically layered earwax plugs.

164 Method Validation and Identification of Halogenated Flame Retardants in Great Lakes Fish J.J. Pagano, State Univ of New York-Oswego, Environmental Research Center; B. Crimmins, Clarkson Univ; M. Milligan, SUNY Fredonia, Dept of Chemistry; T.M. Holsen, X. Xia, P. Hopke, Clarkson Univ. Industrial chemists have been very busy producing numerous flame retardant chemicals and mixtures to replace polybrominated diphenyl ethers (PBDE) and associated technical mixtures DE-71™, DE-79™, and DE-83™. Several of these replacement halogenated flame retardant compounds have been previously detected in Great Lakes water, sediment, air, and biota. Many of the halogenated flame retardants have yet to be identified in the environment, but are candidates based on their production volume, persistence, bioaccumulative potential and toxicity. Analysis of these legacy, emerging, and reemerging contaminants is complicated by the formation of intermediates and losses during routine sample processing, analysis, and/or environmental degradation. It is unclear if the many of the by-products are impurities during the manufacture or degradation products formed in the environment. As part of the Great Lakes Fish Monitoring and Surveillance Program (GLFMSP) we analyzed whole fish composite samples for several halogenated flame retardants in the Great Lakes' top predators utilizing both low and high resolution gas chromatographic and mass spectrometric methods.

165 Analysis of Synthetic Musk Compounds in Great Lakes Fish M. Milligan, SUNY Fredonia, Dept of Chemistry; B. Moore, SUNY Fredonia; X. Xia, B. Crimmins, P. Hopke, Clarkson Univ; J. Pagano, SUNY Oswego. As part of the USEPA sponsored Great Lakes Fish Monitoring and Surveillance Program (GLFMSP), we are analyzing whole fish composites collected at different sites from all five of the Great Lakes for a suite of contaminants such as Hg, PCBs, PBDEs, and organochlorine pesticides. Recently, we have embarked on full scan MS screening and SIM mode targeted analyses of new and emerging chemicals of concern, such as new-generation brominated flame retardants, industrial chemical intermediates, polysiloxanes, and synthetic musks. In this work, we report on preliminary results of synthetic musk compounds found in Great Lakes Lake Trout fish tissue. Seven synthetic musk compounds were chosen for analysis: galaxolide, tonalide, celestolide, phantolide, traseolide, musk ketone, and musk xylene. Five gram whole fish homogenates were extracted using Accelerated Solvent Extraction (ASE), followed by preliminary clean-up using automated gel permeation chromatography. The synthetic musk compounds were further isolated using a de-activated silica gel column, followed by GC/MS-EI analysis. The predominate musk compounds detected in Great Lakes fish were galaxolide and tonalide, known to be the two highest volume synthetic musk compounds. Total synthetic musk concentrations in whole fish ranged from about 3 to 10 ng/g, with L. Ontario demonstrating the highest concentrations. Additionally, the profiles of these eight compounds in Great Lakes fish are very similar to what has been previously measured in air and dissolved water samples in the Great Lakes.

166 Current Use Flame Retardants: Chemicals Used in Polyurethane Foam and Their Measurements in Indoor Environments H.M. Stapleton, Duke Univ, Nicholas School of the Environment; S. Klosterhaus, San Francisco Estuary Institute; A. Keller, P.L. Ferguson, Duke Univ; S. van Bergen, East Bay Municipal Utility District; E. Cooper, Duke Univ; T.F. Webster, Boston Univ School of Public Health; A. Blum, Green Science Policy Institute. Polybrominated diphenyl ethers (PBDEs) were a class of additive flame retardant chemicals used to reduce the flammability of resins and

polymers used in a variety of consumer products, particularly polyurethane foam found in furniture. Due to their persistence, bioaccumulation potential, and potentially toxic, PBDEs have been, or are currently slated for, phase-out in different regions of the world. Despite the phase-out, flammability standards still exist for a number of different products and now other types of halogenated flame retardant formulations are increasingly being used as replacements for PBDEs. Over the past several years our laboratory has analyzed more than 100 polyurethane foam samples collected from both general furniture items (e.g., chairs, couches, etc) and baby products (e.g., nursing pillows, car seats, strollers, sleep positioners, etc.), to identify the most common flame retardants used in these products. Our research indicates that a majority of products containing polyurethane foam, and which are sold in the United States, are treated with several types of chlorinated organophosphate flame retardants (OPFRs). Tris (1,3-dichloroisopropyl) phosphate (TDCPP), is the most common flame retardant detected in foam. One brominated flame retardant mixture known as Firemaster® 550 (FM 550), was also detected in approximately 20% of the products tested. FM 550 is a mixture containing both non-halogenated organophosphates such as triphenyl phosphate (TPP), and iso-aryl phosphate isomers, and two brominated compounds that we refer to as TBB (tetrabromobenzoate) and TBPH (tetrabromophalate). Two chlorinated organophosphate flame retardants not previously documented in the environment were also identified, one of which is commercially sold as V6 and contains tris (2-chloroethyl) phosphate (TCEP) as an impurity. These current use-flame retardant chemicals have also been detected in indoor dust collected from homes along the eastern US Levels of these current-use flame retardants in indoor dust are often comparable to the levels of PBDEs, and suggest that human exposure to these new flame retardants is similar to PBDEs.

167 Emerging Organohalogen Contaminants and Comparative Spatiotemporal Trends and Sources in Herring Gulls From the Great Lakes R.J. Letcher, Carleton Univ, Dept of Chemistry, Environment Canada, Science and Technology Branch, Ecotoxicology and Wildlife Health Division, Great Lakes Institute for Environment, Canadian Wildlife Service; D. Chen, W.A. Gebbink, Carleton Univ, Chemistry; S. Chu, L.T. Gauthier, P. Martin, C.E. Hebert, Science and Technology Branch, Environment Canada; C.D. Weseloh, Canadian Wildlife Service, Environment Canada. Environment Canada's Great Lakes Herring Gull Monitoring Program (GLHGMP) has been ongoing for more than 30 years, where eggs are collected annually from fifteen colony sites. Up until recently, for contaminant monitoring purposes these collected eggs have been used largely for spatiotemporal monitoring of legacy, organochlorine contaminants. However, over the last 4 years, recently collected and archived GLHGMP egg samples have been heavily utilized for screening for priority and previously unknown (to wildlife) pollutants, and subsequently for retrospective examinations of spatiotemporal trends and sources of new substances that may be of health concern to wildlife in the Great Lakes basin. The herring gull has been well-proven to be an excellent biomonitoring species, and although feeds on mainly an aquatic diet, has been shown over the last several decades (depending on the colony in question) and using chemical tracers such as stable carbon and nitrogen isotopes, to be feeding increasingly on terrestrial food sources. As a result, and considering the source of emerging organohalogen contaminants, such dietary changes are being shown to be increasingly useful in elucidating the source of such contaminants to herring gulls. In the present study, we will examine the growing number of bioaccumulative, chlorinated, brominated or fluorinated substances, including flame retardants, surfactants, metabolites and degradation products, being identified in herring gulls (eggs), and the comparative levels, patterns, spatial and temporal trends.

168 NOAA's Enhanced Great Lakes Mussel Watch Program: Monitoring Contaminant Levels in Mussels at Historic Mussel Watch Sites and Areas of Concern (AOC) K. Kimbrough, NOAA, Mussel Watch Program. The Mussel Watch Program (MWP) monitors the status and trends of chemical contamination in US coastal waters, including the Great Lakes using bivalve mollusks. In the Great Lakes, zebra and quagga mussels (*Dreissena* sp.) are the sentinel bivalves used for MWP monitoring. In 2009 and 2010 the MWP expanded its program into Areas of Concern (AOCs) in Lakes Erie, Ontario, Huron, Michigan, and Superior. Results will be presented for legacy contaminants, bivalve histopathology, and contaminants of emerging concern (CECs). Specifically, data will be presented that highlight the magnitude of 2009-2010 levels relative to historic data for the nation. A comparison will also be made between AOCs and ambient MWP sites to characterize the range of concentrations found in this study.

169 Perfluoroethylcyclohexane Sulfonate and Other Perfluorinated Surfactants in the Great Lakes Aquatic Ecosystem A.O. De Silva, Environment Canada, Water Science and Technology Directorate; C. Spencer, Environment Canada, Water Science and Technology Directorate; S.R. de Solla, Environment Canada, Science and Technology Branch; R. Letcher, Environment Canada; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, National Water Research Institute; B. Scott, Environment Canada, Water Science and Technology Directorate; S.B. Gewurtz, Environment Canada, Dept of Geography; S. Backus, Environment Canada; P.V. Hodson, Queen's Univ, School of Environmental Studies. Since Giesy and Kannan's seminal report of perfluorooctane sulfonate (PFOS) in biota in the Great Lakes basin in 2001, several studies have focused on researching perfluorinated chemicals (PFCs) in the Great Lakes. Previous research on PFCs has focused on chemicals with aliphatic perfluorocarbon geometry. Here we present data on a relatively unknown cyclic PFC, perfluoroethylcyclohexane sulfonate (PFECHS). PFECHS was first highlighted by Howard and Muir as a chemical of commerce that is likely persistent and bioaccumulative. Chemical inventories indicate that PFECHS was used in North America and Europe as an erosion inhibitor in aircraft hydraulic fluid but other applications may be possible. Here, we measured ng/L levels of PFECHS in the water from the Great Lakes. Highest concentrations were in L. Michigan and lowest in L. Superior. Lake trout from all the lakes and American eels from L. Ontario indicated consistent PFECHS levels in trout from L. Ontario and Erie (mean 2.5 ng/g w/w whole body homog.). In eel homog., PFECHS was 1.1-4.4 ng/g and in liver, 4.2 -39 ng/g, approx. 20x < PFOS, indicating that like other PFCs, PFECHS has a propensity for liver accumulation. PFC-containing aqueous-film-forming foam (AFFF) for fuel-based fire suppression is one likely source of certain compounds in the Great Lakes. High concentrations of PFOS (ave 2 ppm) were in the plasma of snapping turtles from L. Niapenco, Ontario. L. Niapenco is downstream of an international airport along the Welland River, eventually draining into L. Ont. Spatially resolved sampling of water and benthic inverts here suggested the airport being a dominant PFOS, perhaps due to AFFF usage. PFECHS showed a similar gradient from the airport, suggesting aircraft hydraulic fluids may indeed be a major application of PFECHS.

170 Polychlorinated Biphenyl Congeners in Chicago Air and Lake Michigan Air and Water in 2010 Z. Rodenburg, Univ of Iowa. Polychlorinated biphenyl (PCB) concentrations in air and Lake Michigan water near Chicago declined rapidly following the production ban of Aroclors over 30 years ago. However, since the early 1990s, concentrations of these chemicals have remained relatively constant. During summer of 2010, a field sampling expedition was conducted on Lake Michigan aboard the EPA R/V Lake Guardian approximately 5 km off the coast of Chicago. High-volume air and water samples were collected using Amberlite XAD-2 resin as an adsorption media and quartz fiber filters to collect particles in both phases. Passive air samples using polyurethane foam discs (PAS-PUF) were also collected throughout Chicago and surrounding suburban environments. All samples were extracted via accelerated solvent extraction and analyzed for 209 PCB congeners using tandem mass spectrometry. Quality assurance and control strategies utilized blanks, sample replicates, surrogate standards, internal standard methods and analysis of standard reference materials. Concentration data elicited from each sample was used to calculate instantaneous PCB congener fluxes across the air-water interface at the Lake Michigan location. The results were then used in conjunction with an ongoing regional transport model to predict the effect of specific emissions from the city of Chicago on the magnitude of PCB deposition to Lake Michigan.

171 Comparison of In Silico and Environmental Measurements for Identifying New, Emerging, and Re-emerging Chemicals of Concern in the Great Lakes D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, National Water Research Institute; A. De Silva, B. Lee, Environment Canada; P. Howard, SRC, Inc., Environmental Science Center. A wide range of organic chemicals (~350 substances not including structural isomers/congeners) have been reported in Great Lakes air, waters, waste effluents, sediments and biota over the past 15 years (see Klecka et al RECT 2010 for a list of 326 chemicals). The major classes of detected are current use pesticides (CUPs), pharmaceuticals, steroids and

hormones, alkylphenol ethoxylates, antioxidants, synthetic musks, perfluorinated chemicals, polybrominated diphenyl ethers, and other halogenated and organophosphorus flame retardants. Most of the chemicals have been registered since the 1980s under Food and Drug and Pesticide legislation, or on the Toxic Substances Control Act (TSCA) inventory or Canada's Domestic Substances List, in the case of high production volume "industrial chemicals". Given their relatively long term use and recent discovery they might be better termed "re-emerging" rather than "emerging". Their recent identification in environmental media is mainly the result of application of innovative analytical chemistry with a focus on structural analogs of previously identified compounds and application of new techniques such as LC-MS/MS. But this list represents only a small fraction of the possible chemicals that could enter the Great Lakes. There are thought to be more than 30,000 "industrial" organic chemicals in wide commercial use (>~1 t/y) as well as about 3000 pharmaceuticals and 1000 CUPs. If their possible degradation products, byproducts, and impurities, are included the list of individual analytes expands enormously. Recently, Howard and Muir (EST 2010;2011) identified 610 organics from a list of 22,263 commercial chemicals and also 364 out of 3193 pharmaceuticals that had potential for persistence and bioaccumulation in the Great Lakes region using U.S EPA EPISuite software and expert judgment. Of the 610 industrial chemicals, 62% were halogenated and 8% were siloxanes, while most the pharmaceuticals were substituted aromatics. In general, the identified chemicals had molecular structures associated with low rate of biodegradation such as adjacent halogens, cyclics, perfluorinated, cyclic siloxanes, multiple aromatic rings, and relatively high log Kow of 3 to 8. Most of the 350 substances previously measured in the Great Lakes, or in Great Lakes urban effluents, were among the 974 chemicals we identified independently, indicating the value of applying "in silico" approaches provided that structural information is available.

172 Human Nail and Hair Analysis as Biomarker of Exposure to Perfluoroalkyl Compounds W. Liu, Dalian Univ of Technology, School of Environmental Science and Technology; Y. Jin, Dalian Univ of Technology. Extensive human exposure to perfluoroalkyl compounds (PFAA) together with their persistence and various toxicities have arisen increasing concern. A noninvasive method would improve exposure assessment for large population, especially the children susceptible to contaminants. The aim of the study was to assess the use of PFAA measurements in human nail and hair as biomarker of exposure to PFAAs. Fingernail, toenail, hair, and blood samples were collected from 28 volunteers. The PFAA concentrations were determined by high performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS). Significant correlation was observed between PFAA concentrations in nails, hair, and serum. And nail PFAA level was higher than the serum levels. The accumulation of PFAA in nails and hair, together with their advantages in noninvasive sampling and ability of reflecting long-term exposure made nail and hair PFAA attractive biomarkers of exposure.

173 Determinants of Serum PFC Levels in Pregnant Women: Results from the Chemicals, Health and Pregnancy (CHirP) Study in Vancouver, Canada G.M. Webster, Univ of British Columbia, School of Population and Public Health, School of Environmental Health; M. Shoeib, S. Lee, T. Harner, Environment Canada, Atmospheric Science and Technology Directorate; J.W. Martin, Univ of Alberta, Dept of Laboratory Medicine and Pathology; K. Teschke, Univ of British Columbia, School of Population and Public Health. Perfluorinated compounds (PFCs) have been used as stain, grease and water repellents in consumer products for more than 50 years. Despite their ubiquitous presence in human serum, the sources and pathways of PFC exposure are poorly understood. Most studies have relied on simulated exposures, or have considered measured PFC levels in a small number of exposure media (e.g., only diet, or only air and dust). Few studies have examined relationships between measured PFC exposures and serum PFC levels for the same individuals. This study examined associations between a broad range of potential exposures measured at the individual level (i.e., diet, personal characteristics, indoor exposures and PFCs in indoor dust) and serum PFC levels in 152 pregnant women enrolled in the Vancouver (Canada) – based CHirP study. Data on participants' diets, personal characteristics and indoor exposures (e.g., contact with consumer products and time activity patterns) were collected by questionnaire, and PFCs were measured in vacuum cleaner dust from participants' homes. General linear models were used to identify the most important determinants of serum PFHxS, PFNA, PFOA and PFOS. Final models suggested that pork-based foods, raw fish or shellfish, and food packaging (e.g., microwave and movie theatre popcorn containers) were significant independent predictors of certain PFCs in serum. Parity was strongly and negatively associated with all four PFCs. Ethnicity, time spent in cars, flight time, mattress age, use of stain repellents on carpets, and spot use of stain removers were also predictive of at least one PFC. Dust levels of PFNA and the PFOS-precursor, N-methyl perfluorooctane sulfonamidoethanol (NMeFOSE), were also associated with serum PFNA and PFOS, respectively. These results suggest that both food packaging and bioaccumulation (e.g., into pork, fish and shellfish) contribute to dietary PFC exposures. Associations with pork-based foods are novel and warrant further investigation. The strong negative relationships with parity, suggesting maternal excretion across the placenta and/or through breastfeeding, underline concerns about fetal and infant exposures to PFCs during critical phases of development. Associations of serum PFCs with time spent in cars and airplanes, as well as with stain repellents used on carpets are also novel, and raise questions about the use of PFCs and their precursors in vehicle and airplane interiors, and in post-market carpet care liquids.

174 Human Detoxification of Perfluorinated Compounds D.A. Birkholz, ALS Laboratory Group, Research and Toxicology; S. Genuis, Univ of Alberta, Clinical Associate Professor Faculty of Medicine. There has been no proven method thus far to accelerate the clearance of potentially toxic pefluorinated compounds (PFCs) in humans. PFCs are a family of commonly used synthetic compounds with many applications including repelling oil and stains on furniture, clothing, carpets, and food packaging, as well as in the manufacturing of polytetrafluoroethylene (e.g., Teflon) – a non-stick surfacing often used in cookware. Some PFCs remain persistent within the environment due to their inherent chemical stability and are very slowly eliminated from the human body due, in part, to enterhepatic re-circulation. Exposure to PFCs is widespread and some sub-populations, living in proximity to, or working in fluorochemical manufacturing plants, are highly contaminated. PFC bioaccumulation has become an increasing public health concern as emerging evidence suggests reproductive toxicity, neurotoxicity, hepatotoxicity, and that some PFCs are considered to be likely human carcinogens. A case history is presented where an individual with high concentrations of PFCs in serum provided a) sweat samples after use of sauna; and b) stool samples before and after oral administration of each of two bile acid sequestrants – cholestyramine (CSM) and saponin compounds (SPCs). Stool samples before and after use of a cation-exchance zeolite compound were also examined. PFCs found in serum were not detected in substantial quantities in sweat, nor in stool prior to treatment. Minimal amounts of PFOA, but no other PFCs were detected in stool after SPC use; minimal amounts of PFOS, but not other PFCs were detected in stool after zeolite use. All PFCs congeners found in serum were detected in stool after CSM use. Serum levels of all PFCs subsequently declined after regular use of CSM. Further study is required, but this presentation suggests that CSM therapy may facilitate gastrointestinal elimination of some PFCs from the human body.

175 Legacy and Novel Brominated Flame Retardants in Indoor Dust from India: Characteristics and Implications G. Devanathan, Ehime Univ, Center for Marine Environmental Studies (CMES); T. Isobe, Ehime Univ, Senior Research Fellow Center (SRFC); A. Subramanian, Ehime Univ, Center for Marine Environmental Studies; N. Kajiwara, National Institute for Environmental Studies, Research Center for Material Cycles and Waste Management; K. Asante, Ehime Univ, Center for Marine Environmental Studies; G. Suzuki, National Institute for Environmental Studies, Research Center for Material Cycles and Waste Management; S. Takahashi, S. Tanabe, Ehime Univ, Center for Marine Environmental Studies. Brominated flame retardants (BFRs) including polybrominated biphenyl ethers (PBDEs) and hexabromocyclododecanes (HBCDs) are a group of chemicals which have been widely used in various consumer products to avoid fire accidents. Unfortunately, these chemicals can migrate from products to environment and ultimately reach humans. Concerns have risen as BFRs share similar properties with well-known toxic chemicals such as dioxins and polychlorinated biphenyls (PCBs). As a result, the production and use of these chemicals have been banned/regulated in Europe, North America and parts of Asia but most developing countries are yet to start such actions due to the availability of limited baseline dataset on these chemical contaminants. Elevated levels of BFRs were reported in air and dust from indoors than outdoor

environments and fears stared as we spend most time indoors. Therefore, the present study focused on elucidating the contamination status of BFRs and assessing human exposure through dust samples collected from different microenvironments including e-waste recycling buildings, commercials premises and residential areas in India. Significantly higher ($p< 0.05$) levels of contaminants such as PCBs, PBDEs, 1,2-bis (2,4,6-tribromophenoxy) ethane (BTBPE) and decabromodiphenyl ethane (DBDPE) (median: 7100, 48000, 65000 and 120 ng/g dust, respectively) were found in dust samples from e-waste recycling locations than commercial (median: 23, 460, 220, and 67 ng/g dust, respectively) and residential buildings (median: 13, 1000, 48 and 15 ng/g dust, respectively), suggesting that a major emission source of PCBs and BFRs is the crude e-waste recycling/dismantling activities in India. Levels of HBCDs were relatively low in dust from e-waste recycling buildings (median: 8 ng/g) than residential dust (median: 30 ng/g) indicating the wide use of HBCDs in textiles and other household materials than electrical and electronics products in India. Estimated daily intakes of BFRs via dust ingestion were much higher for toddlers than adults, particularly population involved in e-waste recycling activities are of great concern. More detailed studies of pollution sources and pathways are needed in order to reduce the exposure levels.

176 First Assessment of Human Exposure to Indoor Organic Contaminants in Pakistan N. Ali, Antwerp Univ, Pharmaceutical Sciences, Toxicology Centre; N.V. Eede, A. Dirtu, H. Neels, A. Covaci, Univ of Antwerp, Toxicology Centre. Ingestion of indoor dust has been recently acknowledged as an important of exposure to indoor organic contaminants. Here, we investigated the presence of polybrominated diphenyl ethers (PBDEs), novel brominated flame retardants (NBFRs), organophosphates esters (OPEs), polychlorinated biphenyls (PCBs), and organochlorine pesticides (OCPs) in indoor dust from rural homes and mosques in Gujrat, Pakistan. Dust samples were collected from homes living room floors (n = 31) and from mosque hall (n = 12). PBDEs, NBFRs, PCBs and OCPs were quantified using a GC-ECNI/MS method, while a GC-EI/MS method was employed for the determination of OPEs. Low concentrations were observed for most of the investigated contaminants. Hexachlorocyclohexanes (HCHs) and DDTs were the most prevalent OCPs with median concentrations 0.7 ng/g and 22 ng/g, respectively. PBDEs were only minor constituents in the investigated samples and the most important contributor was BDE 209 (median 40 ng/g). For NBFRs decabromodiphenyl ethane (DBDPE) (median 15 ng/g) was highest contributor followed by 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE) (median 3 ng/g). OPEs were present in higher levels than other contaminants with tri-(2-butoxyethyl)-phosphate (TBEP) and tri-phenyl-phosphate (TPP) having medians of 66 ng/g and 110 ng/g, respectively. Using log transformed data; a two-sample t-test was applied to study correlation between homes and mosques dust. PBDEs and NBFRs showed a significant positive correlation ($p< 0.05$), which indicates similar source of emission for BFRs in indoor environment. Surprisingly, levels of HCHs, DDTs and PCBs Congener CB 153 showed a positive correlation ($p< 0.05$) for both homes and mosques dust samples, indicating that a plausible source of contamination could be dust brought in with shoes. For OPEs, TBEP, TnBP, and TPP showed positive correlation ($p< 0.05$) suggesting similar sources of contamination in indoor dust. Over all the results show that the profile of homes and mosque indoor dust were not very different. One way ANOVA followed by Dunnett's post hoc test showed that the levels of investigated analytes were significantly different and lower than Romania, Belgium and New Zealand dust samples, indicating the variable use of these chemicals in different societies. To author's knowledge, this is the first study to document the presence of indoor organic contaminants in Pakistani dust.

177 US Toddlers Exposure to PBDEs H.M. Stapleton, Duke Univ, Nicholas School of the Environment; S. Eagle, Duke Univ; A. Sjodin, Center for Disease Control and Prevention; T.F. Webster, Boston Univ School of Public Health. Polybrominated diphenyl ethers (PBDEs) are a class of persistent and bioaccumulative flame retardants that are known to be associated with adverse effects on thyroid regulation and neurodevelopment. While a large research effort has focused on adult exposure to PBDEs, less is known about children's exposure and body burdens. In order to better understand factors affecting childrens exposure, we conducted a study which sought to determine if body burdens of PBDEs were significantly associated with house dust and/or PBDE residues on hand wipes collected from the children, and to determine if body burdens were associated with gender, age, race, and education level of the parents. Blood samples, hand wipes and house dust were collected from children between the ages of 12–36 months and who resided in the central North Carolina area between 2009–2010. A short questionnaire was administered by a research associate which collected information on the child's physical and behavioral characteristics, information on breast feeding, and information on the parents race and education levels. PBDEs were detected in every serum sample and the most abundant congeners were those associated with the PentaBDE mixture. Concentrations ranged from 5.2 to 745 ng/g lipid with a geometric mean value of 46.7 ng/g lipid. When PBDE levels were separated into tertiles by age of the child, PBDE levels were significantly higher ($p< 0.05$) in the oldest age group (>24 months) relative to the youngest age group (~12–18 months). Significant associations were also observed between PBDE levels and race and maternal education level, with higher levels observed in African Americans relative to Caucasians, and lower PBDE levels observed with higher maternal education levels. In addition, significant correlations were observed between the serum levels of BDE 47 and residues of BDE 47 measured on hand wipes ($r = 0.60$; $p< 0.0001$) and with BDE 47 levels in house dust (r=0.40; $p< 0.001$). No associations were observed between PBDE levels and duration of breast feeding as an infant. These data suggest that children's exposure to PBDEs from house dust appears to be a leading exposure pathway in toddlers, and not diet or breast milk exposure. Minorities and families with lower educational levels are also at higher risk to exposure to this class of contaminants.

178 Occurrence of Metabolites of Organophosphate Flame Retardants and Plasticizers in Human Urine N. Van den Eede, Univ of Antwerp, Pharmaceutical Sciences; A.C. Dirtu, Toxicological Centre, Univ of Antwerp, Dept of Pharmaceutical Sciences; E. Dirinck, P. Jorens, Univ Hospital of Antwerp; H. Neels, Univ of Antwerp, Pharmaceutical Sciences; A. Covaci, Univ of Antwerp. Organophosphate esters (OPEs) are used as flame retardants and plasticizers in a wide range of consumer products. Because of their increased use in the last decade, they are now highly abundant in the indoor environment. Human exposure to OPEs would occur *via* indoor air and indoor dust, both in which increased levels have been reported. Exposure to these chemicals may therefore be high and needs to be monitored. OPEs are metabolized in the liver to dialkyl phosphates or diaryl phosphates (DAP), depending on the structure of the parent compound. These DAPs can be traced in human urine and can serve to monitor human exposure to OPEs. The aim of this study was to determine urinary concentrations of DAPs in obese persons who were monitored before and after a reducing diet or bariatric surgery. Six DAPs were quantified, namely bis(1-chloro-2-propyl) phosphate (BCPP), bis(2-butoxyethyl) phosphate (BBEP), bis(2-chloroethyl) phosphate (BCEP), diphenyl phosphate (DPP), bis(1,3-dichloropropyl) phosphate (BDCPP) and di-(*iso*/*n*-)butyl phosphate (DBP) which are metabolites of the corresponding triester OPEs. Weak anion exchange solid phase extraction was used to extract DAPs from urine, followed by their separation by liquid chromatography on a Kinetex HILIC 150 x 2.1 mm x 2.6 µm column. Analysis was performed by tandem mass spectrometry in electrospray negative ionization mode. DAPs were quantified on four deuterium-labeled internal standards using multiple reaction monitoring. DAP concentrations were normalized to creatinine levels to compensate for the urine volume. The resulting data were analyzed using non-parametric statistical tests for relations between the levels of DAPs and gender or age group. Time dependent relations were investigated for concentrations of DAPs before the surgery/diet (n=95) with results of 3 months after the surgery/diet (n=55) and 6 months after the surgery/diet (n=39). The creatinine normalized levels were also compared to results from Germany and the United States. Further, the profiles and concentrations of DAPs in urine were compared with the levels and profiles of OPEs in Belgian and European indoor air and dust, which are the main exposure routes of humans to OPEs.

179 Predictors of TDCPP Metabolite in Office-Worker Urine C.C. Carignan, Boston Univ School of Public Health, Dept of Environmental Health; E. Cooper, Duke Univ, Environmental Sciences and Policy; D.J. Watkins, Boston Univ School of Public Health, Dept of Environmental Health; A.J. Fraser, Harvard Univ, Dept of Medicine; W. Heiger-Bernays, M.D. McClean, Boston Univ School of Public Health, Dept of Environmental Health; H.M. Stapleton, Duke Univ, Nicholas School of the Environment ; T.F. Webster, Boston Univ School of Public Health, Dept of Environmental Health. Tris(1,3-dichloro-2-propyl) phosphate (TDCPP)

was removed from use in children's pajamas over three decades ago for health reasons, however, is currently used as a flame retardant replacement for PentaBDE in polyurethane foam. Our aims were to characterize office worker exposure to TDCPP by measuring the urinary metabolite bis(1,3-dichloro-2-propyl) phosphate (BDCPP) using a newly developed bioassay and examine possible predictors of exposure. Urine collected from Boston office workers (n=29) was analyzed for BDCPP using LC/MS-MS and adjusted for specific gravity. Dust samples were analyzed for TDCPP using GC/MS. We detected BDCPP in 100% of urine samples at concentrations ranging from 62 to 1,760 pg/ml and a geometric mean (GM) of 408 pg/ml. We detected TDCPP in 99% of the dust samples with the highest concentrations in vehicles (GM=12,500 ng/g) as compared to offices (GM=6,060 ng/g) and homes (GM=4,210 ng/g in main living area; GM=1,400 ng/g in bedroom). TDCPP concentrations in dust were not associated with vehicle age (1-13 years) suggesting use in vehicles over many years. Based on the scatterplots, we identified a positive but non-significant trend between urinary BDCPP and TDCPP in office dust (r=0.24, p=0.21) that was not observed for dust from the home or vehicle. Removal of two influential points strengthened this association (r=0.45, p=0.02), suggesting that TDCPP in offices may contribute to office worker exposure. Independent of dust levels, average urinary BDCPP was 71% lower in workers from a newly constructed building (p=0.003), suggesting that exposure may be affected by other building characteristics. Additionally, handwashing was associated with reductions in urinary BDCPP concentration (p=0.095). Controlling for handwashing, workers with offices in a newly constructed building had average BDCPP urine concentrations 68% lower than workers with offices in older buildings (p=0.01).

180 Environmental Cancer Epidemiological Case Study Gibraltar H. Sanderson, Aarhus Univ, Environmental Science, National Environmental Research, Dept of Policy Analysis; P. Fauser, Aarhus Univ, Environmental Science. This environmental epidemiological study assessed the relative cancer risk and the role of environmental factors herein in Gibraltar compared to the rest of the EU. The study was commissioned by the Gibraltar government in 2008. The study conducted a weight-of-evidence analysis on credible and available environmental data relative to the reported cancer registry data. Air quality parameters and TBT in the drinking water supply, from desalinated sea water to tap water will be shown as special case-studies. The main cancers types comprising the majority of cancers will be reviewed in light of the environmental exposures. The study found that the cancer incidence rates are within the normal ranges of the rest of the EU. The levels of carcinogens in Gibraltar ambient air are within the normal ranges of what is found in the air in cities in the rest EU and within the guideline values of the EU.The study also uncovered significant uncertainties in relation to assignment of carcinogenecity to endocrine disrupting compounds, which have not so far been reflected in the regulatory appreciation of e.g., TBT carcinogenecity. The study results was presented to the government of Gibraltar earlier this year.

181 Carcinogenic and Non-carcinogenic Health Risks Associated with Former Manufactured Gas Plants (MGP) R. DeHate, GEI Consultants, Inc., Senior Risk Manager; D. Murray, B. Conte, GEI Consultants, Inc. Regulatory agencies are focused on assessing the potential for soil vapor intrusion (SVI) to adversely affect indoor air and the risk posed to occupants of residential and commercial properties overlying and surrounding former MGPs. This study evaluated the potential for SVI at 10 commercial buildings and 26 single family and multi-family residential properties overlying and/or adjacent to three former MGPs in Long Island, New York. The findings were compared to federal and state background data sets. The results did not identify evidence of MGP-related soil vapor intrusion from any of the 36 sites regardless of depth to water table or proximity to MGP source tar or dissolved phase plumes. In addition, risks were calculated based on maximum and mean concentrations for benzene, toluene, ethylbenzene, and xylenes measured in ambient air, , soil vapor, and indoor air samples. These chemicals were selected based on frequency of detection within the data sets. Hazard Indices for non-carcinogenic risk were calculated using the study results and the mean, maximum and 95th percentile concentrations from background data bases. Carcinogenic risks associated with benzene were calculated using both the measured mean and maximum study results and the mean, maximum and 95th percentile concentrations from background data bases. Hazard Indices for exposures near MGPs were less than 1 or were comparable to the regulatory mean and maximum background levels. Cancer risks for residential exposures near MGPs ranged from 1.93x10-6 to 3.68x10-5. However, background residential benzene exposure not related to former MGP sites ranged from 9.9x10-6 to 3.59x10-3. Cancer risks from exposure to benzene concentrations near MGPs were equivalent to or less than cancer risks estimated for a background residence in the northeast United States. No increased health risks were associated with occupied residential or commercial properties overlying or surrounding MGPs.

182 Risk Factors to Blood Dioxin Concentrations in Vietnamese Citizens Living Near Agent Orange Hot Spots at Da Nang and Bien Hoa, Vietnam D.T. Pham, Univ of Wyoming, Dept of Zoology and Physiology (3166); H.M. Nguyen, Office of the National Steering Committee 33; T. Boivin, Hatfield Consultants; H.L. Bergman, Univ of Wyoming, Dept of Zoology & Physiology. Agent Orange was one of a number of defoliants used by the US military in Vietnam from 1961–1971; this herbicide was contaminated with dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin, or TCDD). There are a number of major dioxin "hot spots" resulting from the use, distribution and spillage of herbicides at former US military bases in Vietnam. Recent studies at the former Da Nang and Bien Hoa airbases, completed by Hatfield Consultants and the Vietnamese Ministry of Natural Resources and Environment (MONRE), have found very high TCDD concentrations in soils, sediments, fish, human blood and human breast milk, with concentrations in all media greatly exceeding international standards. Elevated dioxin concentrations in the food chain are likely sources of human dietary exposure, posing a very serious health risk for the Vietnamese population living near these hot spot sites. Human health effects are now well documented for US military veterans and include prostate cancer, leukemia and Type II diabetes among other disease syndromes in adults. Possibly even more worrisome for the continuing exposure of the human population in Vietnam, physical and mental birth defects in children have been linked to TCDD exposure in utero and via breast milk. Based on measurements of blood dioxin and results of epidemiological surveys conducted at Da Nang and Bien Hoa by Hatfield and MONRE, we completed multiple linear regressions to assess importance of several risk factors contributing to blood dioxin levels. Important factors assessed included age, living or working at the contaminated sites, consumption of contaminated foods and lifestyle factors. Results of these and related analyses will be presented.

184 Assessment of Indoor Air Impacts From Naphthalene Associated With Vapor Intrusion at MGP Sites R. DeHate, GEI Consultants, Inc., Senior Risk Manager; B. Skelly, GEI Consultants, Inc. Naphthalene is a constituent of coal tar and often a contaminant found at former Manufactured Gas Plant (MGP) sites. Development at these sites has resulted in residential and commercial areas with potential exposures from vapor intrusion adversely affecting indoor air of residences and buildings. Naphthalene is routinely analyzed in soil vapor intrusion assessments for properties overlying and surrounding former MGP sites. The United States Environmental Protection Agency and the State of California have both proposed a draft unit risk factor for naphthalene. Naphthalene exposure from vapor intrusion may be a public health risk. The purpose of this study was to evaluate three sites located in the northeast United States to determine the frequency of naphthalene detection in indoor air. A total of 79 properties were included in the study. A total of 546 indoor air samples were analyzed for naphthalene by EPA Method TO-14A or TO-15. The properties were sampled on 161 occasions and some properties were sampled up to 14 times. At residential properties indoor air samples were collected in basements and crawl spaces, and in occupied areas such as living rooms and bedrooms. At commercial properties indoor air samples were collected in basements, sump rooms, storage closets and common areas such as lobbies, classrooms, and offices. The number of samples for each property ranged from three to twenty-eight depending on the size of the building, with an average number of four samples collected from each location. A typical sample collection included indoor air testing in the basement area, living room (with a duplicate sample) and a bedroom. These data were then used to evaluate exposure and assess public health risks. Naphthalene concentrations ranged from 0.26 to 51 microgram per cubic meter of air. Only 3 of the 546 indoor air samples detected naphthalene above the ninety-fifth percentile background value of 12 microgram per cubic meter of air. These 3 detections could be explained by sources of naphthalene not associated with vapor intrusion. Naphthalene was detected in less than 1% of the indoor samples. Naphthalene vapor intrusion impacting indoor air was not a public health risk among the 79 properties built on or near the former MGP sites.

185 Advantages and Complexities of Tissue-Based Cleanup Goals K. Godtfredsen, T. Deshler, Windward Environmental LLC; S. Replinger, Windward Environmental, LLC, Environmental Scientist. Recently, the concept of developing tissue-based cleanup goals has been receiving more attention. Although it makes sense to link cleanup goals as directly as possible to the remedial action objective of interest (e.g., reducing risks to seafood consumers), caution needs to be exercised in the development and application of tissue-based goals at sediment sites. Tissue-based goals, coupled with post-remedy monitoring, are best seen in the light of risk communication, which serves an important public benefit. For a number of reasons, however, tissue-based goals should not be used as preliminary remedial goals. Specifically, concentrations of bioaccumulative chemicals in fish, crab, and clam populations can be highly variable as a result of numerous environmental factors, many of which are difficult to predict, much less control. In addition, the derivation of "background" and risk-based goals for tissue must be carefully considered, particularly for "market basket" seafood ingestion scenarios. This presentation will acknowledge the allure of developing tissue-based cleanup goals but also outline key uncertainties and complexities at sediment sites.

186 Utility of Polytopic Vector Analysis (PVA) as a Tool for Differentiating Background Concentrations of Metals from Site-Related Metals Concentrations S. Huntley, ERM, Sediments and Watershed Integrated Management (SWiM) Polytopic vector analysis (PVA) is a multivariate statistical procedure originally developed within the geologic sciences, primarily for oil exploration, but in recent years has been employed for fingerprinting a variety of environmental contaminants, most notably polychlorinated dibenzo-*p*-dioxins and dibenzofurans (PCDD/Fs) and polychlorinated biphenyls (PCBs). PVA differs from more traditional statistical fingerprinting tools such as principal components analysis (PCA) in that it is an "unmixing" model that (1) identifies the number of source end members in the system, (2) quantifies the chemical composition (e.g., fingerprint) of each end member, and (3) determines the relative contribution of each end member to each sample. For sites that are potentially contaminated with metals, PVA may be a powerful tool for differentiating background metals concentrations from site-related metals concentrations. Results are discussed for several site metals datasets in the context of complicating factors including (1) contributions from both natural and anthropogenic background, (2) potentially different geologic lithologies occurring in varying proportions in different samples, and (3) multiple onsite or offsite sources that cannot be explained by either natural or anthropogenic background.

187 Potential Impacts of Climate Change on the Ecology of Dengue and its Mosquito Vector the Asian Tiger Mosquito (*Aedes albopictus*) R. Erickson, Texas Tech Univ, Dept of Environmental Toxicology, TIEHH/ Texas Tech Univ, graduate student; K. Hayhoe, Texas Tech Univ, Dept of Political Science; S. Presley, Texas Tech Univ, Dept of Environmental Toxicology; K. Long, L. Allen, Texas Tech Univ, Dept of Mathematics and Statistics; S. Cox, Texas Tech Univ, Dept of Environmental Toxicolgy. Shifts in temperature and precipitation patterns caused by global climate change may have profound impacts on the ecology of certain infectious diseases. We examine the potential impacts of climate change on the transmission and maintenance dynamics of dengue, a resurging mosquito-vectored infectious disease. In particular, we project changes in dengue season length in three cities: Atlanta, GA; Chicago, IL; and Lubbock, TX. These cities are located on the edges of the range of the Asian tiger mosquito within the United States. We use a disease model that explicitly incorporates mosquito population dynamics and high-resolution climate projections. Based on projected changes under the SRES A1fi (higher) and B1 (lower) emission scenarios, as simulated by 4 global climate models, we found that projected warming shortened mosquito lifespan, which in turn decreased the potential dengue season. These results illustrate the difficulty in predicting how climate change may alter complex systems.

188 The Effects of Suspended Sediment on Two Strains of Walleye (*Sander vitreus*) Eggs and Fingerlings B.C. Suedel, US Army Engineer Research and Development Center, CEERD-EP-R, US Army Engineer Research and Development Center, Environmental Laboratory, Waterways Experiment Station EP-R; C.H. Lutz, J.U. Clarke, C.G. Doug, US Army Engineer Research and Development Center. Restrictions on dredging operations via environmental windows are hindering dredging operations in the Great Lakes and other areas of the United States. Sediment resuspension is often cited as a concern leading to restricted dredging schedules, and is exemplified by walleye (*Sander vitreus*) in western Lake Erie. To address this concern, research was conducted to determine whether suspended sediments affect walleye eggs and fingerlings, mimicking sediment resuspension during dredging operations. In a series of laboratory experiments, hatchery collected northern and southern strain walleye eggs and fingerlings were exposed to multiple levels of suspended sediment collected from western Lake Erie. Newly laid eggs and 45-60 day old fingerlings from two different hatcheries were exposed separately in the Fish Larvae and Egg Exposure System (FLEES) at the US Army Corps of Engineers, Engineer Research and Development Center, Vicksburg, MS. Target concentrations of suspended sediment were 0, 100, 250 and 500 mg/L to mimic suspended sediment concentrations near dredging operations; concentrations were maintained in a flow-through system for three days. After exposure, the eggs were transferred to hatching cups and allowed to hatch. Larvae hatched from exposed eggs and fingerlings were visually inspected for defects, documented, and preserved. The FLEES maintained consistent NTU levels in the exposure chambers during each experiment. Data indicated no overt effects of suspended sediment on either egg hatch success or fingerling survival for either of the northern and southern strains. Gross anatomy and morphology analyses of exposed larvae and fish fry yielded no observable effects. These effects data will better inform the setting of environmental windows for this species in Lake Erie.

189 Evaluation of Ongoing Versus Legacy Sources Contributing to Elevated Bioaccumulatives in Hepatopancreas of Dungeness Crabs From Victoria Harbour, BC W.R. Hovel, Weston Solutions, Inc., Anchor QEA; M. Larsen, B. Lamoureux, Anchor QEA; G. Watson, Transport Canada; E. Shankie, Public Works and Government Services Canada; D. Kettlewell, SNC-Lavalin Environment; P. Allard, C. Mackintosh, Azimuth Consulting Group Inc. A Dungeness crab hepatopancreas consumption advisory is currently in effect in Victoria Harbour, BC as a consequence of elevated concentrations PCBs, dioxins, and furans within crabs. Human health risk assessment has indicated potential risks to consumers who frequently consume whole crab as a result of elevated PCBs and dioxin/furan concentrations in the crab hepatopancreas. In addition to localized areas of legacy sediment contamination, elevated concentrations of bioaccumulatives have been measured at some stormwater outfalls; however, the relative contribution of ongoing waterborne sources versus legacy sediment sources to the Victoria Harbour food web is unknown. For purposes of long-term management of Victoria Harbour sediment, this study was designed to evaluate the relative contribution of ongoing sources to the crab tissues such that the need and extent of sediment remediation and risk management decisions can be further evaluated. Water, sediment, and multiple organisms from Victoria Harbour were collected and analyzed for PCBs and dioxin/furans. To assess data prior to food web modeling, data were analyzed for spatial and temporal trends, PCB and dioxin/furan composition patterns including identification of key risk drivers in crab, and relationships among media. PCBs were measured in surface water during both sampling events, with the highest concentrations (2.4 ng/L) during the wet weather (December) event, at multiple locations, suggesting contribution from ongoing sources. Sediment PCB concentrations decreased towards the harbour mouth. Sediment PCB composition patterns were similar throughout the harbour with one exception; higher concentrations of the less chlorinated congeners were measured in one localized area. In biota, spatial patterns in PCBs varied by species; no spatial variability in crab hepatopancreas PCB concentrations or composition patterns was observed. Greater spatial variation in bioaccumulative concentrations was measured in shiner perch. Veneridae family and *Macoma nasuta* clam PCB concentrations demonstrated downward trends towards the harbour mouth, and were significantly correlated with sediment and water PCBs, indicating the potential contribution from both sources. Food web bioaccumulation modeling, which includes species-specific spatial averaging considerations, is underway to further evaluate contribution from different sources. Results will be discussed in the context of the risk management strategy.

190 An Integrated Evaluation of Methods and Approaches for Assessing Bioavailability of Contaminants in Sediments N. Bonnevie, ARCADIS, Risk Assessment and Ecological Services; D. Rigg, J. Gravenmier, M. Beauchemin, T. Iannuzzi, B. DeShields, P. Doody, ARCADIS. Decisions regarding the management of contaminated sediments need to consider the potential risks from exposure to chemicals, which are controlled by

various biological, chemical and physical factors internal and external to the ecosystem including the bioavailability of the chemicals in the sediments. Approaches for assessing bioavailability on a site-specific basis are inconsistent and too often decisions regarding risks and ultimately remediation are based on generic information or the total concentration of a contaminant(s) in sediments. This can result in an overestimation of risk from particular chemicals, leading to unnecessary remediation. In addition, for those sites where an assessment of bioavailability is performed, future conditions of the site are sometimes not adequately considered. This is becoming an increasing concern given the present focus on habitat/ecosystem restoration as part of or following remediation. In recent years a variety of sampling and analytical tools--both empirical and mechanistic--have been developed to evaluate the bioavailability of contaminants in sediments, helping to focus the investigation on those contaminants or exposure pathways that are most critical and providing a more realistic evaluation of risks. Although some of these methods are still not standardized (e.g., in situ water column samplers, use of in situ SPMDs, analysis of black carbon, analysis of pore water through SPME), in many instances small and inexpensive additions to a sampling program (e.g., adding pore water, total organic carbon, grain size, AVS/SEM, or other measures) can provide valuable data for evaluating factors that influence bioavailability. In this presentation, we will discuss recent developments in the field of bioavailability and their potential implications on both the evaluation of risks and on decisions regarding the need for or extent of remediation. We will describe key advantages and disadvantages of the more popular approaches, such as bioaccumulation models and normalization techniques and consider the increased evolution and utilization of sampling tools focused on understanding bioavailability. Case examples will be used as appropriate to illustrate key issues and considerations. In addition, we will discuss and provide examples regarding the need to consider potential future conditions in an ecosystem as part of the bioavailability assessment and, ultimately, the remedy selection process.

191 Atlantic RBCA Version 3 and Tier I Ecological Standards M. Poirier, Atlantic PIRI (Partnership in Risk Based Corrective Action); R. Mroz, Environment Canada. Atlantic Partnership in Risk Based Correction Action (RBCA) Implementation (Atlantic PIRI) is the multi-stakeholder committee who develops and assists in the ongoing delivery of RBCA in the four Atlantic Provinces. PIRI has a mandate to establish risk-based approaches to manage petroleum contaminated properties in Atlantic Canada. In 1999, Atlantic PIRI adapted the RBCA process, originally developed in the United States, to conditions typically present in Atlantic Canada. Atlantic RBCA has been used as the process for the development of Tier I and Tier II petroleum hydrocarbon assessment/remediation standards protective of human health. The Atlantic RBCA process is supported by two main components: 1) the regulatory-endorsed philosophy of risk assessment, risk management and a tiered approach to remediation; and 2) a technical tool kit (composed of a software model, supporting technical guidance and applicable provincial legislation, regulations, and policy guidance). Since 2007, Atlantic PIRI has also been developing Atlantic RBCA Tier I standards for the protection of ecological receptors with the goal of updating and revising existing ecological receptor screening documentation. A Task Group of scientific subject matter experts from across Canada was formed and developed, adapted and validated ecological based petroleum hydrocarbon criteria for soil, groundwater, surface water and sediment using best available scientific modeling tools. Subsequent sediment toxicity testing validated the modeled predictions. Included with the recent release is a scientific rationale document describing how these standards were adapted and developed. In 2011, the RBCA Tool Kit for Atlantic Canada, Version 3 software and User Guidance were released. Online technical training for users of Atlantic RBCA and updates to ecological receptor screening documentation were also released as key components of Atlantic RBCA implementation in the region. Highlights of Atlantic RBCA Version 3 will be presented including a focused presentation of the scientific rationale used to develop ecological based Tier I standards for petroleum hydrocarbons.

192 Monitoring the Efficacy and Potential Environmental Effects of In Situ Remediation C. Menzie, Exponent, Inc., Exponent, Principal; U. Ghosh, Univ of Maryland Baltimore County, Civil & Environmental Engineering. Activated carbon has been used in a number of pilot studies to remediate sediments contaminated with hydrophobic chemicals such as polychlorinated biphenyls (PCBs), methyl mercury, pesticides, and polycyclic aromatic hydrocarbons (PAHs). The efficacy of remediation has been evaluated by measures of accumulation into passive sampling devices, pore-water measurements, bioaccumulation into organisms exposed to sediments taken to the laboratory, and bioaccumulation into organisms in the field. Results show that these measures provide various perspectives on the risk-reduction potential of in situ remediation. At the scales of pilot studies an important field factor is the "edge effect" that occurs because the pilot study scale is often considerably smaller than the site. For this reason, monitoring needs to be able to recognize the existence and confounding effect of this factor. The presence of edge effects makes some measures of efficacy more reliable than others. The edge effect will diminish as the scale of treatment increases. Modeling also provides a tool for assessing the potential influence of in situ treatment on food-web transfer of the contaminants. A critical aspect of in situ monitoring is the assessment of the potential effects of amendments on the biological communities. Current work involves a combination of laboratory toxicity studies, field community studies, and re-colonization studies. Effects need to be judged within a relative risk framework where the potentially adverse effects of in situ treatment are compared to the potential impacts of alternative remediation approaches. To that end, the EPA's Sediment Management Guidance has been adapted as a framework for comparing the ecological and other costs and benefits of alternative remedial approaches. This paper presents the results of several completed and ongoing in situ treatment projects involving amendment with activated carbon.

193 Measures of Remedy Effectiveness for the Ottawa River Environmental Dredging Project M.A. Mills, USEPA, National Risk Management Research Laboratory; R. Brenner, USEPA Office of Research and Development, National Risk Management Research Laboratory; J.M. Lazorchak, USEPA, Office of Research and Development, National Exposure Research Laboratory, Molecular Ecology Research Branch; K. Fritz, USEPA, Office of Research and Development, National Exposure Research Laboratory; J. Meier, USEPA, National Exposure Research Laboratory – SEE Program; A. Mucha, S. Cieniawski, USEPA, Great Lakes National Program Office; D. Walters, US Geological Survey. Contaminated sediments pose risks to human health and the environment. Managing these risks generally involves three options, dredging, capping, and monitored natural recovery. Developing measures (or metrics) of the near- and long-term effectiveness of these remedies is an active area of research within USEPA and other research organizations. We provide an overview of multiple lines of evidence being developed at Ottawa River, a direct tributary of Lake Erie in Toledo, OH. Environmental dredging under the Great Lakes Legacy Act authority was conducted in 2010 in the lower five miles of river near its mouth. ORD in collaboration with GLNPO, USGS, OEPA, and NOAA are conducting a study to identify appropriate and effective metrics and tools to monitor the effectiveness of the remediation and recovery of the system. Specific areas on the river were targeted for removal to various depths depending on remedial objectives for selected contaminants (primarily PCBs, PAHs, and lead). The lines of evidence include physical, chemical, and biological measures that evaluate the recovery on various temporal and spatial scales. Results presented are for pre-, during- and intermediate post-dredging and include data on fish and invertebrate body burden PCB/PAH concentrations, bullhead blood and liver DNA damage, an invertebrate Index of Biotic integrity, passive samplers, as well as other chemical and physical indicators.

194 Development of Sediment Remediation Effectiveness Guidance for the Great Lakes Legacy Act Program A.P. Mucha, US Environmental Proection Agency, Great Lakes National Program Office; M.A. Mills, USEPA, National Risk Management Research Laboratory; S. Cieniawski, USEPA, Great Lakes National Program Office. The Great Lakes Legacy Act is a contaminated sediment management program focused on Great Lakes Areas of Concern. To better assess whether the Great Lakes Legacy Act remedial actions are effective in meeting its remedial goals and improving the health of the aquatic ecosystem, a guidance document is being developed for use at Legacy sites. Building upon several completed assessments at Legacy remediation sites that have already taken place, the guidance document seeks to provide a decision-making approach, rather than a compendium of methods. While the guidance is specific to Legacy Act sites, the document benefitted greatly from a multi-Agency workgroup that reviewed, critiqued, and helped shape the guidance. Key findings, the approach recommended, and the process used to develop the guidance will be presented, along with case studies for sites where this assessment approach has been implemented.

195 Interactions Among the Biology of American Eel (*Anguilla rostrata*), Exposure to Dioxin-like Compounds, Embryotoxicity, and Recruitment J.M. Casselman, Queen's Univ, Biology; R.S. Brown, Queen's Univ, Dept of Chemistry; J.D. Byer, Queens Univ; P.V. Hodson, Queen's Univ, School of Environmental Studies; M. Alaee, Environment Canada; C.M. Couillard, Fisheries and Oceans Canada, Institut Maurice Lamontagne; M. Lebeuf, Fisheries and Oceans Canada, Maurice Lamontagne Institute; N. Bols, Univ of Waterloo, Dept of Biology. The American eel (*Anguilla rostrata*) is an endangered species in Ontario. Since the 1980s, recruitment of juveniles to L. Ontario declined exponentially, large yellow eels disappeared, and the commercial fishery was closed. One possible cause is the embryotoxicity of dioxin-like compounds (DLCs) that eels accumulate during their growth phase in L. Ontario. Eels accumulate DLCs to the same extent as lake trout (*Salvelinus namaycush*), and trout reproductive failure has been tied to DLC accumulation, among other factors. The eel is semelparous, reproducing once after a 6-mo migration from L. Ontario to the Sargasso Sea, during which feeding stops, tissues are catabolized to sustain migration and oocyte maturation, and lipid stores (20-30% ww) are transferred to oocytes. Eels are also panmictic; eggs and leptocephali are distributed randomly by currents to estuaries and rivers along the east coast of N. America, as far north as Greenland. This phase is initiated by lipids derived maternally. Thus, embryotoxicity and lower recruitment may result from lipid-soluble DLCs. Upon transformation to glass eels and entry to the St. Lawrence R., eels begin a 5–15 y migration up to Cornwall, ON, arriving as juveniles at a dam where a counting ladder provides an index of recruitment. After passing the dam, the eels reside in the upper St. Lawrence R. and L. Ontario for up to 25 y, before maturing sexually and returning to the Sargasso to spawn. This extended life cycle means that eels recruiting to L. Ontario in the 1980s–90s were spawned from parents that integrated the contaminant history of L. Ontario from the 1960s–70s, the period of highest contamination. The extended life cycle of eels, their trophic status, and their high lipid content predict a high sensitivity to DLCs, which are persistent, bioaccumulative, and highly toxic to fish embryos.

196 Spatial Trends of Legacy Persistent Organic Pollutants in Eels J.D. Byer, Queens Univ; M. Alaee, Environment Canada; R.S. Brown, Queens Univ, Dept of Chemistry; M. Lebeuf, Fisheries and Oceans Canada; S. Backus, M. Keir, G. Pacepavicius, Environment Canada; S. Trottier, Fisheries and Oceans Canada; P.V. Hodson, Queen's Univ, School of Environmental Studies. World-wide, freshwater eel (*Anguillid* sp.) populations have undergone severe decline. Persistent organic pollutants (POPs) are currently under consideration as one of many possible causes, related to a reduction in embryo viability following exposure to several classes of POPs. Legacy POPs such as polychlorinated biphenyls (PCBs), polychlorinated naphthalenes (PCNs), organochlorine pesticides (OCPs), polybrominated diphenyl ethers (PBDEs), polychlorinated dibenzo-*p*-dioxins and dibenzofurans are ubiquitous in the environment and the focus of this study. American eel (*Anguilla rostrata*) were collected between 2007-2009 from seven locations in Canada and one in the United States (Hudson River, NY). European eel (*Anguilla anguilla*) from one location in Belgium served as a positive control to assess the current risk of POPs toxicity to eels. Concentrations of individual POPs classes varied greatly between locations, but the general concentration order was PCBs > OCPs > PBDEs >> PCNs > PCDD/Fs for all locations. In eels collected at Canadian locations, the mean ΣPCBs ranged from 26.2 to 403 ng/g ww, and the ΣPBDEs ranged between 2.29 and 23.6 ng/g ww. There was an apparent gradient from west to east across eastern Canada, with higher concentrations occurring in eels collected in Lake Ontario (western most sampling site), most likely related to higher levels of urbanization and industrialization. The ΣPCNs varied between 18.1 and 354 pg/g ww for all locations. The Canadian samples showed the same west to east gradient in concentration. The Belgian and US samples had similar PCN concentrations to the Lake Ontario eels. PCDD/Fs, dl-PCBs, and PCNs that had available toxic equivalent factors in the literature, were used to calculate 2,3,7,8-TCDD toxic equivalence (TEQs) for fish. The geometric mean for total TEQs ranged from 0.77 to 3.59 pg TEQ/g ww for Canadian collection sites, and 4.44 and 8.18 pg TEQ/g ww for the US and Belgian locations, respectively. The estimated no observable effects threshold for lake trout is 5 pg TEQ/g ww. If eels have similar sensitivity to TCDD as lake trout, the current risk of embryo toxicity from POPs is moderate-low.

197 Temporal Trends (1988-2008) of Chemical Contamination in American Eel Captured in Lake Ontario M. Lebeuf, Fisheries and Oceans Canada, Maurice Lamontagne Institute; J. Byer, Queen's Univ; M. Alaee, Environment Canada; S. Trottier, M. Raach, Fisheries and Oceans Canada; S.R. Brown, J.M. Casselman, P.V. Hodson, Queen's Univ. American eels (*Anguilla rostrata*) that grow to maturity in Lake Ontario are known to be highly contaminated with persistent organic pollutants (POPs). This raised the question of the possible role of chemical contamination in the decline of eel recruitment to Lake Ontario in the 1980-90's. However, information on temporal trends of POPs in Lake Ontario eels is lacking. This study aims to provide temporal trend data for legacy POPs including polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins and furans (PCDD/Fs). Polybrominated diphenyl ethers (PBDEs), a class of chemicals more recently regulated in Canada, were also analysed in eels. The temporal trend study was based on three groups of eels captured in Lake Ontario in 1988, 1998 and 2008. Each group of eels was comprised of ten females, averaging 20 years of age, collected between June and July. Each eel was homogenized prior to being analysed. Mean lipid content in the 2008 eel homogenates was significantly lower than in 1988 and 1998. A similar trend was observed in legacy POPs where the contamination was significantly lower in 2008, up to 3 fold, than in previous years. Lipid normalisation did not change the observed temporal trends. Toxic equivalents (TEQs) calculated from PCDD/F, non-ortho and mono-ortho PCB concentration data, using fish toxic equivalency factors, revealed the same trends. The results did not show the decrease of POPs contamination generally reported in sediments and biota between 1988 and 1998 in Lake Ontario. Even more surprising, the same trend was observed for PBDE contamination among the three groups of eels. Most temporal trend studies of PBDEs in biota report an increase until about 2000 followed by a steady state or a slow decrease. In summary, concentrations of all the organohalogen chemicals investigated were not different in eels collected in 1988 and 1998 but were significantly higher than in eels collected in 2008. Results of isotopic ratios $\delta^{15}N$ and $\delta^{13}C$ indicated that eels collected in 2008 are at a lower trophic level compared to 1988 and 1998 eels. These unexpected temporal trends and difference in trophic level suggest that although the three groups of eels were collected in Lake Ontario, they may have grown in different areas of the lake or tributaries.

198 Perfluorinated Surfactants in American Eels A.O. De Silva, Environment Canada, Water Science and Technology Directorate; S. Backus, Environment Canada; P.V. Hodson, Queen's Univ, School of Environmental Studies. Globally, freshwater eel populations have declined. In Ontario, the American eel (*Anguilla rostrata*) is classified as an endangered species due to a severe decline in recruitment to Lake Ontario. It has been hypothesized that chemical contamination may be a factor in the decline. As part of a larger group evaluating the persistent organic pollutants burden in eels, we measured perfluorinated compounds (PFCs) in American eels, collected between 2007-2009 collected at several locations in Canada and the US, and for comparison, European eels (*Anguilla anguilla*) from Belgium. Analytes consisted of perfluorocarboxylates (PFCAs) and perfluorosulfonates (PFSAs) including a newly detected cyclic perfluorosulfonate. Analysis by LC-MS/MS indicated that the dominant PFC congener was perfluorooctane sulfonate (PFOS), comprising 70-85% of the sum of PFCAs and PFSAs. In whole body homogenates, the sum of PFCAs and PFSAs ranged from 40 to 160 ng/g wet weight with the exception of eels from 3 locations which were less contaminated (< 20 ng/g sum). In those 3 locations, PFOS constituted < 50% of the perfluorinated acid burden. Concentrations in eels from the St. Lawrence River were comparable to those from a site in Belgium. Liver concentrations were also measured since it has been previously established that PFSAs and PFCAs preferentially accumulate in serum and liver. Wet weight concentrations of PFCAs and PFSAs were 2 to 3 x higher in liver compared to whole body homogenate, similar to previous observations in trout. The concentrations observed in eels from Lake Ontario and the St. Lawrence River were approximately 2x higher than in other top predators from the same location, lake trout and walleye.

199 Dioxin-like Contaminants May No Longer Be a Risk to the American Eel (*Anguilla rostrata*) in Lake Ontario S.J. Kennedy, Queen's Univ, graduate student; J.D. Byer, Queens Univ; M. Alaee, Environment Canada; R.S. Brown, Queen's Univ, Dept of Chemistry; J.M. Casselman, Queen's Univ, Biology; P.V. Hodson, Queen's Univ, School of Environmental Studies. Starting in the 1980s, recruitment of American eel (*Anguilla rostrata*) to Lake Ontario declined by 99%, resulting in the closure of the eel fishery in Ontario. The decline followed peak contamination of predatory fish species with persistent organic pollutants and recruitment failure of lake

trout associated with high tissue concentrations of dioxin-like compounds. To determine if dioxin-like compounds might also explain the eel recruitment problem, we tested the toxicity of eel extracts to embryos of Japanese medaka (*Oryzias latipes*). Sexually maturing, large yellow and silver eels were sampled in 2007 and 2008 from five locations in eastern Canada, including Lake Ontario, and from the Hudson River (US) and Canal Dessel-Schoten (Belgium) as positive controls. Medaka eggs were injected immediately after fertilization with 1 or 10 nL of eel extract, and scored for signs of toxicity after 11 d. Only extracts from Canal Dessel-Schoten eels caused effects consistent with dioxin-like toxicity in Japanese medaka embryos, indicating that dioxin-like contamination may no longer be a problem in Lake Ontario. However, this conclusion is tentative because medaka are somewhat less sensitive to dioxins than lake trout, and significant mortalities and reduced hatching among treatments at the highest exposure doses suggest that other co-extracted, non-dioxin-like contaminants may affect embryo survival. Compared to the 1980s, the lower concentrations of dioxin-like compounds in sexually-maturing eels implies that recruitment of juvenile eels to L. Ontario should be increasing. This is consistent with a small, but growing number of juveniles climbing the St. Lawrence River eel ladders at Cornwall, Ontario from 2003 to 2009.

200 Embryotoxic Potential of Persistent Organic Pollutants Accumulated by American Eels (*Anguilla rostrata*) from Lake Ontario Between 1988 and 2008 C. Rigaud, Université du Québec À Rimouski; C.M. Couillard, Fisheries and Oceans; J. Pellerin, Université du Québec À Rimouski; B. Legare, Fisheries and Oceans; P.V. Hodson, Queen's Univ; J.D. Byer, Environment Canada. Since the early 1980's, the St. Lawrence River American eel (*Anguilla rostrata*) population is undergoing a dramatic decline associated with recruitment failure, possibly related to the embryotoxic potential of persistent halogenated hydrocarbons (PHHs) which are accumulated in eel tissues and transferred to the eggs. To test this hypothesis, organic extracts were prepared from American eels captured in Lake Ontario in 1988, 1998 and 2008. Extracts from 5 individuals eels per sampling year were concentrated into triolein and then injected into embryos (N=35 per eel extract) of a marine model fish, the mummichog (*Fundulus heteroclitus*), at 0 day post-fertilization (DPF). Embryos were exposed to 10 EEQ/g (Eel EQuivalent per gram of embryo). Survival, growth, malformations, hatching success, cytochrome P4501A induction (EROD activity) and behaviour of *Fundulus* larvae were evaluated at 16 DPF. While survival and hatching success were not impacted by any eel extract, a significant increase in the prevalence of craniofacial deformities as well as a significant reduction in growth and prey capture ability were observed with extracts from 1988 and 1998 eels. All extracts significantly induced EROD activity with lower induction for 2008 extracts compared to the older ones. Our results suggest that, during the 80's and the 90's, PHHs accumulated in American eel tissues have reached concentrations potentially toxic to their offsprings. Experiments with lower charges (0.5 to 10 EEQ/g), evaluation of interspecies sensitivity to PHHs and histological analyses (cerebral apoptosis, brain and retinal damages) are underway.

201 Effects of Contaminants on the Reproductive Success of American Eels A. Carey, K. Oliveira, Univ of Massachusetts Dartmouth, Dept of Biology; A. Roe, US Fish and Widlife Service; W. Hable, Univ of Massachusetts Dartmouth, Dept of Biology. The recent decline in worldwide populations of Anguillid eels is thought to be caused by pollution, overfishing, climate change, and/or habitat destruction. American eels, *Anguilla rostrata,* are known to inhabit contaminated rivers for the majority of their lives until they migrate to the ocean to spawn. Due to their unique catadromous life cycle, mature adults are not accessible for study and little is known about the effects of contaminants on fertilization and larval development. Using methods similar to the maturation of *Anguilla japonica*, *A. rostrata* males and females were artificially matured with weekly hormone injections. Using these procedures, our objectives were to (1) examine the maternal transfer of environmental contaminants to the eggs, (2) examine the effects of contaminant load on the fertility of females, and (3) examine the effects of polychlorinated biphenyls (PCBs) on the reproductive success of male eels. To examine the maternal transfer of contaminants to the eggs, ovulated eggs and muscle tissue are being analyzed for PCBs, dioxins and furans, pesticides, polybrominated diphenyl ethers, and metals. Results, to date, provide important baseline data and will facilitate development of a model for predicting parental contaminant contribution to offspring. To examine the effects of contaminant load on the reproductive potential of females, time to full maturation, ovulation, and fertilization success were evaluated and will be compared to the contaminant load in eggs. To examine the effect of PCBs on male gametogenesis, fertilization, embryogenesis and early larval development, males were co-injected with 2 different concentrations (1.0 or 10 µg/fish) of PCBs. Fertilization success and embryogenesis were assessed 2–4 hours post fertilization (PF), 24 hours PF, and 48 hours PF. Preliminary results show that males injected with 10 µg of PCBs exhibited lower reproductive success and produced embryos with disrupted early embryonic development. Fertilization success was significantly lower in embryos fertilized with sperm from males injected with 10 µg PCBs compared to the controls. Our results will shed light on whether environmental contaminants are contributing to the decline of *A. rostrata*. These findings will be important for future conservation efforts and the management of the American eel, an ecologically and commercially important species.

202 Impacts of Habitat Contamination on the Health of Declining American and European Eel Populations P. Couture, INRS, Centre Eau Terre Environnement; C.M. Couillard, Fisheries and Oceans Canada, Institut Maurice-Lamontagne; L. Bernatchez, Universite Laval, Département de Biologie; P.G. Campbell, INRS-Eau, Terre et Environnement, INRS-ETE, INRS, Centre Eau Terre Environnement; F. Pierron, CNRS; M. Baudrimont, Université Bordeaux 1, Station marine d'Arcachon; H. Budzinski, Université Bordeaux 1, Institut des Sciences Moléculaires; P. Elie, CEMAGREF, Unité Ecosystèmes Estuariens et Poissons Migrateurs Amphihalins; S. Dufour. Muséum National d'Histoire Naturelle, UMR BOREA. The European and American eels are two economically, ecologically and culturally important fish species currently considered in decline and, in the case of the European eel, threatened by extinction. The role of pollution in the decline of these fish is still largely unknown. This new research project is a joint initiative of researchers from Québec and France. Its general objective is to examine the relationships between pollution, both inorganic and organic, and the health of Atlantic eels in the Gironde and the St. Lawrence Estuaries. Indeed, contaminants released in water by urban, industrial, mining and agricultural activities accumulate in yellow eels during their long phase of somatic growth and could affect their growth rate as well as cause tumors and lesions. Furthermore, during their reproductive migration, silver eels mobilize their energy reserves to fuel migration and for gonad maturation. Accumulated contaminants could then be released massively and cause toxicity in the adult or be transferred to embryos. The first objective of this study is therefore to test the hypothesis that contaminants exert a selective pressure on eel populations that will translate into differences in genotypic composition between populations from clean and contaminated sites, using 454 pyro-sequencing to identify SNP markers. The second objective is to understand the influence of the contamination of habitats where yellow eels grow on energy accumulation, metabolic capacities, growth, tissue and cell damage and histopathology, using a range of molecular, biochemical and physiological approaches including the development of a microarray. The third objective is to evaluate the effects of contaminant mobilisation and redistribution on health indicators (oxidative damage, histopathology, genotoxicity), migratory capacities (metabolism, condition) and gonad maturation (hormonal and histological changes, gonad contamination and follicular atresia) of female silver eels. Ultimately, this research, conducted in partnership with key government agencies, will improve our capacity to favour the restoration of Atlantic eel populations, through the development of informed management policies."

203 Reducing Uncertainty in Risk Assessment: Lessons Learned from Studying Transfer of Organic Contaminants from the Abiotic to the Biotic Compartment H. Selck, Roskilde Univ, Dept of Environmental, Social and Spatial Change; D. Salvito, Research Institute for Fragrance Materials, RIFM; V. Forbes, Univ of Nebraska Lincoln, School of Biological Sciences. Potential hazards and risks of new and existing chemicals are assessed by regulatory agencies based on their P (persistance) and B (bioaccumulation) and T (toxicity) potential. Being able to accurately identifying PBT substances is therefore key to protect human health and the environment. The focus of this presentation will be on the importance of environmental and physiological factors for affecting bioaccumulation including biotransformation of organic contaminants in the aquatic environment and thus for their persistence. Examples will include results from a range of experiments performed in collaboration with the Research Inst. for Fragrance Materials (RIFM) using different sediment-associated fragrance materials (FMs), sediment-dwelling deposit-feeders, and different sediment-organic contents. Here we focus on: 1. effects of varying organic matter content in the sediment; 2. impact of species dependent biotransformation differences for the fate (accumulation, biotransformation) of sediment-associated FMs. These studies support the conclusion that the materials presented in the examples are not PBTs. Due to their feeding strategy (ingest massive volumes of sediment) and a digestive system optimized to extract organic material from sediment, deposit-feeders may increase the amount of contaminants taken up from the gut. However, since these organisms, generally, also show high biotransformation capacities which evidently will reduce the body-burden (BB) of organic contaminants, focusing solely on BB will significantly underestimate accumulation and thus increase the uncertainty of e.g., BAF. Since benthic communities may play an important role both in the remobilization of sediment-associated organic compounds but also by affecting their fate (bioturbation, biotransformation) this will also have implications for the way we evaluate the persistence of organic contaminants in risk assessment. To improve reliability of current risk assessment of PBT substances we need to focus future research on factors affecting P and B and focus on the transfer from the abiotic to the lower trophic level as this generates the basis for further B assessment.

204 Exploiting Relationships Between Metrics of Biouptake in Fish to Improve Laboratory to Field Extrapolation D. Mackay, Trent Univ; F. Gobas, Simon Fraser Univ; J. Arnot, Univ of Toronto Scarborough. Biouptake of organic chemicals in a variety of organisms is of continuing scientific and regulatory interest. Metrics such as BCF, BAF, BMF, BSAF and TMF are widely measured, some in laboratory tests and some by field monitoring. Considerable progress is being made in determining and interpreting these quantities. Applying simple and well-accepted mass balance models of uptake and clearance for fish shows that these metrics are closely related thus providing an opportunity, for example, to extrapolate more accurately from a laboratory BCF to a field BAF and a field BMF. These relationships are discussed and it is shown that a combination of laboratory and field data with a model can provide a powerful quantitative description of the biouptake phenomena for both scientific and regulatory purposes. Further, the relatively high degree of reproducibility achievable in laboratory tests could be better exploited for deducing field conditions and effects by some simple modifications to existing test protocols. Suggestions are made for such modifications, for gathering more accurate and relevant chemical properties and physiological parameters of the test organisms and for designing test and sampling programs using tentative advance uptake/clearance models. This could lead to an improved overall biouptake test strategy and to improved risk assessments.

205 Passive Dosing, Passive Sampling and Benchmarking in Fish Bioconcentration Tests M. McLachlan, Stockholm Univ, Dept of Applied Environmental Science; M. Adolfsson-Erici, G. Akerman, A. Jahnke, Stockholm Univ; P. Mayer, Aarhus Univ, National Environmental Research Institute; M. MacLeod, Stockholm Univ. The OECD 305 protocol for determining the bioconcentration factor (BCF) in fish is long, costly, and test animal intensive. Commonly an uptake phase of 28 days is followed by a depuration phase of up to 56 days, and a minimum of 40 fish are required. In addition, inter-laboratory precision of the results is not high. In an effort to improve quality while reducing the costs and test animal requirements, several innovative techniques were developed and tested including: –Passive dosing to maintain constant freely dissolved concentration of the target chemicals during the exposure phase –In-tissue passive sampling of the target chemicals in the fish during the elimination phase –Internal benchmarking via simultaneous exposure of the fish to a chemical with known bioaccumulation behaviour. This led to a revised protocol shortened uptake and elimination phases (4/10 days), and a reduced number of fish (8). The revised protocol and the OECD 305 protocol were run for 10 chemicals using rainbow trout. Good agreement was found between the BCFs measured with the two methods. This supports the feasibility of reducing the cost and animal requirements of fish bioconcentration experiments. In addition to the methodological improvements provided by the passive dosing system, method precision was much improved thanks to the internal benchmarking. The revised protocol should be particularly useful in assessing whether chemicals lie above or below regulatory thresholds, as the internal benchmarking facilitates the determination of relative bioaccumulation behaviour.

206 Use of Isolated Trout Hepatocytes to Predict Measured Hepatic Clearance and Whole-animal Bioconcentration Factors for Six Polyaromatic Hydrocarbons K.A. Fay, P.N. Fitzsimmons, A.D. Hoffman, J.W. Nichols, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division. Hepatic metabolism is an important determinant of chemical bioaccumulation in fish. Consequently, measured in vitro hepatic metabolism may improve model predictions of bioaccumulation. In this study, fresh and cryopreserved trout hepatocytes were used to measure in vitro intrinsic clearance (CLin vitro,int) of six polyaromatic hydrocarbons. These CLin vitro,int values were then extrapolated to the intact organ and compared to measured levels of clearance (CLH) by isolated perfused trout livers. To facilitate these comparisons, hepatocellularity scaling factors were determined for male and female trout. In addition, solid phase microextraction (SPME) methods were employed to determine unbound chemical concentrations in the isolated liver preparation. Generally, the hepatocytes performed well in predicting CLH rates exhibited by perfused livers. Although hepatocellularity values were higher for female trout than for males, predicted CLH values for the six compounds did not differ substantially. Finally, CLH values determined using both hepatocytes and isolated perfused livers were extrapolated to the whole animal and incorporated into a one-compartment bioconcentration model. Model-predicted bioconcentration factors (BCF) were then compared to measured values for strain- and temperature-matched trout. Preliminary results suggest that predicted BCF values are within the range of observed values.

207 Predicting Field Variation of PCB Bioaccumulation in a Temperate Fish Population Under Steady State and Non-steady State Conditions K. Drouillard, University of Windsor, Great Lakes Institute for Environmental Research. Much of the field of bioaccumulation has focussed on hazard assessment and establishing the potential for laboratory organisms to accumulate contaminants above regulatory criteria such as the BCF 5000 rule, to validate global predictions of food web bioaccumulation models or to measure trophic magnification factors at the food web scale. There have been fewer attempts to understand field variation of bioaccumulation metrics as it applies at the population scale in an indicator species and establish the magnitude and causes of field variability required for risk assessment purposes. More recently, non-steady state bioaccumulation dynamics have been recognized to occur in fish populations and yet field sampling designs rarely consider the implications of non-steady state bioaccumulation by fish or how this contributes to field variation in bioaccumulation metrics. This study used a modelling approach to contrast steady state and non-steady simulations of congener specific PCB bioaccumulation in a yellow perch population. The non-steady state bioaccumulation model, coupled with Monte Carlo analysis, considered uncertainty propagation among toxicokinetic parameters, seasonal changes in growth and weight loss and environmental heterogeneity in water and food contamination to simulate seasonal trends in PCB bioaccumulation, likelihood of achieving steady state for congeners of different hydrophobicity and to test whether model uncertainty would mask seasonal trends under realistic field sampling designs. Results of these simulations are contrasted against steady state model predictions to highlight where steady and non-steady state models predict different bioaccumulation patterns, for example congener ratios with age, to recommend sampling designs that could distinguish between steady and non-steady state bioaccumulation and to evaluate the implications of non-steady state bioaccumulation dynamics to field variability of chemical bioaccumulation.

208 A Framework to Improve In Vivo Biotransformation Rate Constant Estimation J. Arnot, ARC Arnot Research & Consulting Inc., Univ of Toronto Scarborough, Dept of Physical and Environmental Sciences; T.N. Brown, Helmholtz Centre for. Environmental Research UFZ, Dept of Analytical Environmental Chemistry; E. Papa, Univ of Insubria, QSAR Res. Unit Environ. Chem/Dep. Structural Functional Biology , Univ of Insubria, DBSF; P. Gramatica, Univ of Insubria, QSAR Res. Unit Environ. Chem. Ecotox./Dep.Structural & Functional Biology; W. Janzen, G. Schuurmann, Helmholtz Centre for Environmental Research UFZ; S. Dimitrov, Prof. Dr. Assen Zlatarov Univ, Dept of Comp. and Inform. Technologies, Univ of Zlatarov, Dept of Comp. and Inform. Technologies; O. Mekenyan, Prof. Dr. Assen Zlatarov Univ, Laboratory of Mathematical Chemistr; B. Meylan, P. Howard, Syracuse Research Corporation. Mass balance bioaccumulation models are required for bioaccumulation, exposure and risk assessment and to compare laboratory and field bioaccumulation metrics (e.g., BCF, BAF, BMF, TMF). The whole body primary metabolic biotransformation rate constant (kM) is a key bioaccumulation parameter required by the models and measured data are limited; therefore, reliable Quantitative Structure-Activity(Property) Relationships (QSA(P)Rs) are needed. A framework to improve kM estimation that maximizes the value of existing laboratory and field bioaccumulation information and provides intelligent testing strategies for future research is outlined and described. An empirical in vivo kM database for fish has been developed and various QSA(P)Rs are being developed and evaluated using different QSAR methods. The different QSA(P)Rs can be compared against the empirical data and against each other to identify potential sources of error in the existing database and merits and limitations of different QSA(P)R methods (e.g., for particular classes of chemicals and functional groups). This aspect of the framework is analogous in many ways to a laboratory "ring test" for chemical testing methods. A comparison of the different QSA(P)R predictions for thousands of organic chemicals provides the opportunity to identify chemicals with structural elements that are not currently well predicted for priority laboratory testing (in vivo and in vitro) in a defensible and efficient manner. New bioaccumulation testing data can then be obtained to expand the existing kM database and the domain of applicability in a second generation of QSA(P)Rs. This framework is expected to result in reduced animal testing, reduced uncertainty in kM estimation, reduced uncertainty in bioaccumulation, exposure and risk assessment, and improved data to compare laboratory and field bioaccumulation metrics.

209 Connecting Uncertainty, Weight of Evidence, Data Consistency and Precaution for the Regulatory Assessment of Bioaccumulation M. Bonnell, Environment Canada, New Substances Division, Environment Canada, Science and Risk Assessment Directorate. There are significant obstacles to developing a standard approach to making decisions on the bioaccumulation potential of a substance that can be adopted by all regulatory authorities. This is because an authority's approach will likely consider or weight evidence differently depending on regulatory context (e.g., the weighting of legal vs. non-legal metrics), the relevancy of different bioaccumulation metrics (e.g., in silico vs. in vitro vs. in vivo results) and how bioaccumulation is defined by a regulatory authority. Regulatory decision-making is also a "normative" process; that is, it incorporates considerations that are based on societal values. Therefore, probably the most important aspect of decision-making is that the process be transparent and reproducible to the degree feasible when using a normative process. This paper will discuss one possible approach to arrive at decisions on the bioaccumulation potential of substances from a regulatory perspective. In this approach, uncertainty is established based on the "strength of inference" a piece of information has to address the question posed by a null hypothesis (e.g., BCF or BAF is below the criterion value). The strength of inference is related to the quality and quantity of available data, and impacts both the weight given to individual pieces of information and the overall level of precaution applied in making the regulatory decision. The weighting of data can be performed using a qualitative or quantitative ranking method. As there can be many lines of evidence for bioaccumulation, the consistency between data or lack thereof should be examined. Lack of consistency adds to the overall level of uncertainty while greater consistency has the opposite impact. Precaution is linked to the degree of uncertainty when weighing evidence to test a hypothesis. In particular, a higher degree of precaution is used when the spread of uncertainty suggests that a false negative is possible in the above null hypothesis. A hypothetical chemical will be used to illustrate the above concepts using a qualitative weighting approach and data consistency matrix.

210 Dispersants Evaluation, Use and Environmental Concentrations during the DWH Incident A.D. Ahnell, BP GUlf Coast Restoration Organization, Science, Technology, Environment & Regulatory Affairs; G.M. Coelho, D.V. Aurand, Ecosystem Management & Associates, Inc.; J.S. Brown, Exponent Inc.; L. Bruce, BP, GCRO. This presentation will provide the context for evaluation and continued use of the dispersants applied to surface oil via aircraft and applied subsurface at the point of oil release. In combination, these data sets support the initial product selection and the large scale dispersant operations that provided an overall net environmental benefit during the spill response and were a key component of the response. The use of aerial dispersant applications as part of BP's initial spill response was one component of the pre-approved dispersant use plan. As application of Corexit products escalated in the initial phase of the response, BP and the USEPA tested additional dispersant products on the NCP list for efficacy and toxicity, but none performed significantly better and there were no significant differences in product toxicity to standard test species. Further support for continued use came from near-surface and sub-surface water sampling. Monitoring data by USCG SMART teams and BP contractors showed that dispersant applications to surface slicks created dispersed oil in the upper water column that rapidly diluted to levels that were not acutely toxic to standard test species in laboratory toxicity tests. Once subsea dispersant application was shown to be effective during initial tests, a monitoring plan commenced to collect data on the nature and extent of the subsurface dispersed oil. Particle size analysis and surface observations support dispersant effectiveness while dissolved oxygen concentrations showed only small decreases from enhanced biodegradation, and none exceeding the 2 mg/L lower limit set by USEPA. A large majority of the water samples collected and later analyzed by GC/MS showed oil and dispersant concentrations were orders of magnitude below acute toxicity effects thresholds for marine life. Data collected during the DWH incident provide significant insights into the net environmental benefit offered by surface and subsea dispersant applications use. Further research should use the DWH incident data as context in selecting environmentally meaningful exposure regimes in when designing toxicology and biodegradation studies of physically and chemically dispersed oil. Due to the complexity of the topic and breadth of the information presented an extended time period is requested.

211 Deepwater Horizon Long-Term Monitoring Study Shows Continuing Depletion of PAH in Oil and Sediment Samples from MC252-Impacted Areas J.S. Brown, Exponent Inc.; L. Cook, Exponent; A. Ahnell, BP – GCRO. After the Deepwater Horizon (DWH) accident, certain Louisiana shorelines were impacted by MC252 oil. During the DWH response, the Long-Term Monitoring Program (LTM) was implemented by the Incident Command to study oiled shorelines in the absence of clean-up or remediation treatments to evaluate the natural weathering and biodegradation of MC252 in shoreline environments. The LTM study sites selected included key sensitive habitat types of the coastal region impacted by MC252 oil including: salt marsh, tidal channel marsh, phragmites marsh, mangrove, and shell berm. Additionally, un-oiled shoreline segments were selected as reference sites to characterize background hydrocarbons in marsh, mangrove, and shell berm habitats. Oil and sediment samples were collected at each site from the high tide, upper intertidal, and lower intertidal areas. Multiple sampling surveys were performed at each site to study changes over time. Samples were analyzed for polycyclic aromatic hydrocarbons (PAH), total and saturated petroleum hydrocarbons (TPH and SHC), and geochemical biomarkers (steranes and triterpanes). Sediment samples were also analyzed for total organic carbon (TOC) and grain size. Over a six month period, changes in PAH and SHC concentrations and chemical signatures in the oil and sediment samples were assessed to determine the processes acting on the petroleum hydrocarbons in each habitat type. Depletion of key chemical parameters was calculated for individual PAH, summed PAH, and summed alkanes using the conserved biomarker hopane, in comparison to fresh MC252 crude oil. MC252 impacted shoreline areas showed losses of PAH associated with dissolution, evaporation, biodegradation, and photo-oxidation. The majority of the depletion associated with dissolution, evaporation, and photo-oxidation likely occurred during the transport of the oil to the impacted areas. The earliest samples collected from these sites showed greater than 90% depletion for total PAH in all oil and sediment samples. Depletion of heavy PAHs (4-6 rings) and alkanes was not as rapid as total PAH and thus provided an extended range with which to observed trends with time. Continued depletion of heavy PAHs and alkanes was noted at several of the LTM sites, with further evidence of biodegradation.

212 Identifying and Characterizing a Polar and Recalcitrant Fraction in Weathered Macondo 252 Well Oil C. Aeppli, C.A. Carmichael, R.K. Nelson, C.M. Reddy, Woods Hole Oceanographic Institution, Dept of Marine Chemistry and Geochemistry. To investigate weathering of oil from the Deepwater Disaster one year later, we collected oil-soaked sand patties along the coasts of Mississippi, Alabama, and Florida as well as the Chandeleur Islands. These sand patties were easily found by searching for the orange-hue of the oil that was observed immediately after the spill. Analysis of the solvent extracts by gas chromatography with flame ionization detection (GC-FID), gas chromatography with mass spectrometry (GC-MS), and comprehensive two-dimensional gas chromatography (GCxGC) first confirmed by biomarker analysis that the oil was from the Macondo Well, that there were only traces of aromatic hydrocarbons, and that compounds with less than 17 carbons were no longer present. Furthermore, our analyses revealed that the oil-soaked sand patties generally contained less than 10% of solvent-extracted mass. Interestingly, only half of the extractable mass could be characterized by gas chromatography, presumably the other 50% of the material being too polar to be analyzed by GC. To investigate the polar nature of the extracts, we then analyzed the carbon, hydrogen, nitrogen, sulfur, and oxygen content. The whole extract from one sample contained 10% oxygen by mass while the original oil contained < 1% detectable oxygen. These results suggests that either abiotic or biotic oxygenation of the spilled oil caused such dramatic changes in the spilled. In addition, standard silica gel chromatography showed that the extract was evenly distributed between the saturated fraction and the polar fraction (eluting with hexane and dichloromethane/methanol, respectively). Together these results show that considerable weathering has occurred within one year since the spill. In order to identify the nature and products of such degradation processes, we plan to further characterize these polar fractions using infrared spectroscopy and liquid chromatography MS analysis. Nevertheless, this study has shown significant losses of hydrocarbons as well as changes consistent with oxygenation. Given the significant mass, and the so far poor understanding of the environmental fate of the described polar fraction, our findings imply that using commonly applied techniques solely based on GC amenable fractions to assess the environmental impact of the Deepwater Horizon incident may lead to a significant overestimation of natural oil attenuation.

213 Laboratory Measurements of Dissolved and Droplet PAHs in MC252 Oil-Water-Dispersant Mixtures Inform Partitioning After Deepwater Horizon Oil Spill P. Boehm, Exponent, Environmental & EcoScience Group, Exponent, Environmental Group, Exponent, Inc., Environmental & EcoScience sGroup; K. Murray, Exponent, Senior Scientist; D. Shea, North Carolina State Univ, Dept of Biology. The bioavailability of and risk from polycyclic aromatic hydrocarbons (PAH) from crude oil in water are dependent on whether they are dissolved or associated with droplets or particles. To adequately characterize the dissolved fraction of oil and its PAH constituents in a water sample and avoid the over-estimation of the dissolved PAH concentrations, any whole/droplet/particulate oil must be accounted for. There are two possible approaches to this problem: 1) the oil and water can be physically separated for analysis, or 2) the amount of the dissolved PAH can be calculated from the measured data from unfractionated samples using properties of PAH chemistry. To evaluate and understand the advantages and limitations of each approach, a series of laboratory experiments were conducted, and the results were compared to samples which were physically fractionated in the field after the Deepwater Horizon oil spill. Seawater and oil and seawater, oil, and dispersant mixtures were generated in the laboratory and then sampled. A whole, unfractionated sample was collected as were samples separated into particulate and dissolved fractions using two methods employed on ships during the field program. Alkanes and PAHs were measured in the dissolved and particulate fractions and corresponding unfractionated samples. Tested methods include the modified Payne filtration method (Payne et al. 1999) which uses a glass fiber filter to capture particles and direct analysis of the dissolved fraction in the filtrate and the Large Volume Sampler which utilizes a vortex separator and 0.45 µm filters for particulate analysis and sorption to a PUF cartridge to determine the dissolved concentrations. Results showed that an excellent mass balance in the experimental system (i.e., we could account for 100% of the material when comparing whole, unfractionated water samples to the sum of the fractions in the processed aliquot of the same sample). Reproducibility was good within each method though the composition of the fractions trapped by the filter (droplet) and passed through the filter ("dissolved") varied somewhat owing to differences in filter sizes. In no case did the "dissolved fraction" resemble the water soluble fraction generated using standard WAF procedures. The analytical results were used to develop a method to calculate particulate concentrations from unfractionated water samples based on constant oil composition and minimally soluble individual oil components.

214 Rapid Biodegradation of Aromatic and Saturated Hydrocarbons Associated with MC252 Oil in the Water Column and on the Shorelines of the Gulf of Mexico R. Atlas, Univ of Louisville, Univ of Louisville, Dept of Biology; P. Boehm, Exponent, Environmental & EcoScience Group, Exponent, Environmental Group, Exponent, Inc., Environmental & EcoScience sGroup; L. Cook, Exponent, 1 Clock Tower Place. Physical and chemical dispersion of the MC252 oil released into the Gulf of Mexico between April 20 and July 15, 2010 resulted in detection of fine droplets at approximately 1100-1300 meters that generally moved in a southwesterly direction while larger droplets moved to the surface and formed a slick, with some of the oil moving northward and eastward to shorelines. Evidence for the biodegradation of the oil comes from detailed chemistry measurements using GC-MS analyses. These analyses showed a decreasing ratio of C17/pristane and C18/phytane as the oil moved away from the wellhead at 1100-1300 meters. Analyses based upon ratios of phenanthrenes and dibenzothiophenes and on ratios of high molecular weight aromatics and aliphatics to the conserved hopane confirmed extensive biodegradation of the aliphatic and polycyclic aromatic hydrocarbons in the deep sea. The extent of measured biodegradation was higher in the deep sea than in surface oil slicks where higher oil concentrations and lower surface area may have limited rates of biodegradation. Oil that spread out on shorelines also showed evidence of extensive biodegradation. The indigenous microorganisms were well-adapted to oil biodegradation. Microbial biodegradation of the oil removed many of the toxic components and reduced the overall impact of the oil released from the well.

215 Microbial Gene Functions Enriched in the Deepwater Horizon Deep Sea Oil Plume J. Zhou, Univ of Oklahoma. The Deepwater Horizon oil spill in the Gulf of Mexico is the deepest and largest offshore spill in US history and its impacts on marine ecosystems are largely unknown. Here, we used GeoChip-based high throughput metagenomic technology to show that the microbial community functional composition and structure were dramatically altered in a deep-sea oil plume resulting from the spill. GeoChip 4.0 contains more than 135,000 probes from 152,000 genes involved in C, N, S and P cycling, organic contaminant degradation, metal resistance, antibiotic resistance, stress responses, metal resistance, virulence, bacterial phage-mediated lysis, and soil beneficial microorganisms. A variety of metabolic genes involved in both aerobic and anaerobic hydrocarbon degradation were highly enriched in the plume compared to outside the plume, indicating a great potential for *intrinsic* bioremediation in the deep-sea. Various other microbial functional genes relevant to carbon, nitrogen, phosphorus, sulfur and iron cycling, stress responses, metal resistance, and bacteriophage replication were also enriched in the plume. Together, these results suggest that the indigenous marine microbial communities were capable of adaptation and succession in response to the oil spill and they could play a significant role in biodegradation of oil spills in deep-sea environments.

216 Surface Dispersion and Biodegradation of the Macondo MC252 Crude Oil P.S. Daling, SINTEF,, Marine Environment Technology.; O.G. Brakstad, SINTEF; F. Leirvik, SINTEF, Materials and Chemistry, Marine Environmental technology. At the Pencacola Seatac meeting in April, 2011, a weathering study was performed, including a weathering experiments in the SINTEF flume, where a high degree of natural dispersion were observed within 12 hours when the fresh released oil was exposed to simulated breaking wave sea conditions. Two series of follow-up experiments have recently been performed in the SINTEF flume weathering basin in order to get more detailed measurements of the droplet size distribution generated from the surfacing oil both due to natural dispersion under breaking wave conditions, and chemically enhanced dispersions by using low dosages of Corexit 9500. A LISST-100X Laser Particle Sizer, a particle visual microscope (PVM) and a high resolution camera were use for documenting the droplet size distribution. The oil loading used in the flume experiments were reflecting a" realistic" dispersed oil concentrations (20 – 100 ppm) that can be obtained in the upper meter of the surface water column in the field short time after a re-dispersion of the surface oil slick. Physically and chemically dispersed

flume experiment samples were collected for studies of dispersed oil biodegradation. Samples were distributed into closed vials and incubated for a period up to 2 months at the relevant GoM sea surface temperatures (30-32 oC) with continuous agitation. The samples were removed for analyses at pre-defined intervals. Some samples were used as "abiotic" controls by addition of biocide (HgCl2). The biodegradability of various oil components (alkanes, aromatics, iso-prenoides) were determined by comparing the result from biotic versus the abiotic samples using GC-FID and GC-MS. In addition, the biodegradability of 10-20 µm thick oil films (also representative for "metallic" oil films) immobilized on hydrophobic absorbents were examined in closed vials with normal pre-conditioned (30-32°C)seawater and with a biodegradation period of up to 28 days. Fabrics with immobilised oil in sterile seawater were used as controls (seawater poisoned with HgCl2). Fabrics were removed for analyses at pre-defined intervals for oil extraction and analyses by GC-FID and GC-MS. Biodegradation was determined by comparison of results from biotic samples and abiotic controls and also compared to previous similar experiment with other crude oils under other (North Sea) environmental conditions. The results from this surface dispersion and biodegradation study will be presented.

217 Natural Oil and Gas Seeps and Oil Slicks in the Mississippi Canyon Protraction Area: Origins and Historical Baseline before the DWH Incident P.D. Carragher, BP GUlf Coast Restoration Organization, Science, Technology, Environmental and Regulatory Affairs; A. Kornacki, Weatherford , BP GCRO, 1315 West Brooklake; C. Scherschel, BP, BP, 1315 West Brooklake; R. Frost, BP, Upstream Technology, 1315 West Brooklake. Oil and gas seepage is a pervasive occurrence in the Gulf of Mexico that has existed for many millions of years. This paper will trace the transport of hydrocarbons from deep in the earth to the sediment water interface, and then to their ultimate fate as a natural surface slick is weathered. Seep data obtained from before the DWH oil spill will be reviewed to provide a view of the baseline or naturally existing system. With the advent of deepwater exploration, data exists that enables us to establish the geological origin of the petroleum in natural seeps that forms at depths of greater than 15,000ft below the surface; track the oil and gas migration to the seabed, often along the sides of salt domes; map and visualize the expression of the seeps in the shallow sediments and at the sea floor; and, in the case of gas seeps in particular, document their rise through the water column. Naturally occurring surface oil slicks are detectable by satellite and other remote sensing capabilities. Carbonate hardgrounds of biological origin are formed by, and sustained for periods of time by seeping hydrocarbons. Other fauna anchor on these hardgrounds and build complex and diverse deepwater communities. Sediments in the vicinity of natural seeps contain complex mixtures that may include some or all of the following components; – fresh oil, biodegraded oil, hydrocarbon gases of thermal and/or microbial origin, and recent organic matter. Quantitative methods that separate the relative contribution of these components have been applied to more than a hundred deep water sediment samples that pre-date the DWH incident. Preliminary interpretation of these data will be presented. Natural seepage may be continuous or occur in a series of geyser-like eruptions, and over time this episodic process creates a variety of seabed craters and other features. Preliminary results of an AUV survey covering an area of natural seeps will be presented to illustrate these conditions. Naturally occurring surface oil slicks are present on the surface of the sea in the vicinity of the Mississippi Canyon Protraction area. Preliminary results from a satellite based study documenting the location, size and area of these natural slicks will be presented, along with examples of the tie to natural seepage on the seafloor and the deep subsurface origin. Supporting material will be presented in the accompanying posters.

218 Introduction of a Quantitative Label-free, Non-gel Based Proteomic Method for Use in Aquatic Ecotoxicological Study of Small Fish Species K. Ralston-Hooper, Visiting Dupont Research Scientist at Duke Univ, Nicholas School of the Environment ; R. Hoke, DuPont, Haskell Global Centers; D.L. Villeneuve, USEPA, Mid-Continent Ecology Division; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; M. Turner, E. Soderblum, A. Moseley, Proteomics Core Facility, Institute for Genome Science & Policy, Depts of Cell Biology, Medicine, and Neurobiology, Duke Univ Medical Center; L. Ferguson, Duke Univ, Dept of Civil and Environmental Engineering, Duke Univ, Nicholas School of the Environment , Pratt School of Engineering, Dept of Civil & Envionmental Engineering. Two-dimensional electrophoresis remains one of the most exploited techniques for protein separation but significant limitations are associated with this gel-based method. This particular technique remains cumbersome, time consuming, and results in the identification of a small number of proteins (30-50% of proteome). A non-gel, label-free, high throughput technique could facilitate the realization of the full potential of proteomics in ecotoxicology. Our goal is to apply an open, unbiased, label free, non-gel based proteomics technique to determine differentially expressed proteins in the fathead minnows (FHM), *Pimephales promelas*. Initial research has demonstrated that proteins were successfully extracted, digested, and analyzed using ultra pressure liquid chromatography coupled with mass spectrometry followed by spectral search against NCBI Actinopterrygii (ray-finned fishes) database. The number of unique proteins in brain, gonad, and liver samples were 159, 155, and 167, respectively. Many of these proteins were associated with metabolic and cellular processes. This method was then applied to examine differential proteomic profiles of FHM exposed to the potent antiestrogen, Fadrozole (FAD), at concentrations of 0, 0.04, and 1 µg/L. Liver tissues of exposed organisms were extracted, digested, and analyzed. These differentially expressed proteins provide valuable insight into how endocrine disrupting compounds (EDC) perturb the CYP pathway resulting in adverse effects. The overall goal of this project is to serve as a "proof-of-concept" evaluation of ecotoxicologically-relevant tissues using a label-free, non-gel based proteomics method. This high throughput proteomics technique coupled with other "omic" technologies will provide a systems biology approach to examine mechanism of action of environmental contaminants.

219 Leveraging Semantic Integration of Web and Experimental Resources in Interpreting Toxicology Data M.M. Hindle, A. Riazanov, Univ of New Brunswick, Dept of Computer Science & Applied Statistics; C.J. Martyniuk, Univ of New Brunswick, Canadian Rivers Institute and Dept of Biology; C.J. Baker, Univ of New Brunswick. In order to interpret experimental omics data, toxicologists are faced with a bewildering array of disconnected bioinformatics databases and tools. For example, tools for microarray analysis, gene annotation, functional gene set enrichment, and network analysis. Drawing together web tools and resources is frequently an unnecessary and frustrating technical exercise in identifying links across database records and the connecting input and output formats of tools. Interpreting experimental omics data in the context of the current available knowledge and methodologies from a single query platform with explicit semantics would be a valuable asset for ecotoxicology in the analysis of their DNA, transcriptomics, proteomic, and metabolomic experimental data. We have created 30+ SADI semantic web services, resources and tools pertinent to the interpretation of omics toxicological data. These services expose a wide range of algorithms, domains and databases: sequence alignment and protein domain finding tools (e.g., BLAST, HMMR3, and InterProScan), databases containing experimentally validated protein functions (e.g., ZFIN and MGI), and central repositories of sequence and microarray data (e.g., GEO and NCBI-RefSeq). All these services can be leveraged through queries submitted to a SHARE web client. This paradigm provides a single access-point on the web for a toxicologist to submit semantically rich queries, which are answered using appropriate databases and tools. This frees the toxicologist from learning unnecessary details concerning tool interfaces, and the semantic idiosyncrasies of databases. It also has the potential to reveal otherwise hidden links between experimental data and is readily scalable to high throughput omics data. We present a series of exemplar queries for toxicology, which facilitate the interpretation of transcriptomics data in the context of public knowledge and current tools. These queries include common tasks, specific to a user's experimental data set, such as the annotation of probes with the gene ontology for a custom fish microarray experiment. The example queries also address broader open-world queries, such as the impact of a toxicant on the transcriptome, which is based on evidence in published data. These queries demonstrate how a toxicologist can use semantic web services to better understand their data using the most recent public knowledge, and view their results in the context of other published experimental results.

220 Metabolomic Insights into Thyroid Hormone Action and Disruption C. Helbing, Univ of Victoria, Dept of Biochemistry & Microbiology; M. Lesperance, L. Lu, Univ of Victoria; J. Han, C. Borchers, UVic-Genome BC Proteomics Centre; R. Ng, M. Takhar, Univ of British Columbia; N. Veldhoen, Univ of Victoria; R.C. Skirrow, G. van Aggelen, Pacific Environmental Sciences Centre, Environment Canada. Frog tadpoles require

appropriate thyroid hormone signalling to undergo metamorphosis into a froglet. Exogenous administration of thyroid hormones to young tadpoles induces a precocious metamorphosis and substances that alter thyroid hormone action will impact this postembryonic developmental process. Very little is known about serum-associated metabolites within the tadpole that change in response to thyroid hormone and identification of key metabolites could serve as effective biomarkers for thyroid hormone disruption. We injected premetamorphic *Rana catesbeiana* (American bullfrog) tadpoles with 10 nM 3,5,3'-triiodothyronine in the presence and absence of exposure to nanosilver and analyzed the serum metabolites after 2 days post-injection. Serum metabolites were liquid/liquid extracted into organic and aqueous phases following protein precipitation and analysed using direct infusion-Fourier transform ion cyclotron resonance mass spectrometry (DI-FTICR MS). The same samples were also examined with ultra performance liquid chromatography (UPLC) –MS using BEH C-8 and HSS-T3 columns. Metabolites were ionized by electrospray and detected in both positive-ion and negative-ion modes. We identified over 10,000 metabolite features with both techniques. Metabolites identified in lipid metabolism, bile acid synthesis, and nucleotide metabolism were found to be differentially present using nonparametric and correspondence analyses, suggesting that these pathways are important targets for thyroid hormone action. The utility of a serum metabolite approach for the detection of thyroid hormone disruption will be discussed.

221 Assessment of the Relative Contribution of Wastewater Treatment Plant Effluents to the Adverse Impacts on Fish Health – A Genomic Approach D. Martinovic-Weigelt, Univ of St. Thomas, Dept of Biology, USEPA, Mid-Continent Ecology Division, Mid-Continent Ecology Division, Univ of St. Thomas, Biology; A. Mehinto, Univ of Florida; J. Miller, St. Cloud State Univ, Biosciences, St. Cloud State Univ; N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology; H. Schoenfuss, St. Cloud State Univ, Aquatic Toxicology Laboratory, St. Cloud State Univ, Dept of Biological Sciences MS-273 The effects of wastewater treatment plant (WWTP) effluents on fish were studied at three locations, selected to represent a variety of treatment technologies, population sizes and geographic distributions. At each location, a mobile exposure laboratory trailer was set up to conduct 48-hr exposures of male fathead minnows to the wastewater effluent, and upstream and downstream receiving waters. Following the exposures we analyzed gene expression in the livers using a 15,000 gene microarray developed specifically for fathead minnows. Gene expression in fish was altered when they were exposed to WWTP effluents or to the surface water collected either upstream or downstream of WWTPs. One of the prominent observations made in the microarray study was that all the effluents had an effect on genes that regulate iron metabolism and immune responses in fish. Overall, WWTP effluents had an effect on gene expression that was more similar to downstream sites than to upstream sites, suggesting a detectable effluent signature at all of the downstream sites. These findings suggest that WWTPs are an important contributor to aquatic pollution, and that they have potential to adversely impact multiple physiological pathways important for an organism's fitness (immune system functioning, reproductive success and aerobic metabolism), which is consistent with the complex composition of WWTP effluents. We are currently integrating the results of this study with longer term exposures (4, 8, 14 d), conducted at the same locations, in an attempt to determine if the observed effects on gene expression can be related to the apical endpoint effects (e.g., histopathology, reproductive health, plasma vitellogenin, and secondary sex characteristics).

222 Histaminergic Signaling in the Central Nervous System of *Daphnia* and a Role for it in the Control of Phototactic Behavior M. McCoole, The Univ of Louisiana at Monroe, Dept of Toxicology; K. Baer, The Univ of Louisiana at Monroe, College of Pharmacy; A. Christie, Mount Desert Island Biological Laboratory. *Daphnia magna* and *Daphnia pulex* are well-established model organisms in the fields of ecotoxicology and toxicogenomics. Among the many assays used for determining the effects of environmental and anthropogenic stressors on these animals is monitoring for changes in their phototactic behavior. In most arthropods, histamine has been shown to play a key role in the visual system. Currently, nothing is known about histaminergic signaling in either *D. magna* or *D. pulex*. Here, a combination of immunohistochemistry and genome mining was used to identify and characterize the histaminergic systems in these daphnids. In addition, a behavioral assay was used to assess the role of histamine in their phototactic response to ultraviolet (UV) light exposure. An extensive network of histaminergic somata, axons and neuropil was identified via immunohistochemistry within the central nervous system of both daphnids, including labeling of putative photoreceptors in the compound eye and projections from these cells to the brain. Mining of the *D. pulex* genome using known *Drosophila melanogaster* proteins identified a putative ortholog of histidine decarboxylase (the rate-limiting biosynthetic enzyme for histamine), as well as two putative histamine-gated chloride channels (hclA and hclB orthologs). Exposure of *D. magna* to cimetidine, an H_2 receptor antagonist known to block both hclA and hclB in *D. melanogaster*, inhibited their negative phototactic response to UV exposure in a reversible, time-dependent manner. Taken collectively, our results show that an extensive histaminergic system is present in *Daphnia* species, including the visual system, and that this amine is involved in the control of phototaxis in these animals.

223 Metabolite Profiling and Receptor Binding Assay Provide Direct Physiological Evidence of Androgen Receptor Antagonism by Bisphenol A in Fish D. Ekman, USEPA, National Exposure Research Laboratory; P. Hartig, M. Cardon, T. Collette, E. Durhan, E. Gray, K. Jensen, M. Kahl, Q. Teng, D. Villeneuve, G. Ankley, USEPA. Widespread environmental contamination by bisphenol A (BPA) has created the need to fully define the mode(s) of action (MOA) of this pollutant in order to properly assess risk. Long recognized as an estrogen receptor (ER) agonist, BPA has recently also been suggested as having androgen receptor (AR) antagonistic properties. However, direct physiological evidence of this activity has not yet been established. In order to address this deficiency, we employed a metabolomic approach using in vivo exposures of fathead minnows (FHM) to BPA either alone or in co-exposure with 17b-trenbolone (TB), a strong AR agonist. Changes in liver metabolite profiles in female FHM in response to these exposures were determined using high resolution ^{1}H-NMR spectroscopy and multivariate and univariate statistics. Using this approach, we observed direct evidence of the ability of BPA to mitigate the impact of TB exposure, consistent with an anti-androgenic mode of action. In addition, urinary metabolite profiles in male FHM exposed to BPA revealed signatures similar to those produced by exposure to the recognized antiandrogens vinclozolin and cyproterone acetate. Finally, an in vitro transcriptional activation assay was used to confirm the AR antagonistic activity of BPA to the FHM AR. The results of these varied analyses (both in vivo and in vitro) provide several strong lines of evidence for ascribing an anti-androgenic MOA to BPA in addition to the established ER agonism.

224 Effects of Bisphenol A on the Ovarian Transcriptome of Two Small Fish Species D.L. Villeneuve, USEPA, Mid-Continent Ecology Division; N. Garcia-Reyero, Jackson State Univ, Dept of Chemistry; L. Escalon, US Army Engineer Research and Development Center, Environmental Laboratory; K.M. Jensen, USEPA, Mid-Continent Ecology Division; J. Cavallin, USEPA; E. Makynen, E. Durhan, M. Kahl, L. Thomas, USEPA, Mid-Continent Ecology Division; E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Us Army Engineering Research & Development, Environmental Processes & Effect Division; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division. Bisphenol A (BPA) is a high production volume chemical widely used in the manufacture of polycarbonate plastics, epoxy resins, and many other commercial products. BPA has long been characterized as a xenoestrogen, and recent work suggests potential additional modes of endocrine action. To improve our understanding of the potency and diversity of BPA's effects at the molecular level, effects of the chemical on ovarian transcript profiles as well as targeted endpoints with endocrine/reproductive relevance were examined in two fish species, fathead minnow (*Pimephales promelas*) and zebrafish (*Danio rerio*), exposed in parallel using matched experimental designs. Four days of waterborne exposure to 10 μg BPA/L caused significant vitellogenin induction in both species. However, zebrafish were less sensitive to effects on hepatic gene expression and steroid production than fathead minnow and the magnitude of vitellogenin induction was more modest. The concentration-response at the ovarian transcriptome level was non-monotonic and violated assumptions that underlie proposed methods for estimating hazard thresholds from transcriptomic results. However, the non-monotonic profile was consistent among species and there were nominal similarities in the functions associated with the differentially expressed genes, suggesting potential activation of common pathway perturbation motifs in both species. Overall, the results

provide an effective case study for considering the potential application of ecotoxicogenomics to ecological risk assessments and provide novel comparative data regarding effects of BPA in fish. The contents of this abstract neither constitute nor reflect official USEPA policy.

225 eMICE 2011 – An Environmental Metabolomics Intercomparison Exercise D. Bearden, National Institute of Standards and Technology, Analytical Chemistry Division, National Institute of Standards and Technology; M.R. Viant, J. Byrne, NERC Biomolecular Analysis Facility – Birmingham Node; A. Boroujerdi, T. Schock, National Institute of Standards and Technology, Analytical Chemistry Division. Previous results of an international intercomparison exercise for NMR-based environmental metabolomics showed that NMR metabolome analysis yields robust results with consistent trends in metabolite-based biomarker identification among laboratories. This type of demonstrated comparability strengthens confidence in the concept as the technique is considered for regulatory environmental studies. Based on the lessons learned from the first effort, a second exercise was developed, and updated data collection and processing protocols were used, together with a considerably larger number of international participants, to further investigate the comparability and suitability of NMR-based metabolomics data for environmental research, assessment and regulatory roles. The exercise design emphasizes the steps that occur after sample collection and initial sample preparation. The samples used for the exercise were a set of simplified artificial metabolite mixtures and a set of fish muscle extracts from a marine aquaculture feeding study. The data collection protocol was extended to include 2-dimensional (2D) JRES spectra and additional measurements involving temperature calibration and signal-to-noise ratios. In the end, 13 labs contributed 16 data sets from instruments operating at 4 different magnetic field strengths. Factors to be evaluated in the exercise include the final stages of sample preparation, NMR data collection at multiple NMR-field strengths, quantitative evaluation and multivariate data analysis (principal component analysis). Several data quality evaluation protocols for multivariate data sets have been utilized to assess participants' success with the exercise. This presentation will provide an analysis of the second intercomparison results.

226 Application of EPA Guidelines in a Bioavailability-based Assessment of Ambient Water Quality Criteria for Zinc D.K. DeForest, Windward Environmental LLC; E.J. Van Genderen, International Zinc Association, Assistant Manager, Environment. The United States Environmental Protection Agency's (EPA's) current ambient water quality criteria for zinc in fresh water are hardness-based and were last updated in 1995. Since then, two significant advancements have been made regarding the assessment of zinc toxicity to aquatic organisms. First, the acute and chronic ecotoxicity databases have been complemented by several new studies and taxonomic groups, thereby satisfying the EPA's minimum phylogenetic diversity requirements for chronic zinc toxicity (chronic criteria were historically derived using an acute-to-chronic ratio). Second, several acute and chronic biotic ligand models (BLMs) for zinc have been developed and validated for fish, invertebrates, and algae. Considered together, the objective of this effort was to develop a zinc BLM that could efficiently predict both acute and chronic toxicity from published studies that evaluated a wide range of water chemistries (e.g., dissolved organic carbon, pH, hardness). Although several of the published zinc BLMs demonstrated good predictions for the available datasets, a unified model was objectively generated by averaging the biotic ligand binding constants for zinc (Zn^{2+}) and competing cations (Ca^{2+}, Mg^{2+}, Na^{+}, H^{+}) from all studies. Moreover, toxicity predictions were further improved by optimizing the biotic ligand binding constant for the $ZnOH^{+}$ species. Only the critical accumulation parameter for each species/endpoint was changed during the auto-validation of each BLM (published or unified). Following selection of the optimized model, normalized species sensitivity distributions (using geometric mean critical accumulation concentrations for each species/exposure type) were constructed for eight water types for the estimation of 5th percentile effect concentrations (analogous to EPA's final acute values and final chronic values). A comparison of results from this assessment and historical criterion derivation practices will be discussed.

227 A Retrospective Analysis of Manganese in Lake Trout (*Salvelinus namaycush*) Otoliths: Links to Reproductive Failure L.C. Carroll, Univ of Manitoba, Dept of Environment and Geography, Fisheries and Oceans Canada, Freshwater Institute, Freshwater Institute, Univ of Manitoba, Environment and Geography; N. Thebeau, Ministry of Natural Resources, Red Lake District; N. Halden, Univ of Manitoba, Dept of Geological Sciences; M. Hanson, Univ of Manitoba, Dept of Environment and Geography, Univ of Manitoba, Faculty of Environment; V. Palace, Dept of Fisheries & Oceans Canada, Dept of Fisheries and Oceans. Microchemical analysis of an increasing number of trace elements in fish otoliths has become an important tool to determine environmental exposure. Over the last decade a decline in abundance of the lake trout (*Salvelinus namaycush*) population of Red Lake, Ontario has been documented, coincident with apparent recruitment failure. Since 2001 spawning assessments, surveys, and bioassays focussed on the trout's primary breeding shoals in Red Lake's Pipestone Bay have been conducted to attempt to discover the causal agent for the ongoing recruitment failure. The Red Lake area has a history of gold mining so that metals associated with this industry warrant attention. Manganese (Mn) is associated with mining, and previous water quality data from Red Lake show elevated concentrations. Mortality was also associated with Mn in an acute toxicity study performed by local authorities. An analysis of Mn in archived lake trout otoliths (1963-2008) was performed using laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). Manganese concentrations in otolith from lake trout captured from Red Lake and from two reference sites (Trout Lake and Confederation Lake) were compared to determine if temporal variations supported a role for Mn in recruitment failure. Over a ten year period Mn concentrations in otoliths obtained from the three lakes were: Pipestone bay: 0.00 – 6.61μg/g; Trout Lake: 0.00 – 4.24 μg/g; Confederation Lake: 0.00 – 10.19 μg/g. There were significant differences ($P < 0.001$) in yearly Mn concentration in all three lakes. It appears that Mn is incorporated into otoliths at low concentrations. Mn concentrations were highest in otoliths from Confederation Lake compared to the other two lakes. Even though Mn concentrations were low, peaks associated with certain time periods could be discerned. There was no mining activity directly on Red Lake or Trout Lake, however, elevated Mn concentrations were measured in otolith sections corresponding to the period between 1980 and 1990. These results do not allow Mn to be ruled out as a causal agent of lake trout recruitment failure in Red Lake.

228 Application of a Multi-metal BLM to Predict Toxicity in Metal Contaminated Sediments from the TSMD. 1 – Background, Sampling, and Analysis Methods W. Brumbaugh, US Geological Survey, Columbia Environmental Research Center; C.G. Ingersoll, USGS, Columbia Environmental Research Center; J.M. Besser, US Geological Survey, Columbia Environmental Research Center; N.E. Kemble, US Geological Survey, Columbia Environmental. Research Center, USGS – Biological Resources Division, Columbia Environmental. Research Center; D. MacDonald, MacDonald Environmental Sciences Ltd.; R. Santore, HDR|HydroQual; A. Ryan, HDR/HydroQual; P. Paquin, HDR|HydroQual. The Tri-State Mining District (TSMD) is an historic lead and zinc mining area that includes portions of Kansas, Missouri, and Oklahoma, USA. Historic mining activities in the area have resulted in contamination of surface water, groundwater, sediments, and flood plain soils by lead, zinc, and other heavy metals. As part of an advanced screening level ecological risk assessment being conducted by the US Environmental Protection Agency (USEPA), we conducted comprehensive chemical analyses and whole-sediment toxicity assessments for stream sediments collected from 76 locations within the TSMD. Sediments were analyzed for grain size, fraction of organic carbon (foc), acid-volatile sulfide (AVS), simultaneously-extracted metals (SEM), total recoverable metals, polycyclic aromatic hydrocarbons, and organochlorine compounds. Pore water, sampled by centrifugation/filtration just before onset of 28-d toxicity testing with the amphipod *Hyalella azteca* and by in situ dialysis (peepers) on days 7 and 28 during testing, was analyzed for dissolved organic carbon, major cations and anions, and trace metals. For this project, availability of high quality sediment pore water data which includes a comprehensive list of metals, as well as factors known to affect metal bioavailability allowed us to perform Biotic Ligand Model (BLM) calculations on sediment pore waters. To perform these calculations, the existing BLM was modified to allow simultaneous simulations for individual metals such as Cd, Cu, Ni, Pb, and Zn. This combined simulation allowed the model to consider chemical interactions between metals, including chemical competition for binding sites on organic and inorganic ligands. This presentation serves as an introduction to the companion presentation that describes the results of the BLM calculations.

229 Application of a Multi-Metal BLM to Predict Toxicity in Metal Contaminated Sediments from the TSMD: Pt. 2 – BLM Modeling R. Santore, A.C. Ryan, P. Paquin, HDR|HydroQual; C.G. Ingersoll, USGS, Columbia Environmental Research Center; W. Brumbaugh, J.M. Besser, US Geological Survey, Columbia Environmental Research Center; N.E. Kemble, US Geological Survey, Columbia Environmental. Research Center, USGS – Biological Resources Division, Columbia Environmental. Research Center; D. MacDonald, MacDonald Environmental Sciences Ltd. A variety of methods are available for estimating potential risks associated with metals in sediments, including empirically based guidelines (e.g., TECs and PECs) for total concentrations in bulk sediments, and comparison of mechanistically based guides (e.g., SEM and AVS) with or without consideration of sediment organic matter. When pore-water metal concentrations and general water chemistry is available, comparisons against water quality criteria are possible according to equilibrium partitioning theory. For this project, 76 sediment samples collected across a gradient of metal contamination from the Tristate Mining District in Missouri, Kansas and Oklahoma were evaluated using 28-d whole-sediment toxicity tests with the amphipod *Hyalella*. Sediments were characterized with high quality sediment pore-water data and whole-sediment data including a comprehensive list of metals, as well as factors known to affect metal bioavailability (Brumbaugh et al.), which allowed us to perform Biotic Ligand Model (BLM) calculations on sediment pore waters . To perform these calculations, the existing BLM was modified to allow simultaneous simulations for metals including Cd, Cu, Ni, Pb, and Zn. This combined simulation allowed the model to consider chemical interactions between metals, including chemical competition for binding sites on organic and inorganic ligands. Interactions between metals on biotic ligand sites were also incorporated. For these samples, BLM results indicated that observed toxicity was most likely to be associated with Cd, Pb, and Zn. Since these metals are all associated with inhibition of calcium ion uptake, the assumption in the multiple-metal BLM is that their interactions occur on the same biotic ligand site, and their effects are additive. In general, the BLM running all metals simultaneously and considering Cd, Pb, and Zn effects in a dose-additive way produced a better comparison with observed toxicity than the BLM with any one metal alone. Performance of the BLM for identifying which samples were toxic was compared with other sediment screening methods such as the use of TECs, PECs, and SEM-AVS and was generally more accurate in differentiating sediments where toxicity to *Hyalella azteca* was observed.

230 Metal Classification Using a Unit World Model: Assessing Removal Rates from the Water Column and Remobilization from Sediment with Ticket-UWM K.J. Rader, Mutch Associates, LLC, Manhattan College, Civil and Environmental Engineering; R.F. Carbonaro, Manhattan College, Civil and Environmental Engineering, Manhattan College, Dept of Civil and Environmental Engineering; K.J. Farley, Manhattan College, Civil and Environmental Engineering, Manhattan College, Civil & Environmental Engineering. In the European Union, regulations pertaining to Classification, Labeling, and Packaging (CLP) of chemical substances/mixtures follow the United Nations Globally Harmonized System (UN GHS). Recently, an update to the classification system for metals and sparingly soluble metal compounds (SSMC) has been proposed that includes a new paradigm for long-term aquatic hazard assessment. Included in the update is a provision for demonstrating removal from the water column to assess the "persistence" of metals. In analogy to organic chemicals, removal of the "persistent" classification for metals requires greater than 70% removal within 28 days. However, unlike organic chemicals where removal from the water column can occur via degradation, metal removal occurs through sorption/precipitation and sedimentation processes which transfer metal to the sediment. Therefore, removal of the "persistent" classification for metals requires one to demonstrate not only rapid removal from the water column, but also limited remobilization potential from sediment. A unit world model for metals in lakes, TICKET-UWM, has been developed that builds on screening-level hazard assessment calculations for organic chemicals. This model considers key processes affecting metal transport, fate, and toxicity—several of which are unique to metals. These include complexation by aqueous ligands such as dissolved organic carbon (DOC), adsorption to particulate phases such as particulate organic carbon (POC) and iron/manganese oxides, binding to biological receptors (biotic ligands), dissolution kinetics of metal powders, cycling of organic matter and sulfide production in lakes, and transport of dissolved metals and solids between the water column and sediment. To assess its use as a screening-level aquatic hazard assessment tool, the TICKET-UWM was used to simulate removal rates of several metals including Cu, Ni, Zn, and Pb from the water column of a generalized lake system and from actual lakes. In general, both model-predicted and observed removals exceeded 70% in 28 days. The TICKET-UWM was able to reproduce observed water column copper dynamics reasonably well. Remobilization assessments suggest that feedback from the sediment for single dose events has a generally limited impact on water column concentrations. Metal precipitation with sulfide in sediment is important for sequestering metals and preventing loss to the water column via diffusive fluxes.

231 The Use of Biotic Ligand Models in Environmental Risk Assessments: An European Perspective P. Van Sprang, ARCHE. Recently EU risk assessment reports on copper, nickel and zinc has been finalized and adopted. In the environmental effects assessment chapter chronic toxicity data for different trophic levels have been compiled and thoroughly screened for the derivation of the species sensitivity distribution (SSD). Safe threshold concentrations are subsequently calculated as the lower 5th percentile of the SSD. In addition, for all metals mentioned bioavailability corrections using chronic Biotic Ligand Models (BLM) were used to normalize the chronic effects data of the SSDs for different selected EU water conditions at both the local and regional scale and compared with monitoring data of dissolved metal. This presentation aims at providing an overview of the approaches used in Europe for a tiered bioavailability correction for the metals Cu, Ni and Zn. The differences in strategy used between the EU and US for the development and validation of BLM will be highlighted. Furthermore the presentation will focus on the predictability and applicability of the BLMs towards different surface water conditions and for different species. Finally, the incorporation of the bioavailability correction into the EU regulatory context will be presented.

232 The Use of Multi-Linear Regression to Derive Site-Specific Water Quality Criteria for Metals: A Complementary Approach to the Biotic Ligand Model K.V. Brix, Univ of Miami, RSMAS, Marine Biology and Fisheries; D.K. DeForest, Windward Environmental LLC; L.M. Tear, Windward Environmental; A.C. Ryan, HDR|HydroQual; M. Grosell, Univ of Miami, RSMAS; W.J. Adams, Rio Tinto, Product Stewardship. Over the past 15 years there has been a concerted effort to develop Biotic Ligand Models (BLMs) for the derivation of site-specific US-based Water Quality Criteria (WQC) or European Environmental Quality Standards (EQS) for metals. BLMs are now available for a range of metals and are widely applied in ecological risk assessments. In Europe, both regional and national water quality criteria are under development that will incorporate BLMs, and in North America the USEPA has promulgated a BLM-based WQC for Cu in freshwater. Despite its availability, to date, no state in the US has adopted this new criterion into its numeric standards. There are likely a number of reasons for this, but the perception that the BLM is too complicated is frequently cited as a reason for lack of adoption at the state level and the USEPA has postponed development of BLM-based WQC for other metals as a result. To address this issue, we developed a complementary approach to the BLM, which begins by using the BLM framework to identify key water quality parameters influencing metal toxicity. These key parameters are then used to develop simple multi-linear regression (MLR) models that predict metal toxicity on a species-specific basis. Regressions from species-specific MLRs are then pooled in a manner analogous to the pooling of slopes used in previous US-based hardness-dependent WQC. The resulting final criteria equations are equivalent in form with hardness-dependent WQC equations, but with one or two additional terms (typically dissolved organic carbon and pH). Comparison of MLR-based versus BLM-based WQC for Cu, Ni, Pb, and Zn indicates MLR performance is comparable to the BLM. We suggest that this MLR-based approach, which includes a mechanistic foundation like the BLM, but requires less input data and has an output that is similar to the widely acceptable hardness-dependent WQC, may be more amenable to adoption at the state level.

233 Transformation/Dissolution Studies on Tungsten Metal and Compounds, with Speciation of the T/D Solutions J.M. Skeaff, D.J. Hardy, CANMET-MMSL, Natural Resources Canada. Speciation is held to be a key factor in controlling the ecotoxicity of metals in solution. We have applied the UN Transformation/Dissolution Protocol (T/DP) for Metals and Sparingly Soluble Metal Compounds to examine the T/D characteristics of W metal and several W compounds at pH 6 and 8.5 at loadings of 1, 10 and 100 mg/L: sodium tungstate, Na2WO4.2H2O; yellow tungsten

trioxide, WO3; three samples of tungsten carbides, WC; tungsten metal, W; ammonium paratungstate (APT), (NH4)10(H2W12O42).4H2O; ammonium metatungstate (AMT), (NH4)6(H2W12O40).6H2O, and blue tungsten oxide, WOx (x assumed to be 2.9). All presented a degree of reactivity with the aqueous media in terms of total dissolved W and the WO42- anion. The generally good agreement between the concentrations of total dissolved W and the WO42- anion suggested that all dissolved W existed primarily in the form of the WO42- anion. Based on the percentage of W in the compound dissolved at 28 days and 1 mg/L loadings, the solubility rankings are: Na2WO4.2H2O ~ (NH4)10(H2W12O42).4H2O ~ (NH4)6(H2W12O42).4H2O > WO3 > WOx > W metal > WC For the tungsten carbides at pH 6, we were able to develop a regression correlation of seven-day WO42- concentrations to surface area loading: log (WO42-, micro g/L) = -2.2388 + log 1.0287 log (A, mm2/L) (n = 27; r2 = 0.987) in which A is the measured surface area loading of tungsten carbide. We provide worked examples of how the T/D data could be used to derive hazard classification outcomes for these W compounds and metal. The T/D data enable producers to submit these classification outcomes to regulatory agencies to ensure compliance with environmental protection measures.

234 Timing and Mechanism of Cell Death Induction and Alteration of Thymocyte Development upon Exposure to DES and Methoxychlor Metabolite, HPTE C. Broussard, The Univ of La Verne, Univ of La Verne, Biology, Univ of La Verne, Professor of Biology; F. Mourad, The Univ of La Verne; P. Escalante, The Univ of La Verne, Biology; H. Johnson, D. Sortillon, C. Broussard, K. Pierce, The Univ of La Verne. Endocrine disrupting chemicals (EDCs) include a class of molecules that act as agonists or antagonists of the estrogen receptor or other hormone receptors. High production volume EDCs like pesticides and chemicals such as bisphenol A find their way back into the environment after their intended use. The prevalence of these chemicals poses a risk to aquatic and terrestrial organisms. Perhaps the most vulnerable populations are developing embryos, as events that occur during development can have long term consequences for the resulting adult organism. Studies in the last ten years have indicated that EDCs not only alter the reproductive system, the brain, and behavior, but may also impact immune responsiveness. We were interested in probing the mechanism of action of EDCs on the development of the immune system. Previously, we investigated the effects of diethylstilbestrol (DES) and hydroxyphenyltrichloroethane (HPTE) on embryonic thymocyte development and found that both appear to induce cell death and alteration of differentiation. Here we report on a recent investigation of the timing and mechanism of DES- and HPTE-induced immune effects in an in vitro thymocyte differentiation assay. In the current study, thymocyte apoptosis was probed using Annexin V and PI staining, as well as a chromatin condensation assay, in cultures established with varied periods of exposure to EDCs. The signaling status of thymocytes was probed by CD5 surface staining. Results indicate a short exposure duration for induction of apoptotic effects and possible selective targeting of thymocyte populations for death. This research is supported by NIEHS ES017345-01. The opinions expressed in this work are solely the authors'.

235 Associations of Perfluorochemicals (PFCs) with Immune, Biochemical and Hematological Parameters in Bottlenose Dolphins P. Fair, NOAA, National Ocean Service; T. Romano, Mystic Aquarium; T. Hulsey, Medical Univ of South Carolina; J.S. Reif, Colorado State Univ, Dept of Environmental and Radiological Health Sciences, College of Veterinary Medicine and Biomedical Sciences; G.D. Bossart, Georgia Aquarium; J. Adams, NOAA, National Marine Fisheries Service; M. Houde, Environment Canada; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, National Water Research Institute; C.D. Rice, Clemson Univ; A. Schaefer, Harbor Branch Oceanographic Institution at Florida Atlantic Univ; P.M. Margie, Univ of Las Vegas. Despite the widespread occurrence of perfluorochemicals (PFCs), very little is known regarding the impact of these contaminants on the health of wildlife populations. This study, therefore, investigated the relationship between PFCs and health/immune parameters in two populations of Atlantic bottlenose dolphins. A repeated cross-sectional comprehensive health assessment study was conducted during the summers of 2003-2005 near Charleston, SC (CHS; n=80) and the Indian River Lagoon, FL (IRL; n=82). Correlative data analysis stratified by site examined relationships between PFC levels in serum and immune, biochemical and hematology parameters. Significant relationships between immunological measures were observed with ∑PFC, as well as individual PFCs including PFOS. B cell proliferation and numbers of CD2+, CD4+, CD19+, CD21 and MHCII+ cells were positively correlated with PFC levels in CHS dolphins. Similar results were observed for IRL dolphins with two of these parameters: B cell proliferation and numbers of CD21+ cells. PFC levels were also positively associated with lymphocyte numbers, CPK, ALP, cholesterol, TIBC, iron, and triglycerides and negatively with eosinophils in CHS dolphins. ALT, ALP, BUN, BUN/creatine, Ca, CPK, and LDH were positively correlated with PFC levels in IRL dolphins. Serum proteins exhibited negative relationships with PFC concentrations. The number of significant associations with PFCs and the strength of these relationships were higher in CHS dolphins likely corresponding with their higher PFC concentrations. Bioaccumulation of PFC contaminants in dolphins may modulate immune responses and alter hematological and serum analytes and pose a threat to the health and viability of these populations.

236 Immunotoxic Effects of Persistent Organic Pollutant Exposure on Juvenile Northern Leopard Frogs (*Lithobates pipiens*) T.L. Cary, Univ of WI – Madison, Forest and Wildlife Ecology, Univ of WI-Madison, Zoology, Univ of WI-Madison, Forest and Wildlife Ecology; Y. Tsai, Univ of Wisconsin, Forest and Wildlife Ecology; W.H. Karasov, Univ of WI – Madison, Forest and Wildlife Ecology. Immunotoxicology is an emerging field and has the potential to increase knowledge regarding sublethal toxicity of contaminant exposure, including alterations in disease susceptibility. Worldwide presence of persistent organic pollutants such as polybrominated diphenyl ethers (PBDE) and polychlorinated biphenyls (PCB) have prompted increased interest in studying the potential immunotoxicity of these compounds. We conducted a dietary tadpole exposure study in order to assess how environmentally relevant levels of PBDEs impact the immune function of post-metamorphic frogs. Beginning at the free-swimming stage, *Lithobates (Rana) pipiens* tadpoles were exposed to DE-71, a pentabromodiphenyl ether mixture, at environmentally relevant levels (0, 1.0, 6.1, 71.4, 634 ng/g) through metamorphic climax. To assess how DE-71 exposure affects the adaptive immune response, we used an enzyme-linked immunosorbent assay (ELISA) to measure specific-IgY production in post-metamorphic frogs following immunization with keyhole limpet hemocyanin (KLH). Additionally, a similar ELISA method was used to determine total antibody production of both IgY and IgM isotypes. DE-71-exposed frogs had decreased secondary antibody response to KLH compared to unexposed frogs ($p = 0.024$), however, total IgY and IgM antibody production were not altered by PBDE exposure ($p = 0.355$ and 0.328, respectively). These findings lend evidence that larval exposure to PBDEs may influence specific antibody production in juvenile *L. pipiens*, but may not affect circulating levels of non-specific antibodies. To further analyze how persistent organic contaminants influence immune function in amphibians, we are currently conducting a dietary exposure to PCB-126, a known immune suppresor in other taxa. These results will be forthcoming, and discussed in comparison with the effects of DE-71 exposure.

237 Epizootic Shell Disease in American Lobsters from Long Island Sound Associated with Reduced Immunecompetancy and not Contaminant Exposure A. McElroy, Stony Brook Univ, School of Marine and Atmospheric Sciences; M. Homerding, Skokomish Tribe; G. Taylor, B. Allam, Stony Brook Univ, School of Marine and Atmospheric Sciences. Epizootic Shell Disease (ESC) is known to affect American lobsters (*Homarus americanus*) along the northeast coast of the US Forming erosional pits in the exoskeleton, ESD decreases the economic value of the lobster catch and in extreme cases can be lethal. First documented in 1997 in the waters off southern Rhode Island, prevalence and geographic distribution of disease incidence seems to be expanding. In New York waters, prevalence exceeds 20% of individuals in Eastern Long Island Sound (ELIS), but is barely detectable in the more contaminated waters of Western Long Island Sound (WLIS). As part of a larger consortium of researchers investigating the etiology of ESD in New England, we sought to assess immune capacity of lobsters with and without shell disease and the relative immune capacity of individuals from the ELIS and WLIS populations. Lobsters from Maine were also evaluated as a reference population. A large suite of defense factors were examined including: hemolymph antimicrobial activity and bacterial load, shell thickness, as well as a number of hemocyte parameters such as cell counts, phenoloxidase activity, reactive oxygen species production, and phagocytic activity. Despite high inter-individual variability in defense-related factors, multivariate analyses showed that lobsters from ELIS presented significantly reduced immune performance relative to lobsters from either WLIS

or Maine. Disease severity was negatively correlated with several immune parameters suggesting that the disproportionately high prevalence of ESD in ELIS may be related, at least in part, to reduced immunocompetency of ELIS lobsters. These data support the importance of evaluating multiple components of immune response when evaluating disease susceptibility, and suggest that despite significantly elevated exposure to contaminants, WLIS lobsters have developed resistance to ESD and possibly other infectious diseases. Funding was provided through RI Sea Grant and the Lobster Research Initiative.

238 Immune Response of Rainbow Trout (*Oncorhynchus mykiss*) Coexposed to Benzo[*a*]pyrene and *Aeromonas salmonicida* L.J. Phalen, N.S. Hogan, G.Z. MacDonald, K. Thorpe, M.R. Vandenheuvel, Canadian Rivers Institute, Univ of Prince Edward Island, Biology. Environmental toxicants such as polycyclic aromatic hydrocarbons (PAHs) are thought to be immunosuppressive. This study aimed to determine whether the use of four rainbow trout leukocyte-specific antibodies coupled with fluorescence assisted cell sorting analysis (FACS) could detect changes caused by the PAH benzo[*a*]pyrene (B[*a*]P) to the immune response elicited by rainbow trout in response to inactivated *Aeromonas salmonicida* (*A.s.*). Fish were exposed intraperitoneally to 2.5 or 25 mg B[*a*]P/kg BW simultaneously with formalin inactivated *A.s.* for 1, 3 or 7 days in two replicate trials. Absolute erythrocyte and leukocyte counts were measured in blood using a $DiOC_6$ staining technique coupled with FACS. Leukocytes were isolated from spleen, peritoneum, head kidney and blood, stained using fluorescently labelled antibodies to determine the proportions of B-cells, T-cells, thrombocytes and myeloid cells using FACS. Liver monoxygenase enzyme activity and fluorescent bile metabolites were used to evaluate exposure. Bile metabolites showed consistent exposure proportional to dose though there were differences in liver monoxygenase activity trends between trials. An approximate 25% decrease of the number of total leukocytes in whole blood was observed at high dose on day 7 only in Trial 1. A decrease in B-cell proportions was found at the high dose on day 3 and 7 in spleen (~10% each) and at low and high dose on day 7 in peritoneum (~16% and 21% respectively). A decrease in percentages of viable cells was found at high dose on days 3 and 7 in peritoneum (~13% and ~40% respectively) and head kidney (~4% and ~6% respectively). An approximate 26% increase in the number of myeloid cells was seen at high dose on day 7 in peritoneum. These results imply that leukocytes die at the site of injection in the peritoneum and that movement of B-cells from spleen populations could be resulting in splenic B-cell depletion.

239 Titanium Dioxide Nanoparticles Modulate Innate Immune Response and Increase Mortality of Fish Exposed to Bacterial Pathogen B. Jovanovic, Iowa State Univ, Biomedical Sciences; K. Kimura, Iowa State Univ; D. Palic, Iowa State Univ, Dept of Biomedical Sciences. Previously we have demonstrated that titanium dioxide nanoparticles (nano-TiO_2) can change function of neutrophils in fish models both in vitro and in vivo. Neutrophils are primary sentries for bacterial infection in healthy individuals, and their role is to entrap and kill the invading pathogens. Here, we investigate how fish (*Pimephales promelas*), immunocompromised by nano-TiO_2, respond to accompanying infection of *Aeromonas hydrophila* bacteria. Briefly, fish exposed to low environmentally relevant sublethal concentration of nano-TiO_2 coupled with *A. hydrophilla* infection displayed 50-90% mortality of experimental population. On the contrarily, control group exposed only to *A. hydrophilla* have only 10% mortality, while nano-TiO_2 treated group and no treatment group do not show any sign of mortality or morbidity. The results are coupled with histopathology reports and ICP-MS analysis of nano-TiO_2 distribution in fish organism with particular outline on hematopoietic organs. In conclusion, environmentally relevant concentration of manufactured nano-TiO_2 has potential to obliterate fish populations by impairing their immune response toward bacteria during possible disease outbreaks in aquatic ecosystems. This is by our knowledge the first attempt in Science to understand the interplay between nanoparticles, immune system and bacterial infection in any animal model.

240 Immuntoxicity of Atrazine and Nonylphenol in Rainbow Trout (*Oncorhynchus mykiss*): A Tale of Immune Function, Disease Challenge and Genomics L.K. Shelley, Simon Fraser Univ, PHD student; P.S. Ross, Fisheries and Oceans Canada, Institute of Ocean Sciences; K.M. Miller, K.H. Kaukinen, Fisheries and Oceans Canada, Pacific Biological Station; C.J. Kennedy, Simon Fraser Univ, Dept of Biological Sciences. Microarray technologies are increasingly being used to examine changes in gene expression in fish following exposure to either pathogens or chemicals individually, but have rarely been applied in immunotoxicological studies in which responses to both pathogen and chemical exposures are considered together. Atrazine and nonylphenol are commonly identified contaminants in aquatic habitats, however, relatively few studies have considered the potential impact of these suspected endocrine disrupters on immune function. Rainbow trout, *Oncorhynchus mykiss*, were exposed to either atrazine (555 µg/L) or 4-nonylphenol (18 µg/L) for four days, followed by a one hour immersion challenge with the bacterial pathogen Listonella anguillarum. Fish were then monitored for pathogen-related mortality for fourteen days. Blood and tissue samples taken before and after disease challenge revealed both contaminant and disease-related changes to plasma cortisol concentrations, hematocrit, leukocyte differential and spleen somatic index. In addition, 4-nonylphenol treatment increased mortality of fish three fold following the disease challenge. Liver samples from the control, atrazine and nonylphenol groups were used in 32K salmonid microarrays (cGRASP, 32K version 1) to assess genomic responses to both chemical exposure and chemical + disease challenge treatments. Results reveal significant changes in liver gene transcription following all treatments which may be related to the alterations in physiological indicators and the increase in disease susceptibility of treated fish. Overall, this study provides insight into the molecular mechanisms underlying the physiological effects of both atrazine and nonylphenol exposure in fish, with microarray technology providing considerable new insight into the immunotoxicity of contaminants in fish.

241 Assessment of Immune Gene Expression and *Trypanosoma carassii* Infection in Goldfish Exposed to Naphthenic Acids and Oil Sands Process Water M.O. Hagen, S. Mitchell, B.A. Katzenback, A. Oladiran, E. Garcia, M. Karpman, D. Beauparlant, Univ of Alberta, Biological Sciences; M. Gamal-El Din, D.W. Smith, Univ of Alberta, Civil and Environmental Engineering; J. Martin, Univ of Alberta, Laboratory Medicine and Pathology and Public Health Sciences; M. Belosevic, Univ of Alberta, Biological Sciences. The separation of bitumen from the oil sands generates large quantities of oil sands process water (OSPW), which cannot be released into the environment, until it is successfully remediated. In this study, we exposed goldfish for up to 12 weeks to either commercial NAs or aged OSPW using a real-time continuous flow exposure apparatus. We measured the gene expression of three pro-inflammatory cytokines (IFNg, IL1-b1, and TNFa-2), anti-inflammatory cytokine IL-10, and pro-inflammatory cytokine receptors (IFNR1-1, IFNR1-2, TNFR1, TNFR2), in the gill, kidney, and spleen of the exposed fish using quantitative-PCR (qPCR). We observed a general up-regulation of IFNg, IL1-b1, and TNFa-2 gene expression after acute (one week) exposure of fish to either commercial NAs or OSPW. Sub-chronic (12 weeks) exposure of fish to NAs caused a significant down-regulation in immune gene expression in fish exposed to higher doses (10 and 20 mg/L of NAs). In contrast, gene expressions in fish exposed to aged OSPW were similar to those of non-exposed controls. In general, there were no differences in gene expression of pro-inflammatory cytokine receptors between exposed and non-exposed fish except for the kidney, where the gene expressions of TNFR1 and TNFR2 were up-regulated and IFNG1-1 was down-regulated after sub-chronic exposure to OSPW. To determine whether goldfish host defense was affected by exposure to 5 mg/L and 20 mg/L of NAs, fish were infected with a blood parasite *Trypanosoma carassii* and their ability to control the infection and immune gene expression documented. After acute exposure to NAs (one week), fish exhibited significantly higher parasitemia compared to non-exposed controls. In contrast, after sub-chronic (60 days) exposure of fish to NAs, fish had higher parasitemia and greater mortality compared to non-exposed controls. Thus, the exposure of goldfish to NAs elicited a significant enhancement in pro-inflammatory gene expression and increased resistance to parasitic infection after acute exposure to NAs or OSPW, and down-regulation of immune gene expression and increased susceptibility to parasitic infection after sub-chronic exposure to NAs or OSPW.

242 Fungicides: Shifts in Registration and Usage in the United States G. Orrick, S. Hill, USEPA, Office of Pesticide Programs. Registration and usage of fungicides have shifted over the past decade. As a result, some new fungicides have become widely used, which may influence fungicide occurrence in water bodies. Fungicide usage patterns over the past ten years will be presented with a focus on the new fungicides introduced to the market during this time period. The environmental fate and toxicity properties

of historical and new fungicides will also be summarized, compared, and contrasted.

243 Occurrence of Fungicides in Surface Waters Across the USA K. Kuivila, K.L. Smalling, M. Hladik, J. Orlando, T. Reilly, US Geological Survey. Fungicides are pesticides designed to control fungal diseases, and tend to be understudied during routine monitoring of contaminants in aquatic environments. Used on a wide variety of crops, fungicides are typically applied repetitively throughout the growing season. Other uses include landscape maintenance, turf, and applications by homeowners. Chlorothalonil, a broad-spectrum fungicide, has been widely applied for over 50 years, but recently the registration and use of other new fungicides has been increasing. Most fungicides are moderately hydrophobic (log Kow of 2.5-4.5) and are persistent in water and sediments. To better understand the environmental occurrence of fungicides, methods were developed to analyze 34 current-use fungicides in water and sediments by using gas chromatography/mass spectrometry. Method detection limits for all compounds were in the low ng/L range for water and µg/kg range for sediments. In a series of studies from eight different states across the United States, surface-water samples (water n = 321 and sediment n = 89) were collected from a variety of agricultural-use settings (leafy greens, potatoes, rice, strawberries, and stonefruit orchards). Overall, twenty fungicides were detected in water and sediments. Two fungicides, azoxystrobin and boscalid, were detected primarily in water. Azoxystrobin was detected in 55% of water samples and at the highest concentration (128 µg/L), while boscalid was detected the most frequently (65% of samples) and at a maximum concentration of 3.60 µg/L. Three fungicides (chlorothalonil, myclobutanil, and pyraclostrobin) were found frequently in both water (detection frequency from 12 to 25%) and sediments (detection frequency from 15 to 27%). Tebuconazole was detected only in sediment (17% of samples) and at the highest concentration (1.38 mg/kg). Future studies, in collaboration with toxicologists, will include the analysis of fungicides in aquatic organisms to link measured tissue concentrations to potential effects.

244 Fungicides and Current Use Herbicides in the Western Basin of Lake Ontario (Canada) Monitored Using POCIS Passive Samplers C.D. Metcalfe, Trent Univ, Environmental & Resource Studies, Trent Univ, Dept of Environmental & Resource Studies; H. Li, Trent Univ, Water Quality Centre; P.A. Helm, Ontario Ministry of the Environment, Environmental Monitoring and Reporting Branch. Fungicides are discharged into the aquatic environment with municipal wastewater and they are also transported into the aquatic environment in urban and agricultural runoff. In this study, we evaluated the spatial distribution of fungicides, as well as some current use herbicides in the near shore zone of the western basin of Lake Ontario and in urban creeks discharging into the basin by using passive sampling with the polar organic chemical integrative sampler (POCIS). Passive sampling provided estimates of time-weighted average concentrations of contaminants over a deployment period of 28 days. Sampling rates (Rs) of the target compounds into POCIS determined in static assays at 20°C ranged from 0.293 ± 0.032 L/d for myclobutanil to 0.648 ± 0.042 L/d for climbazole, except for Rs < 0.1 L/d for the herbicides, 2,4-D, dicamba and mecoprop and the fungicide, methyl-thiophanate. In POCIS samplers deployed at near shore stations and in urban creeks, the fungicides, azoxystrobin, myclobutanil and chloroneb, and the herbicide, dicamba were not detected at any of the monitoring sites. Carbendazim was detected in POCIS deployed at all stations; often accumulating to µg amounts over the deployment period. Several azole fungicides (fluconazole, propiconazole, tebuconazole, climbazole), as well as methyl-thiophanate and iprodione were also detected in POCIS. For all fungicides but methyl-thiophanate and carbendazim, the target compounds co-occurred with meprobamate, a persistent prescription pharmaceutical that was monitored in POCIS as an indicator of contamination by municipal wastewater. Note that clotrimazole, a widely used anti-fungal agent applied to the skin was only detected at one location, but this compound has been shown to be effectively removed by wastewater treatment. The presence of methyl-thiophanate, iprodione and carbendazim can probably be attributed to their use as anti-fungal biocides in agriculture and for the treatment of lawns and turf. The presence of several herbicides accumulated in POCIS in large amounts (i.e., atrazine, diuron, mecoprop) indicates that urban and/or agricultural runoff is the source of these contaminants. Time-weighted average concentrations of the fungicides and herbicides in water will be calculated using the Rs values determined in the laboratory.

245 Fungicide Use in US Crop Production M. Leggett, CropLife America; L. Gianessi, CropLife Foundation; W. Jones, CropLife America. A large majority of fruit and vegetable production in the US is reliant on the use of fungicides to protect them from destruction by plant pathogenic fungi. Fungicide applications, largely copper and sulfur have been a necessary part of agricultural production since the early 1900s. Synthetic fungicides have been applied to US crops since the early 1950's. Approximately 100 million pounds of fungicide are applied to US Crops annually in an ongoing struggle to stem the onset of plant disease. There are approximately 600 different compounds known as fungicides that can be grouped into 13 or more distinct classes with respect to mode of action. Of these, there are currently about 150 that are formulated and sold in commercial products globally. Application of compatible mixtures of fungicides is a common and recommended practice which is critical for effective disease control and to the maintenance of effectiveness of newer systemic and more specific fungicides since fungicide resistance can develop quickly if not well managed. The availability of varied disease control options facilitates effective management. Often non-chemical options for disease control are weak or non-existent, applications to some crops are often made repeatedly throughout the growing season. As with other pesticide compounds, the development process for fungicides includes extensive toxicological, fate and ecotoxicological testing prior to registration. In addition to current and changing patterns of use there are considerations in risk assessment that are somewhat unique to fungicides. New disease pressures and new patterns of use of fungicides are emerging that should be considered in the management of fungicides.

246 Toxicity, Sub-lethal Effects and Potential Modes of Action of Select Fungicides for Freshwater Fish and Invertebrates A.A. Elskus, US Geological Survey, S.O. Conte Anadromous Fish Research Laboratory; K. Kuivila, K.L. Smalling, US Geological Survey. Relatively few data are available on the effects of fungicides on non-target organisms in the aquatic environment, despite decades of agricultural and urban use. Given the basic modes of action through which fungicides exert toxic effects (mitosis and cell division, nucleic acids synthesis, respiration, amino acids and protein synthesis, signal transduction, lipids and membrane synthesis, sterol biosynthesis in membranes, glucan synthesis, melanin synthesis in cell wall, host plant defense induction, multi-site contact activity, with some whose mode of action is still unknown), one might expect these chemicals to be potent toxicants for all biological life. Indeed, an increasing number of studies report dramatic, and in some cases severe, effects of fungicides on fish and invertebrates at environmentally relevant concentrations. A series of complimentary studies are measuring the occurrence of fungicides in various use-settings across the USA. The fungicides selected for review are those detected most frequently and at the highest concentrations: azoxystrobin, boscalid, chlorothalonil, cyprodinil, fenarimol, fenbuconazole, fludioxinil, iprodione, myclobutanil, propiconazole, pyraclostrobin, pyrimethanil, tebuconazole, vinclozolin, and zoxamide. The presentation will review published literature, including striking fungicide effects on non-target organisms (fish and aquatic invertebrates), such as azoxystrobin effects on invertebrate community structure, fish respiration and reproduction, chlorothalonil alteration of fish immune function, the endocrine-disrupting activities of the P450-demethylase-inhibiting fungicides, and the presence and toxicity of boscalid, a recently introduced fungicide increasingly detected in waterways bordering agricultural settings. We also will discuss potential modes of action, sensitive organisms and life-stages, and data gaps.

247 Fungicide-induced Declines of Freshwater Biodiversity Modify Ecosystem Functions and Services J. Rohr, Univ of South Florida, Dept of Integrative Biology; T. McMahon, N. Halstead, L. Martin, T. Raffel, J. Romansic, Univ of South Florida; R. Boughton, Archbold Biological Station; P. Crumrine, Rowan Univ; S. Johnson, Univ of Florida. Despite the widespread use of fungicides, we know little about their impacts on freshwater ecosystems. Fungicides can be toxic to a variety of freshwater organisms, leading to possible negative effects on biodiversity and potential changes in ecosystem properties. However, research on indirect effects of contaminants on ecosystem properties is virtually nonexistent. We treated freshwater mesocosms with a solvent control or 1x or 2x the expected environmental concentration (EEC, ~164 µg/L) of chlorothalonil, the most commonly-used fungicide in the US, and quantified 34 community-level and 11 ecosystem-level responses to test for indirect effects of this chemical on ecosystem functions mediated by changes in biodiversity. We also conducted laboratory dose-response studies to examine how chlorothalonil influenced

survival, immunity, and corticosterone levels of amphibians, a highly imperiled freshwater group. In the mesocosms experiment, chlorothalonil did not significantly affect the survival of the macroarthropod community but the EEC increased the mortality of amphibians (nearly 100% mortality), gastropods, zooplankton, algae, and a macrophyte, resulting in a significant reduction in taxonomic richness. Chlorothalonil also significantly affected ecosystem functions and services, reducing decomposition rates, decreasing water clarity, elevating dissolved oxygen, and increasing net primary productivity as a result of algal blooms. A path analysis supported a model whereby both top-down (reduction in algal herbivores) and bottom-up (reduction in macrophytes) effects of chlorothalonil facilitated the algal bloom late in the experiment, which drove the shift in ecosystem functions. In the laboratory experiments, the ~EEC caused 100% mortality of all four amphibian species tested within 24h, and 1/10000th of the EEC caused significant mortality of two species. Three species showed a non-monotonic dose-response, with low and high concentrations causing significantly greater mortality than intermediate concentrations and controls. For Cuban treefrogs, corticosterone exhibited a similar non-monotonic dose response and chlorothalonil concentration was negatively associated with liver tissue and immune cell densities (< 17.6µg/L). This work emphasizes the need to further link contaminant-induced changes in biodiversity to altered ecosystem functions and to re-evaluate the safety of chlorothalonil to biodiversity.

248 Effects of Fungicide Formulations on Ecosystem Function in Playas and Adjacent Native Grasslands and Croplands S. Swain, Oklahoma State Univ, Zoology; L.M. Smith, Oklahoma State Univ; J.B. Belden, S.T. McMurry, Oklahoma State Univ, Dept of Zoology. Fungicides are used throughout the world to combat pathogenic fungi. They are commonly used on a large variety of crops and although they are meant to be used to fight fungal infections only when necessary, they are often applied throughout the growing season. The use of fungicides has dramatically increased in the past decade, particularly in the highly cultivated Great Plains of the USA. Fungicides, such as Quilt and Headline, which are relatively new classes of fungicides, are also EPA labeled to promote plant yield and health, leading to excess spraying of fungicides. In addition, runoff and drift during aerial application could contaminate surrounding landscapes, notably playas in the Plains area. The effects of Quilt and Headline on non-target fungal species such as beneficial decomposers have yet to be studied, specifically in playas of the High Plains (HP). Therefore, soil from playas and their adjacent uplands throughout the HP in native grassland and cropland will be collected and used to monitor effects on non-target fungal species by measuring ergosterol 7 and 14 days post fungicide application (at levels of 0, .1x, 1x and 10x the label rate). Ergosterol is a sterol only found in fungi and is a useful tool to measure fungal biomass and is targeted by propiconazole, an active ingredient in Quilt. In order to monitor mitochondrial processes, respiration will be measured using an alkaline trap method with an airtight container and NaOH capturing carbon dioxide evolved by the microorganisms. Similar to ergosterol measurement, respiration will be sampled with the same levels of fungicides. Both fungicides contain strobilurins whose mode of action targets fungal metabolism. Measuring respiration and ergosterol will monitor the effect of fungicides on the carbon cycling processes in HP playas, with emphasis on the difference between native grassland and cropland playa responses. Results will be presented on fungal biomass and respiration as these are key ecosystem functions affecting most ecosystem services.

249 Sublethal Effects of Strobilurin Fungicides on Development and Growth of Larval Great Plains Toads (*Bufo cognatus*) E.A. Hooser, S.T. McMurry, J.B. Belden, Oklahoma State Univ, Dept of Zoology; L.M. Smith, Oklahoma State Univ. Use of strobilurin fungicides has increased in the past few years to control disease outbreaks and in part, because of proclaimed plant yield benefits. As with most pesticides, drift and overspray during aerial applications, and runoff following storm events, can lead to contamination of non-crop areas, including wetlands embedded in agricultural fields. Pesticide concentrations at these off-site locations would be expected to be lower than concentrations intended for crop applications, and unlikely to cause mortality in non-target organisms. In this study we examined the sublethal effects of three strobilurin fungicides, Headline®, Stratego®, and Quilt®, on developmental rate and body size at metamorphosis of *Bufo cognatus* tadpoles. These metrics are good indicators of individual fitness and have implications for population viability. These endpoints are also relevant as the mode of action for the active ingredients is inhibition of cellular respiration and ATP acquisition. Thus, time to metamorphosis and body size (growth) were chosen as they represent processes hindered by insufficient energy reserves. Tadpoles were exposed to sublethal concentrations of each fungicide continuously throughout the larval period, starting at Gosner stage 25 and terminating at stage 46. A replicated (n=6) static renewal system was used throughout the exposure period. Results from this experiment extend previous acute toxicity studies and provide the only known data on sublethal effects in an amphibian model.

250 Biotransformation of Polyfluorinated Chemicals in the Environment – Thinking Beyond the Conventional Wisdom of Hydrocarbon Biochemistry N. Wang, E.I. du Pont De Nemours & Co., Inc., E.I. du Pont de Nemours & Company; R.C. Buck, B. Szostek, P.W. Folsom, L.M. Sulecki, P.K. Cooper, J. Gannon, E.I. du Pont de Nemours & Company. Perfluorinated alkyl carboxylates (PFCAs) and sulfonates (PFSAs) are widely detected in the environment due to their broad and historical applications. The sources of PFCAs and PFSAs found in the environment include direct emissions and indirect precursor degradation. The 8:2 fluorotelomer alcohol (8:2 FTOH, C8F17CH2CH2OH) is a key raw material used in the manufacture of FTOH-based products and its biotransformation leads to PFCAs and polyfluorinated carboxylic acids. Recently, 8:2 FTOH-based products and longer-chain analogs are being replaced with shorter chain length products based on 6:2 FTOH (C6F13CH2CH2OH). Our work indicates that biotransformation of 6:2 FTOH and 8:2 FTOH in various environmental matrices (e.g., soil and activated sludge) leads to two major classes of transformation products: perfluorinated carboxylic acids and 4:3, 5:3 and 7:3 polyfluorinated acids [x:3 acids, F(CF2)nCH2CH2COOH, n = 4, 5 or 7]. The pathways leading to PFCA formation and x:3 acid further degradation by microbes in the environment are markedly different and much more complex than the ones predicted based on the molecular structures of 6:2 FTOH, 8:2 FTOH, and x:3 acids as well as metabolic pathways of hydrocarbon analogs. The PFCA formation and x:3 acid further degradation are via novel "one-carbon removal mechanisms" instead of microbial α- and ß-oxidation. The first key step for α- and ß-oxidation is to activate a polyfluorinated acid by acyl-CoA synthetase to form a thioester such as 5:3 acid-CoA ester, followed by four enzymatic steps to form corresponding one- or two-carbon shorter fluorinated acids. However, our experimental evidences with high-resolution mass spectrometry analysis show that polyfluorinated acids such as 5:3 acid cannot be activated by acyl-CoA synthetase for subsequent α- and ß-oxidation. Instead, 5:3 acid can be directly decarboxylated to form one-carbon shorter 4:3 acid via "one-carbon removal mechanisms". This is the first report that carboxylic acids can be decarboxylated without the need to be activated by acyl-CoA synthetase. The multiple carbon-fluorine bonds of 5:3 acid prevent it to be activated but perhaps also provide intrinsic free energy for the decarboxylation without activation leading to 5:3 acid further degradation. The details of the "one-carbon removal mechanisms" and bioenergentics of 5:3 acid biotransformation will be discussed.

251 Concentrations and Biomagnification of Perfluorinated Compounds in Lake Food Webs in the Canadian High Arctic G. Lescord, Canadian Rivers Institute, Univ of New Brunswick, Biology Dept; K. Kidd, Canadian Rivers Institute, Univ of New Brunswick, Biology; D. Muir, A. De Silva, M. Williamson, C. Spencer, Environment Canada. Perfluorinated compounds (PFCs) can be found in air, sediment, seawater and biota across the Canadian High Arctic, however previous studies on PFC biomagnification have focused on the marine systems. Due to the remote location of Arctic systems and the relative stability of PFCs, it is hypothesized that Arctic lakes receive most of their PFCs from long range transport and atmospheric deposition. Once PFCs are deposited onto these lakes, they are bioaccumulated by lower trophic level organisms and biomagnify up the food webs to Arctic char. The main goal of this study is to determine the concentrations and biomagnification of various PFCs in the food webs of six lakes on Cornwallis Island, Nunavut. Two of these lakes (Meretta and Resolute) are located next to an airport, a local point source of contamination due to the past use of PFOS compounds for fire fighting. The remaining four lakes receive all PFC inputs atmospherically, offering a unique opportunity to compare the two contaminant sources within the same region. The six lakes were sampled repeatedly for sediments, invertebrates, and fish during and after the annual snow melt in July 2010 and 2011. Water samples were collected periodically to assess temporal changes in PFC concentrations. All samples were analyzed for a range of PFCs and the food web was characterized using stable isotopes; nitrogen isotopes were

used to assess trophic level and carbon and sulfur isotopes were used to assess energy source. Rates of PFC biomagnification through the food web will be quantified and compared among lakes through regression analysis. PFOS was the dominant PFC in adult char from all lakes. The mean PFOS detected in Meretta and Resolute Lake char muscle was 30 fold higher than in the four atmospherically supplied lakes (32.42 vs. 0.79 ng/g wet weight). Other notable PFCs in the char were PFNA and PFOSA (means of 0.72 +/- 0.21, 0.79 +/- 0.27 ng/g, respectively) in Meretta Lake and PFPeA and PFNA (means of 0.21 +/- 0.08, 0.16 +/- 0.07 ng/g, respectively) in fish from the four remote lakes. In water, mean PFOS concentrations were 300 times greater in Meretta and Resolute Lakes than in the other four lakes (25,021 ng/L vs. 77 ng/L, respectively). In the atmospherically contaminated lakes, the dominant PFC was PFOA (mean of 265 +/- 39 ng/L). All other PFC analyses sediments and biota are ongoing. Results from this study will improve our understanding of the concentrations of PFCs in Arctic lakes and offer critical baseline information for future studies.

252 Dietary Bioaccumulation of Perfluorinated Phosphonates (PFPAs) and Perfluorinated Phosphinates (PFPiAs) in Juvenile Rainbow Trout, *Oncorhyncus mykiss* H. Lee, Univ of Toronto, Chemistry, Univ of Toronto, Dept of Chemistry, Univ of Toronto; S.A. Mabury, Univ of Toronto, Dept of Chemistry; A.O. De Silva, Environment Canada, Water Science & Technology Directorate, Environment Canada, Water Science and Technology. Perfluorinated phosphonates (PFPAs) and perfluorinated phosphinates (PFPiAs) are high-production volume fluorinated surfactants used as leveling and wetting agents in waxes, coatings, and cleaning fluids. Recent observations of the PFPiAs at sub µg/L concentrations in human sera confirm human exposure to commercial products containing these fluorinated surfactants. Waste release of such products from domestic, commercial, and industrial sources may contribute to the load of these chemicals in aquatic systems. In fact, the PFPAs were observed in Canadian surface waters and wastewater treatment plant (WWTP) effluents, while the PFPiAs were observed in WWTP sludge. The present study examines the bioaccumulation potential of PFPAs and PFPiAs in juvenile rainbow trout (*Oncorhyncus mykiss*) through dietary exposure under flow-through conditions. Fish were administered a daily dose (1.5% body weight) of commercial fish feed containing a mixture of C6, C8, and C10 PFPAs or a mixture of C6/C6, C6/C8, and C8/C8 PFPiAs, all prepared with authentic standards provided by Wellington Laboratories (Guelph, ON). Control fish were given non-dosed feed. Whole body concentrations were determined by extracting and analyzing whole fish in triplicate at timepoints during the 25-day exposure and 30-day depuration phases to calculate analyte-specific bioaccumulation factors, elimination rate constants and half-lives. The relationship between substitution at the phosphonate and/or phosphinate headgroup and extent of bioaccumulation will be explored through comparison of bioaccumulation factors calculated for each PFPA and PFPiA congener. The important role of the acid headgroup in driving the differential accumulation of perfluorocarboxylates (PFCAs) and perfluorosulfonates (PFSAs) in biological tissues has been previously reported. PFSAs have been demonstrated to bioaccumulate to a greater extent than their PFCA analogs of equal perfluorinated chain length in rainbow trout. The bioaccumulation potential of PFPAs and PFPiAs, also perfluorinated acids, is predicted to vary with headgroup and chain length.

253 Investigating the Biological Fate of Fluorotelomer Unsaturated Acids and Aldehydes A. Rand, Univ of Toronto, graduate student, Univ of Toronto, Chemistry; S. Mabury, Univ of Toronto. Fluorotelomer unsaturated acids and aldehydes (FTUCAs and FTUALs) are intermediate metabolites that form from the biotransformation of fluorotelomer alcohols (FTOHs), found as impurities in commercial fluorinated surfactants and polymers. Studies have shown that these commercial products can also biologically transform to yield FTOHs, which further metabolize to ultimately produce PFCAs. PFCAs are persistant and potentially toxic, however, previous work suggests that the PFCA precursors may actually be more toxic than PFCAs themselves. The purpose of this current study was to assess the reactivity of FTUCAs and FTUALs with model proteins. In vitro experiments were carried out in an aqueous buffer system (pH 7.4), where FTUCAs and FTUALs of varying fluorinated chain lengths were reacted with apomyoglobin and human serum albumin to determine 1) whether these metabolites react with nucleophilic residues within proteins and 2) their covalent binding stochiometry, using direct injection time-of-flight mass spectrometry (TOF-MS). The FTUALs formed one adduct with apomyoglobin while in comparison, the FTUCAs were not reactive. This finding demonstrated the selectively of FTUCAs towards biological nucleophiles containing cysteine. Previous work determining the reactivity of the unsaturated intermediates with amino acids also showed that reaction rates depended upon the amino acid: cysteine >> histidine > lysine >> arginine. FTUCAs and FTUALs were also spiked into in vitro cellular systems to determine the extent of protein binding in the presence of these reactive intermediates. This is the first study which probes the reactivity of FTUCAs and FTUALs with nucleophiles other than thiol groups, further elucidating their fate within biological systems.

254 Perfluorinated Compounds in a US National Effluent Sampling S.F. Nakayama, National Institute for Environmental Studies, Center for Environmental Health Sciences; M.A. Mills, USEPA, National Risk Management Research Laboratory; R. Marfil-Vega, USEPA, ORISE Research Participant to the National Risk Management , Univ of Cincinnati; K. Tadele, US Environmental Protection Agency, National Risk Management Research Laboratory; A.L. Batt, USEPA Office of Research and Development, National Exposure Research Laboratory; M. Kostich, USEPA Office of Research and Development, EERD; J.M. Lazorchak, US Environmental Protection Agency, Office of Research and Development, USEPA Office of Research and Development, National Exposure Research Laboratory, USEPA, Molecular Ecology Research Branch. Mounting evidence suggests that municipal wastewater is one of the primary sources of perfluorinated compounds (PFCs) to the aquatic environment. As there is no treatment technology to date proven to efficiently remove the PFCs during drinking water treatment, it is extremely important to characterize nationally representative wastewater effluents in order to evaluate the extent of PFC occurrence and assess their impact on ecosystem and humans. Fifty large municipal wastewater treatment plants in the United States were identified from the 2004 Clean Watershed Needs Survey. These plants produce about 16% of all the municipal wastewater in the US. A one-time grab or 24-h composite sample (total of 9 litres) of finished effluent from each plant were collected by EPA Regional or Plant personnel, then shipped to EPA – Cincinnati laboratory. For each effluent sample, the concentration of perfluorinated compounds were quantified along with selected pharmaceuticals, steroid hormones, alkylphenolic compounds, Bisphenol A, and the estrogenic potential in a fish assay. For PFCs analysis, solid phase extraction method was employed coupled with liquid chromatography tandem mass spectrometry. Perfluorinated compounds were found in most of the effluents in a wide range of concentrations. The result from the national effluent study will be discussed in the presentation.

255 Sources of Perfluorooctanoate in Remote Locations J.P. Benskin, AXYS Analytical Services Ltd; L. Ahrens, Environment Canada, Science And Technology Branch; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, Environment Canada, National Water Research Institute; C. Spencer, Environment Canada, Aquatic Ecosystem Protection Research Division; B. Rosenburg, Fisheries and Oceans Canada, Arctic Aquatic Research Division; G. Tomy, Dept of Fisheries & Oceans Canada, Dept of Fisheries & Oceans; H. Kylin, Swedish Univ of Agricultural Sciences, Aquatic Sciences and Assessment; R. Lohmann, Univ of Rhode Island, Graduate School of Oceanography, Univ of Rhode Island; V. Phillips, Univ of Regina, Dept of Biology; V. StLouis, Univ of Alberta, Biological Sciences; A.O. De Silva, Environment Canada, Water Science & Technology Directorate, Environment Canada, Water Science and Technology; J.W. Martin, Univ of Alberta, Dept of Laboratory Medicine and Pathology. The extent to which historical (i.e., electrochemically fluorinated) and contemporary (i.e., telomer) manufactured perfluorooctanoate (PFOA) contribute to concentrations in remote environments is widely debated. So too is the dominant mechanism of long-range transport. Here, relative contributions of historic and contemporary-manufactured PFOA were assessed in seawater samples from the Arctic, Atlantic, and North and Norwegian Seas, as well as in dated alpine sediment cores from the Canadian Rockies, using an established isomer profiling technique. Eastern Atlantic PFOA was largely (83 – 98%) historic; but this decreased to as little as 33% close to the Eastern US seaboard. PFOA in the Norwegian Sea was also near exclusively historic, but the relative contribution decreased to ~50% near the Baltic Sea. In the Arctic, a spatial trend was observed whereby PFOA in seawater originating from the Atlantic was predominantly of historic origin (up to 99%), whereas water in the Archipelago (i.e., from the Pacific) was predominantly of contemporary origin (as little as 17%

historic). Perfluorinated carboxylate isomer profiles (C7-C13 perfluoroalkyl chain lengths) in dated alpine sediment cores were exclusively linear and temporal trends from the 1950s-2008 were consistent with fluorotelomer emissions estimates over this time. Taken together, these results suggest that atmospheric deposition of contemporary-PFOA, or related precursors, is the dominant source of PFOA to the Canadian Arctic Archipelago (and western Arctic), while historically manufactured PFOA and direct oceanic transport is the dominant source of PFOA to the North Atlantic Ocean. Observations of contemporary PFOA in coastal regions, coinciding with elevated PFOA concentrations, suggests that continued production of PFOA is increasing the burden of this contaminant in the world's oceans.

256 Spatial Distribution and Loadings of Particle Sorbed and Dissolved Perfluorinated Compounds in the Basin of Tokyo Bay Y. Zushi, National Institute for Environmental Studies, Center for Environmental Measurement; F. Ye, Yokohama national Univ, Graduate School of Environment and Information Sciences; M. Motegi, K. Nojiri, S. Hosono, Center for Environmental Science in Saitama; T. Suzuki, Y. Kosugi, K. Yaguchi, Tokyo Metropolitan Institute of Public Health; S. Masunaga, Yokohama national Univ. A number of studies on perfluorinated compound (PFC) pollution in water environment have been reported. However, the information on many types of PFCs including their partitioning behavior in water environment is limited. We analyzed over 30 types of PFCs including precursors both in dissolved phase and particle solid phase in 50 samples of river water collected from entire part of Tokyo Bay basin. PFCs were detected from suspended solids (SS) with the range of < 0.003 – 4.4 ng/L (0.11 – 2470 ng/g-dry SS). The concentrations of PFCs in SS (ng/L) were one to two order(s) of magnitude lower than that of PFCs in dissolved phase. The predominant PFCs in SS were PFOS (median: 0.24 ng/L), PFNA (median: 0.17 ng/L) and PFUnDA (median: 0.12 ng/L). Longer chain PFCAs (C12 – C17) were frequently detected above LOQ from SS samples (56 – 80%) whereas those in dissolved phase were lower than LOQ (> 60% samples) in most samples. Relatively high levels of PFCs (total of 35 PFCs) in SS were observed in urbanized area, such as building and traffic area. The concentration of PFCAs including PFOA and PFNA were significantly correlated with the geographic index such as artificial area (R2 of linear regression curve in double logarithmic plot: 0.09 – 0.55). On the other hand, PFOS and FOSA were significantly correlated with arterial traffic area ((R2 in double logarithmic plot: 0.29 – 0.55). Those spatial trends were similar with the case in dissolved PFCs, though R2 in regression analysis were lower compared with the case in dissolved PFCs. The dissolved PFCs were more appropriate indicator to obtain the information on PFC sources. We have estimated the loadings of PFCs into Tokyo Bay from 6 main rivers and found that more than 90% of total PFCs flowed into Tokyo Bay as dissolved phase. However, 40.0 – 83.5 % of long chain PFCAs, such as PFDoDA, PFTrDA, PFTeDA and PFPeDA were transported as particle phase. Rain runoff event might increase the loadings of PFCs in SS. We should pay more attention to particle phase PFCs, especially for longer chain PFCs.

257 Temporal Changes Over Twenty Years of Perfluoroalkyl Sulfonates and Carboxylates in Herring Gull Eggs from Sites Across the Laurentian Great Lakes W.A. Gebbink, Carleton Univ, Dept of Chemistry; R.J. Letcher, Carleton Univ, Dept of Chemistry, Environment Canada, Science and Technology Branch, Ecotoxicology and Wildlife Health Division, Science and Technology Branch, Environment Canada, Great Lakes Institute for Environme, Canadian Wildlife Service; C.E. Hebert, Environment Canada, Science and Technology Branch, Ecotoxicology and Wildlife Health Division; C. Weseloh, Environment Canada, Environment Conservation Branch. We investigated the temporal trends of perfluorocarboxylic (PFCA) and sulfonic acids (PFSAs) and selected precursors in herring gull eggs from seven colony sites across the Laurentian Great Lakes of North America. The herring gull eggs collected in 1990 and 1997 to 2010 (1 pool of 13 eggs per year per site) were screened for PFCAs (C6-C15), PFSAs (C4, C6, C8, C10), fluorotelomer unsaturated acids (6:2, 8:2, 10:2 FTUCAs), fluorotelomer alcohols (6:2, 8:2, 10:2 FTOHs) and perfluorosulfonamides (PFOSA and NMeFOSA). Declines in ∑PFSA concentrations occurred in egg pools from all the colonies, which was significant for Agawa Rocks (Lake Superior) and Channel-Shelter Island (Lake Huron); however, concentrations increased significantly for Toronto Harbour (Lake Ontario). Perfluorooctane sulfonate (PFOS) dominated the PFSA pattern in the eggs at all colonies and all years, ranging from 79.9 to 99.4%. Declining concentrations of PFOS in the eggs from most colonies could be related to the phase out of PFOS and its precursors in 2002 by the 3M Company; however, the increasing concentrations at Toronto Harbour might be a result from being close to highly urbanized areaa. PFOSA (PFOS precursor) was detected in the eggs between 1990 and 2006; post-2006 PFOSA was below detection limit at all the colonies. Declining concentrations were observed between 1990 and 2006 at all the colonies with the exception of Agawa Rocks and Channel-Shelter Island. The ∑PFCA concentrations increased significantly in the eggs from Agawa Rocks, Fighting Island (Detroit River), Niagara River, and Toronto Harbour. The eggs from Gull Island (Lake Michigan), Channel-Shelter Island and Chanatry Island (Lake Huron) showed no significant changes during 1990 and 2010. The PFCA pattern was dominated by PFDA, PFUnA, PFDoA, and PFTrA, and generally the patterns were consistent among years and colonies. PFCA precursors (FTOHs and FTUCAs) were below detection limit in the egg pools from all years and colonies. Environmental degradation of these precursors could explain the increasing trends of PFCAs as production volumes of these telomer based compounds are still increasing. Declining concentrations of the C8 PFOS, PFOA and PFOSA, might be a result of the 2002 phase out of the C8 chemistry by 3M in North America. However, increasing production volumes of fluorotelomer based compounds, and degradation of these compounds to PFCAs might explain increasing trends of PFCAs.

258 Hydrocarbons and Legacy Organochlorine Pesticides and PCBs in Sediments from Terminos Lagoon, Mexico B. Ramirez-Vargas, EPOMEX, Universidad Autonoma de Campeche; E. Cach-Perez, Campeche Autonomous Univ/EPOMEX Center; L. Alpuche Gual, Campeche Autonomous Univ/EPOMEX Center, Centro Epomex; G. Gold-Bouchot, Cinvestav Unidad Merida, Marine Resources. As a part of a pilot project to enhance Mexico's capabilities for coastal monitoring a sampling was carried out in Terminos Lagoon, in the Southern Gulf of Mexico. This is Mexico_ largest coastal lagoon, located at the stuary of the Grijalva-Usumacinta river system that accounts for 35 % of total freshwater runoff in Mexico and is the second in the Gulf of Mexico. A total of 60 sampling stations were planned in a probabilistic design, stratifying in six subareas using the hydrological and sedimentological characteristics of the lagoon. Fish, water and sediments were collected for a wide variety of chemical and biological analyses, but here only the results for hydrocarbons and pesticides in sediments are presented. Results indicate that there are significant differences between the six areas, and that the number of sampling stations can be decreased. Results are discussed in terms of the fraction of stations exceeding the ERL and ERM guidance values. This is important for coastal management.

259 Levels and Distribution of Polychlorinated Biphenyls In The Vicinity of Chinese Great Wall Station, Antarctica Q. Zhang, Y. Li, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, State Key Laboratory of Environmental Chemistry and Ecotoxicology; P. Wang, D. Geng, G. Jiang, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences. The Antarctica is considered to be a clean and pristine area due to less anthropogenic activities. However, more and more studies have reported the detection of various POPs in the Antarctic environment. In this study, various environmental samples including air (high-volume air samples and PUF-disk passive air samples), soil, sediment, lichen and moss were collected in the vicinity of Chinese Great Wall Station on the King George Island, Antarctica, in the austral summer between December 2009 and February 2010, to investigate the levels and distribution of polychlorinated biphenyls (PCBs) in this remote area. The analysis of PCBs was performed using high-resolution gas chromatography coupled with high-resolution mass spectrometry (HRGC/HRMS) with an isotope-dilution method. The air concentrations of total PCBs ranged between 82-167 pg m-3 from high volume air sampling, and were dominated by light homologues (Di to Tetra-CBs). There was a 1-3 fold deviation of PCB concentrations between the active and passive sampling data. Therefore, PUF-disk passive air sampling can be used to assess PCBs distributions in the Antarctica atmosphere, although the wind speed are always high during the sampling campaigns. The three sampling sites closing to several Antarctic Research Stations showed higher PCB concentrations than the other two sites, which may reflect potential influence from human activities. In the soil and sediment samples, PCB concentrations were in the range of 60.1-1436 pg g-1 dry weight (dw). In the lichen and moss, they were between 404-745 pg g-1dw and 406-952 pg g-1dw, respectively, of which no significant difference was observed between the grass types. The most abundant isomers were the lower chlorinated CBs in all the samples except

for the dropping-amended soils from Ardley Island, where HxCBs dominated. Furthermore, the indicator CBs, CB-118, -138 and -153 were of high concentrations besides CB-28 in all the samples, which might indicate local source exist (e.g., biotic activities). Notably, CB-11 was significantly detected, the higher ratio of CB-11 in the natural soil than in the dropping-amended soil suggested different source from biotic activities. Therefore, the contamination profiles indicated long-range atmospheric transport could be the main source of PCBs in King George Island; however, it was also apparently influenced by local sources (e.g., research station, tourism and biotic activities).

260 Polycyclic Aromatic Hydrocarbons in Continental Shelf Sediment of China: Implications for Anthropogenic Influences on Coastal Marine Environment L. Liu, Guangzhou Institute of Geochemistry; J. Wang, Health Canada; Y. Guan, South China Normal Univ; E.Y. Zeng, Guangzhou Institute of Geochemistry, State Key Lab of Organic Geochem. Sediment samples collected from the continental shelf of China, embracing Yellow Sea, inner shelf of the East China Sea, and the South China Sea, were analyzed for polycyclic aromatic hydrocarbons (PAHs), from which the potential influences of terrestrial anthropogenic activities on the coastal marine environment were assessed. The concentrations of anthropogenic PAHs (Σ19PAH, List S1 in the Supporting Information) were 27_220 ng/g dry weight, with a mean of 90 ng/g. An alongshore decreasing trend of Σ19PAH concentrations was observed in the inner shelf sediment of the East China Sea, suggesting fluvial input was the major source of PAHs in the region. On the other hand, sediment PAHs in Yellow Sea and the SCS were principally derived from atmospheric deposition. Compositional pattern analyses suggested that Yellow Sea sediments were dominated by high molecular weight (5-6-ring) PAHs, accounting for 50_72% (average: 60%) of total PAHs, whereas low molecular weight PAHs contributed to 42_96% (average: 66%) of total PAHs in the South China Sea sediment. This spatial variability of PAH compositions was ascribed to the regional climatic divergence and/or regional source profiles. The generally higher Σ19PAH levels (27_220 ng/g with a mean of 110 ng/g) in the Yellow Sea sediment than those in the SCS sediment (28_210 ng/g with a mean of 75 ng/g) were probably resulted from larger emissions of PAHs from domestic coal combustion and coke industry in North China than in South China.

261 Spatial Variability of Factors Influencing the Distribution of Triclosan in Sediments and Water of an Urbanized Estuarine Embayment D.R. Katz, M. Cantwell, J. Sullivan, USEPA, Atlantic Ecology Division; M. Perron, Brown Univ, School of Engineering; M. Charpentier, Raytheon Company; R.M. Burgess, USEPA, Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, USEPA, USEPA. Triclosan (TCS) is a broad spectrum anti-microbial compound added to many consumer and personal care products. TCS enters water bodies primarily through wastewater treatment plant (WWTP) effluent and may be introduced by combined sewer overflows or surface water runoff. In estuarine waters, TCS adsorbs onto particles and may be preserved for long periods of time after deposition to sediments. The spatial variability and factors influencing deposition of TCS in marine ecosystems are the subjects of this research with a focus on Greenwich Bay, a sub-estuary of Narragansett Bay, Rhode Island. Sample locations were chosen using a statistically randomized, tessellated hexagonal grid design. After extraction and cleanup, sediment and water samples were derivatized and analyzed by GC/MS-EI. Overall, results show a high correlation to the sediment organic carbon content (r2 = 0.79). Locally elevated sediment concentrations of TCS in Greenwich Cove, which directly receives effluent from a local WWTP, provide evidence that it is a major source of TCS to the area. Dissolved water concentrations were spatially variable, suggesting there may be other discrete sources of TCS to Greenwich Bay, or that additional factors outside the sub-embayment may have a role in TCS flux to this area. A sediment core collected from the center of the bay shows a sustained decline in TCS concentration from approximately 1990 to the present. This corresponds with increases in sewer connections and improvements in WWTP technologies employed in the watershed.

262 Quondam Times Orcharding Creates Modern DDT-Problems A. Ruus, Norwegian Institute for Water Research (NIVA), Norwegian Inst. for Water Research, N.I.V.A., Norwegian Inst. for Water Research; N. Green, NIVA; A. Maage, NIFES; C.E. Amundsen, Bioforsk; M. Schoyen, J. Skei, NIVA. The Sørfjord (Western Norway) has a long history of agriculture (since the 13th century), as well as industry (since the early 20th century). DDT was used as an insecticide in the orchards along the fjord shortly after World War II and until 1970, when it was banned as a general pesticide in Norway. Environmental concerns followed later and The Norwegian State Pollution Monitoring Program has been continuous in the fjord since 1979. It has inter alia comprised analyses of different contaminants in mussels, fish and sediments. Since the early 1990s, elevated concentrations of DDT were found in mussels and fish. Furthermore, on some locations DDT-concentrations in mussels increased towards present day, despite the discontinuation of use. In 2006, the highest concentrations were encountered so far, corresponding to approximately two orders of magnitude higher concentrations than what is regarded as a Norwegian background. Analyses of sediment core sections also showed increased input of DDT to the fjord towards present day. Shifts in climatic parameters (e.g., precipitation), as well as a decline in atmospheric sulphate deposition, followed by increased amounts of soil dissolved organic carbon, may have contributed to these observations. These findings show that although agreements and regulation of hazardous substances decrease or terminate their release to the environment, other factors may come into play that counter the effect of lowered concentrations in environmental samples.

263 The Fate of Organochlorine Contaminants in Seabirds from an Arctic Colony: Bioaccumulation, and Transfer to Coastal Nesting Sites and Predators K.L. Foster, Trent Univ, Dept of Chemistry; M.L. Mallory, Environment Canada, Canadian Wildlife Service; L. Hill, J.M. Blais, Univ of Ottawa, Program for Chemical and Environmental Toxicology. Seabirds accumulate contaminants from the prey that they consume, and thus are frequently used as biomonitors of marine contaminants. Seabirds also serve as a contaminant link or vector of marine-derived contaminants to coastal, terrestrial regions near their nesting sites, where they deposit these contaminants in their carcasses, partially digested food and excreta. In the present study, the bioaccumulation of organochlorine contaminants by northern fulmars (Fulmarus glacialis) from a colony at Cape Vera, Devon Island in the Canadian High Arctic (76°15′N, 89°14′W), and the subsequent transfer of these accumulated contaminants to coastal environments and terrestrial predators of the birds, are examined. Measured organochlorine concentrations and associated fugacities are presented for the liver, carcasses, and digesta collected along sections of the digestive tract including prey. Segmenting the digestive tract enabled a snap shot of contaminant fate within the birds, including contaminant uptake from prey items into the bird, and contaminant metabolism, through stages of digestion. Carcass contaminant concentrations are seldom monitored for seabirds, yet we have demonstrated their utility in assessing the transfer of marine contaminants to terrestrial predators such as the Arctic fox (Alopex lagopus). Elevated concentrations of contaminants in avian stomach oils, which are used to feed chicks and for defensive purposes, increase chick exposure and are relevant to bioaccumulation in young seabirds. The benefits of considering both concentrations and fugacities are demonstrated and provide information on the absorption and distribution of chemicals within the fulmars and contaminant transfer to offspring and predators.

264 Quantitative Determination of Pharmaceutically Active Compounds in Singapore's Marine Environment S. Bayen, National Univ of Singapore, Dept of Civil and Environmental Engineering; H. Zhang, National Univ of Singapore, Dept of Civil and Environmental Engineering, National Univ of Singapore; M. Desai, National Univ of Singapore, Tropical Marine Science Institute; B.C. Kelly, National Univ of Singapore, Dept of Civil and Environmental Engineering. The discharge of pharmaceutically active compounds (PhAC's) into the environment via household, municipal and industrial wastes is a pressing public health issue. Some of these chemicals have been reported as toxic to aquatic organisms in the literature and high environmental concentrations may cause toxic effects. Here, we present the development of analytical methods for the quantitative determination of several PhAC's in surface waters, sediments and biota from Singapore's marine environment. Target analytes include common human pharmaceuticals such as Atorvastatin, Carbamazepine, Citalopram, Diltiazem, Diphenhydramine, Fluoxetine, Norfluoxetine, Propanolol, Sertraline, Thiabendazole, Trimethoprim, Venlafaxine, Warfarin and Gemfibrozil. We conducted a comprehensive field survey of surface waters, sediments and organisms at various locations from Singapore's coastal marine environment. Seawater samples were filtered/extracted using a filtration apparatus containing glass fibre filters and solid-phase extraction (SPE) disks. Both acidic (pH=2) and

neutral (pH=7) extractions were tested and evaluated. We report distinct performances of each extraction protocols for the various analytes. Marine sediments and tissue samples were extracted using solvent extraction followed by SPE. Identification and quantification of target compounds was performed using liquid chromatography-electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS). ^{13}C or deuterated mass-labeled standards were used for quantification (isotope dilution). Results of analyte recovery tests, procedural blanks and replicate sample analyses demonstrate generally good performance of the methods for the majority of target analytes. We encountered significant matrix effects (ionization suppression and enhancement), highlighting the need for careful quality control/assurance and utilization of mass-labelled surrogate standards. The significance of the occurrence, levels and patterns of various PhACs in Singapore's marine environment are discussed.

265 Development and Evaluation of a Multimedia Environmental Fate Model for Phthalate Esters in the False Creek, British Columbia G. Zandpoor, Simon Fraser Univ, Dept of Biological Science, Simon Fraser Univ; H. Lai, Simon Fraser Univ; M.G. Ikonomou, Dept of Fisheries and Oceans, Institute of Ocean Sciences; F.A. Gobas, Simon Fraser Univ, School of Resource and Environmental Management (Faculty of Environment), Simon Fraser Univ. Di-phthalate esters (DPEs) are widely used commercial chemicals. Their main application is as plasticizers. DPEs are high volume production substances that have been observed to be present in environmental media from many locations around the world. There is concern over the potential impacts of di-phthalate esters and their main metabolites, the mono-alkyl phthalate esters (MPEs), in wildlife and humans. This concern is partly caused by the lack of a quantitative understanding of the environmental fate of these chemicals in the environment. To improve the understanding of the relationship between the release of DPEs into environment and resulting concentrations of DPEs and MPEs in abiotic and biotic media, we developed and tested a multimedia environmental fate and food web model to describe the distribution and transformation of DPEs and MPEs in an aquatic ecosystem. To test the model, we conducted a field study of the distribution of DPEs and MPEs in a marine Inlet in Vancouver, Canada. In this presentation, we present the model, describe the field study and discuss the performance of the model. We demonstrate that the calculated sediment water partition coefficients (organic carbon normalized) are in good agreement with the corresponding independently measured values for both DPEs and MPEs. The only exception was dimethyl phthalate (DMP). Both model calculated and observed bioaccumulation factors of DPEs and MPE in fish and benthic invertebrate species are also presented. The model was applied to assess the combined loadings of DPEs into the Inlet and to assess the real-world half-life time of DPEs and MPEs in an aquatic environment. The multimedia mass balance environmental fate model in conjugation with a food web model provides a better understanding of the distribution and transformation of DPE in aquatic ecosystems. The model can be used in other aquatic environments, with their own system specific and chemical specific parameters. The model is expected to be useful for preliminary ecological risk assessment in order to predict exposure concentrations, internal body burdens and possible remediation targets.

266 Measurement of Nanoparticles in Food and Biological Samples R. Peters, RIKILT, Wageningen Univ, Residues & Contaminants; S. Weigel, H. Bouwmeester, RIKILT, Wageningen Univ. A variety of nanomaterials are being used in consumer products, in food packaging materials, in some food supplements and even some food products; e.g.titanium-, iron- and zinc oxides, silver and silica. As a consequence, diffusion into the environment and direct and indirect consumer exposure to nanoparticles is likely. Detection and characterization of nanoparticles in products, food, biological and environmental samples is an essential part of understanding the potential benefits as well as the potential risks of the application of nanoparticles. Silica is added to food items as an anti-caking agent known as E551. While this normally exists of micro-sized particles the material is a nano-formulated material with primary particle sizes in the nano-range. Hydrodynamic chromatography combined with ICPMS (HDC-ICPMS) is used to determine silica nanoparticles in food items and in models mimicking human digestion to determine the biological availability of nano-sized silica. Using HDC-ICPMS the presence of nano-sized silica in several food items could be shown and subsequent measurements in the biological model systems indicate that this nano-sized silica remains available after digestion. Single particle ICPMS (SP-ICPMS) is used as a screening tool for nanoparticles in food and biological samples. In SP-ICPMS nanoparticles in the sample are introduced into the ICPMS plasma producing a plume of analyte ions resulting in a signal spike in the mass spectrometer. From this the particle size, size distribution and concentration can be calculated. The method was validated using the NIST gold reference materials 8011, 8012 and 8013 and tested for the determination of other nanoparticles such as silver, titanium-, iron- and cerium oxide, and silica. It is used in practice for the determination of gold, silver and titanium oxide nanoparticles in food supplements, in translocation experiments with cellular monolayers, and in biological samples from digestion model studies. In addition, the method was used to detect silver nanoparticles in the livers of rats that were exposed to silver nanoparticles through their food.

267 Nanoecotoxicological Research Tools: Current State of Affairs and Future Needs R. Tantra, National Physical Laboratory, Division of Analytical Sciences. Nanomaterial characterisation is integral to understanding the toxicological implications of such materials in the environment. The accuracy and reliability of data will be crucial if we are to understand the toxicity of nanomaterials and subsequently control the risk by monitoring key parameters linked to toxicity. Knowing what to measure and how to measure it are the main challenges. In this talk, we will be presenting an overview of progress in the use of various techniques, which are being used to obtain a comprehensive set of characterisation parameters under the PROSPEcT LINK project. This project represents the UK's contribution to a recent OECD (Organisation for Economic Co-operation and Development) sponsorship programme for the testing of manufactured (CeO2 and ZnO) nanomaterials, in relation to their potential risk of damage to the aquatic environment. We will discuss the various techniques employed (from routine based tools such as SEM, CPS disc centrifuge, Doppler Microelectrophoresis to more state-of-the art techniques such as TOF-SIMS) their advantageous and limitations in their applications in nanoecotoxicological research. Our findings have shown that although existing characterisation tools are of some use in a research setting, there is no doubt that new platforms and reference materials are very much required. In particular, for the purpose of classification and regulating nanomaterials, the development and validation of high-throughput platform is needed.

268 Speciation Analysis of Silver Nanoparticles and Silver Ions in Environmental Waters and Antibacterial Products J. Liu, J. Chao, S. Yu, R. Liu, Z. Tan, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences. The rapid growth in the commercial use of silver nanoparticles (AgNPs) will inevitably increase silver exposure in the environment and the general population, and development of methods for analysis of AgNPs is needed. We developed a method for the separation, identification, characterization and determination of trace AgNPs in environmental waters. AgNPs were selectively concentrated from environmental water samples without disturbing their sizes and shapes by Triton X-114 (TX-114)-based cloud point extraction (CPE). The enrichment factor was 100 and the recoveries from various environmental samples were in the range of 57-116% at 0.1-146 μg/L spiked levels of AgNPs. The AgNPs preconcentrated in the TX-114-rich phase were identified by TEM/SEM-EDS/UV-Vis spectrum, and quantified after microwave digestion by ICP-MS with a detection limit of 0.006 μg/L. This proposed method can be adopted to track of AgNPs in environment. The TX-114-based CPE was also used as an efficient separation approach for the speciation analysis of AgNPs and Ag+ in antibacterial products and environmental waters. AgNPs were quantified by determining the Ag content in the TX-114-rich phase with ICP-MS after digestion, the total silver content was determined by ICP-MS after digestion, and the total Ag+ concentration was obtained by subtracting the AgNP content from the total silver content. The limits of quantification (S/N = 10) were 0.4 μg/kg for AgNPs, 3 μg/kg for total Ag+, and 0.2 μg/kg for total silver, respectively. This proposed method is applicable for studying the transformation of AgNPs in environment and the toxic effects of AgNPs and Ag+. To elucidate the toxical roles of the freely dissolved Ag+ and the AgNP-adsorbed Ag+, hollow fiber supported liquid membrane (HFSLM) extraction was coupled with ICP-MS for speciation analysis of Ag+. Two extraction modes of HFSLM, the negligible depletion extraction and the full depletion extraction, were coupled to ICP-MS for analyzing the freely dissolved Ag+ and the total Ag+ content, respectively. The AgNP -adsorbed Ag+ was obtained by the difference between the total and the freely dissolved Ag+ content. The recoveries of total Ag+ in AgNPs dispersions ranged from 86% to 98% at spiking levels of 10 ppb and 20 ppb Ag+. The

detection limits of freely dissolved Ag+ and total Ag+ were 0.9 ppb and 1.5 ppb, respectively.

269 Nanomaterial Release from Products is not Related to Hazard Data: Methods and Data Lacking S. Froggett, (consultant) Center for Risk Science Innovation and Application, ILSI Research Foundation; R.A. Canady, Center for Risk Science Innovation and Application, ILSI Research Foundation. Advances in incorporation of engineered nanomaterials (ENM) into composites have occurred in tandem with the identification of possible hazards of the pristine ENM prior to compositing. However, review of research of release of ENM from nano-composites conducted for the NanoRelease project (www.ilsi.org/ResearchFoundation/Pages/NanoRelease1.aspx) shows little attention is being paid to ENM release from the composites. Consequently, it is not clear whether potential risks of that material are informed by current ENM hazard research. A crucial finding of the review is that our understanding of the risks associated with uses of nanomaterials will continue to be insufficient until substantial progress is made on methods to measure ENM release from uses of ENM. In the available reports, consumer products containing nano-silver, nano-titania and carbon nanotubes have been investigated under several exposure scenarios, including, weathering, abrasion, UV and washing. The data show three possible release scenarios: nanoscale particles of some kind (almost always, similar to materials without added ENM), nano-scale particles with some carrier matrix and some ENM (often), and finally, ENM alone (rare). This review of the nanomaterial release literature illustrates a data gap relevant to the field of environmental risk assessment. Perhaps most critical, our review suggests that fate and transport modeling, exposure assessment, and risk assessment frameworks in general for ENM uses should not be based on pristine engineered nanoparticles, but rather should be based on the released composites of ENM and the carrier matrix.

270 Comparison of Two Separation Techniques, Asymmetrical Field Flow Fractionation and Hydrodynamic Chromatography, for Mixtures of Gold Nanoparticles E. Gray, Colorado School of Mines, Environmental Science and Engineering; T. Bruton, Arizona State Univ; p. westerhoff, Arizona State Univ, Arizona State Univ, School of Sustainable Engineering and The Built Environment; R. Halden, R. Halden, Arizona State Univ; J. Ranville, Colorado School of Mines, Chemistry and Geochemistry, Colorado School of Mines; C. Higgins, Colorado School of Mines, Environmental Science and Engineering; P. Herckes, Arizona State Univ. In recent years concern has been raised over the potential for environmental release of engineered nanoparticles (ENPs) as a result of increased ENP use and production. Robust methods to detect and characterize these ENPs in environmental samples are still being developed. This paper compares two techniques currently applied to ENPs; hydrodynamic chromatography (HDC) and asymmetrical flow field flow fractionation (AF4), both coupled with inductively coupled plasma mass spectrometry (ICP-MS). The goal of this study was to determine and compare the detection limit, resolution, and recovery obtained when separating mixtures of gold particles using common flow parameters, using each technique. The limit of quantification for both techniques is approximately 5 mg/L and the limit of detection is an order of magnitude lower at 500 µg/L. AF4 is capable of separating mixtures of 5, 20, 50 and 100 nm gold ENPs with greater resolution than HDC. These resolution differences are most pronounced at the lower size range of 5 to 20 nm. Sample recovery ranged from 67 to 81 percent for HDC while AF4 recovery values range from 31 to 68 percent. The elevated sample loss observed using AF4 results from both reversible and irreversible particle attachment to the semipermeable membrane used in the AF4 channel.

271 Novel Approaches for the Detection of Single Walled Carbon Nanotubes in Environmental Matrices P. Schierz, Duke Univ, Dept of Civil and Environmental Engineering, Duke Univ, Pratt School of Engineering; A.N. Parks, P. Ferguson, Duke Univ. Single-walled carbon nanotubes (SWNT) are considered a new class of emerging environmental contaminants. Fate and toxicity studies rely heavily on reliable analytical methods to detect SWNT in environmental matrices at environmentally relevant concentrations [ppb-level]. NIRF spectroscopy has advanced as a highly selective and information-rich technique for sensitive detection and structural characterization of SWNT materials. We have demonstrated the capabilities of this technique through the quantitative analysis of SWNT in sediment and biotic matrices at environmentally relevant concentrations. The analytical power of NIRF allows for the structural characterization of SWNT samples before and after toxicity, bioavailability and fate studies. Furthermore, for an assessment of the environmental fate of SWNT such as transport behaviour and bioavailability, structural information including shape, length distribution andagglomeration state are essential. Our approach to address these analytical challenges is the use of asymmetric field flow field fractionation AF4 as a separation method prior to NIRF spectroscopic analysis to determine SWNT length distribution and to reduce matrix complexity by separation of NOM and SWNT. Metal catalyst residues (e.g., Co, Mo, Ni, Fe, etc.) are known to be associated with SWNT as a byproduct of the manufacturing process. We have examined the potential of AF4 coupled with inductively coupled plasma-mass spectrometry (AF4-ICP-MS) to trace CoMoCat SWNT in environmental samples from the presence of residual Co and Mo metal catalysts. The use of AF4-NIRF and AF4-ICP-MS in concert will facilitate a more thorough understanding of the environmental fate, transport, and behavior of SWNT.

272 Screening Waters Impacted by Municipal Wastewater for Metal-bearing Nanoparticles by Single Particle-Inductively Coupled Plasma Mass Spectrometry E.M. Heithmar, US Environmental Protection Agency, Office of Research and Development, National Exposure Research Laboratory, USEPA, Research Chemist; S.A. Pergantis, Univ of Crete, Chemistry; E.M. Siska, Student Services Contractor to EPA. Metal – and metal oxide- based engineered nanomaterials are being increasingly used in consumer products in either intentionally or incidentally dispersible forms, and their release into municipal wastewater streams is inevitable. In order to obtain an estimate of their current occurrence and an upper-bound of their concentration in waters impacted by municipal wastewater, a rapid method for screening these waters is required. We have previously presented a preliminary application of single particle-inductively coupled plasma mass spectrometry (SP-ICPMS) for the screening-level analysis of surface water for metal-bearing nanoparticles. In this study, we apply SP-ICPMS to analysis of water significantly impacted by municipal wastewater. The increased continuous background and matrix effects associated with the more complex matrix and methods for mitigating these will be discussed. The benefits of recently introduced instrumentation on the analysis will be demonstrated. In addition to targeted determination of silver-, titanium-, and cerium-bearing nanoparticles, a novel approach to rapidly screen for a range of metals will be presented. Results for several water samples taken immediately downstream from municipal wastewater treatment plants in the US will be presented.

273 Comparison of Nanoparticle Characterisation Methods Using Specifically Tailored Multimodal Particle Suspensions A. Jamting, National Measurement Institute, Nanometrology Section; V.A. Coleman, H.J. Catchpoole, M. Roy, J. Herrmann, National Measurement Institute. Understanding the impact of engineered and naturally occurring nanoparticles on environmental and biological systems is of critical importance, particularly when assessing risks. In order to evaluate the impact, nanoparticle systems need to be fully characterised to correlate physico-chemical properties with observed effects. It is therefore essential that the characterisation instrumentation is rigorously understood in terms of detection sensitivity, measurement range and validity. The National Measurement Institute Australia has established a comprehensive nanoparticle characterisation laboratory and is developing expertise in a range of characterisation methods for nanomaterials. One of the complexities of this area of investigation is that different instruments measure different physical properties or measurands to derive particle size. Here we present results from a range of measurements on multimodal suspensions of well characterised materials to highlight the benefits and limitations of different particle sizing instrumentation. The techniques investigated include dynamic light scattering, differential centrifugal sedimentation, transmission electron microscopy, asymmetric flow field-flow fractionation coupled with static and dynamic light scattering detectors, nanoparticle tracking analysis and a recently developed instrument based on single particle measurements using a micro-channel resonator, providing ultra high-resolution mass sensing.

274 Cumulative Impacts of Mountaintop Mining on an Appalachian Watershed T. Lindberg, R. Di Giulio, Duke Univ, Nicholas School of the Environment ; E. Bernhardt, Duke Univ, Biology. Surface mining is the dominant driver of land cover and land use change in Northern and Central Appalachia. Some watersheds in West Virginia have more than 25% of their area covered by surface mine permits. Studies show that at 10% there is a

decline in biodiversity and water quality. Our study system on the Upper Mud River in West Virginia, USA has been extensively mined since the 1970's. From its headwaters to a point 14km downstream, 49% of the 56sq. km watershed has been impacted by surface mining. During our study we found average stream conductivity to be 10 to 15 times greater than typical unmined Appalachian streams. During four monthly surveys we sampled the stream 52 times at 15 sites and found that average stream conductivity increased from 156 µS cm-1 upstream of mining activity to 1525 µS cm-1downstream of the last impacted tributary. Our synoptic approach to sampling the Upper Mud River was novel in that we were able to capture water chemistry data from the headwaters above all current and historical surface mining, within each affected tributary and then from points upstream and downstream of each confluence. At this scale we were able to show conclusively the cumulative impacts on mainstem water quality due to multiple inputs from watersheds that receive surface mine effluents. To further quantify the connection between surface mining and water quality we utilized spatial analysis to measure the areal upstream proportion of the watershed that was surface mined at 15 sampling points on the mainstem and then correlated that to the measured concentrations of mining related pollutants and conductivity. We found that increasing concentrations of sulfate, selenium, magnesium, calcium, and others were significantly correlated ($R2>0.85$, $p< 0.0001$) to the amount of upstream mining disturbance. Median conductivities had a correlation of 0.96 meaning almost all of the change in conductivity from upstream to downstream sites could be explained by the amount of upstream surface mine activity in the watershed. We also provide evidence that although reclamation of these mines may provide some decrease in the mobilization of nitrogen and selenium; it appears that dissolution of weathering related minerals that contribute to high conductivity in the receiving stream remain high decades after reclamation.

275 Longitudinal Effects of Coal Mining/Valley Fills on Benthic Invertebrate Communities of Streams in Southern West Virginia S.P. Canton, GEI Consultants, Inc., Ecological Division; J.S. Lynch, GEI Consultants, Inc; R.W. Gensemer, GEI Consultants, Inc, Ecological Division; G.D. DeJong, C.F. Wolf, GEI Consultants Inc. We sampled the benthic macroinvertebrate populations of 12 streams in southern West Virginia, including nine streams with valley fills present in the upper reaches and three reference streams with no mining impacts. The proposed ecological impacts of coal mining/valley fill (CM/VF) operations on benthic invertebrate communities have been linked primarily to elevated concentrations of total dissolved solids, but spatial variability in water quality and benthic communities is poorly understood in these systems. The goal of this study was to determine the nature and extent of potential impacts that exist from the valley fill and associated impoundment and the downstream extent of those impacts. Parameters analyzed included density, number of taxa, number of EPT taxa, and relative abundance of mayflies, concurrent with matching water quality parameters (i.e., temperature, conductivity, calcium, potassium, sodium, magnesium, carbonate, bicarbonate, sulfate, chloride, pH, hardness, nitrate-N, and selected metals), habitat, periphyton, and detrital parameters. Longitudinal differences between sites on the same stream and between CM/VF and reference streams were observed, with some streams showing improvement in metric values in a downstream direction. Most invertebrate parameters were significantly different between CM/VF and reference streams at the most upstream site but were not significantly different at the most downstream site. Correlations between invertebrate metrics and water quality and habitat parameters were observed. Analysis of the pooled water chemistry data indicated that most of the differences observed between CM/VF and reference sites were statistically significant ($p \leq 0.01$). CM/VF sites had significantly higher median values than reference sites for bicarbonate, calcium, chloride, magnesium, nitrate, potassium, selenium, sodium, sulfate, conductivity, hardness, pH, and temperature. We conclude that invertebrate assemblages in streams below valley fills did, indeed, differ from those in reference streams in some respects, with invertebrates often being abundant in both types of streams but having fewer taxa and EPT taxa represented in CM/VF streams. Overall, it appears the composition of the invertebrate assemblages observed in these streams varies as a result of a combination of ionic chemistry, soil characteristics related to iron and aluminum, substrate characteristics, and channel features related to erosion.

276 Do Water Quality and Habitat Conditions Affect Macroinvertebrate Communities in Headwater Streams in Southern West Virginia? S.P. Canton, GEI Consultants, Inc., Ecological Division; G.D. DeJong, R.W. Gensemer, GEI Consultants, Inc. We described the benthic invertebrate communities inhabiting the extreme upper reaches of headwater streams in the coal mining region of southern West Virginia. These headwaters are representative of ephemeral or intermittent steams where mountaintop coal mining/valley fill (CM/VF) operations occur. The proposed ecological impacts of CM/VF operations on benthic invertebrate communities have been linked mostly to elevated concentrations of total dissolved solids, but direct loss of headwaters communities is also of concern. Most ecological studies conducted in the extreme headwaters of freshwater streams focus primarily on terrestrial/aquatic linkages and not the composition of the aquatic communities. Therefore, we sampled 12 headwater streams in three different protected natural areas of southern West Virginia to evaluate the natural variability of their benthic invertebrate communities. A diverse benthic invertebrate community was found, consisting of at least 129 benthic invertebrate taxa. Variability analyses revealed low levels of similarity between the invertebrate communities in headwaters streams. Benthic habitat was similar among sites, with the same kinds of habitat features occurring at most sites. Correlation analyses of water chemistry parameters (conductivity, calcium, potassium, sodium, magnesium, carbonate, bicarbonate, sulfate, chloride, pH, hardness, nitrate-N, and selected metals) with benthic invertebrate metrics (number of taxa, number of EPT taxa, percent EPT taxa, and Ephemeroptera abundance) showed that water chemistry parameters were not strong predictors of the benthic invertebrate metrics. The strongest relationship was a negative correlation between potassium concentration and the number of EPT taxa. Only two correlations between water chemistry and invertebrate community parameters were statistically significant ($p < 0.050$), both involving potassium concentrations. There were no significant correlations between conductivity and any benthic invertebrate metric. pH was low (< 6.0) at some sites where EPT taxa were not encountered as frequently, but this was not a consistent pattern. Our study suggests that the taxa encountered and levels of dissimilarity between the invertebrate communities in headwaters streams with otherwise similar habitat and water quality are consistent with the hypothesis that headwaters communities are established opportunistically from a larger regional pool of organisms.

277 In Situ Quantification of Major Ions to Improve Detection/Remediation of Threats to Environmental Health A. Mueller, H. Hemond, Massachusetts Institute of Technology, Dept of Civil and Environmental Engineering. It is well known that the quantity and balance of major ions has profound effects on ecosystem structure and health and can drive changes in natural floral and faunal species. Unfortunately, ecological studies are often forced to rely exclusively on indicator measurements, such as pH and electrical conductivity, when completing in situ assessments due to the high cost of traditional grab sampling campaigns. This generally leads to availability of only incomplete and low-resolution data which may not provide the information necessary to diagnose or remediate threats to specific ecosystems. One such historical example was identification of the causes of stream acidification: while sulfate deposition was initially suspected, further research pointed to substantial contributions from nitrogen species as well. In contrast, data covering the full spectrum of dissolved ionic species and available in real-time would provide researchers the ability to lead high-resolution, adaptive sampling campaigns from the start, resulting in more precise identification of problem regions and better targeted grab sampling should high accuracy lab analysis be required. To address this gap, we have undertaken development of an in situ instrument for real-time identification of dissolved ion species, initially targeting both the dominant ionic species and those frequently involved in eutrophication processes, specifically: Na^+, K^+, Ca^{2+}, Mg^{2+}, NH_4^+, Cl^-, NO_3^-, SO_4^{2-}, CO_3^{2-}, and H^+. This instrument relies primarily upon ion selective electrode technology, coupled with novel signal processing algorithms that allow mixed responses to be successfully decoupled. Relevant environmental parameters, e.g., temperature and electrical conductivity, are measured simultaneously and provide additional information to improve the accuracy of the signal processing results. An initial test of this combined hardware/software technique has been undertaken using data provided by the US Geological Survey, collected over the past 50 years using traditional sampling techniques. Response of instrument hardware to similar samples allows simulation of sensor responses to all points in this 50-year data set. Samples are then run through the software algorithm with results analyzed for both accuracy and precision over a wide range of ionic concentrations.

278 Total Dissolved Solids Concentrations of Tecolote Creek, San Diego, CA; Effects on Sentinel and Native Species B.J. Mastin, Weston Solutions, Inc., Natural Resources; S. Gruber, Weston Solutions, Inc., Weston Solutions; W. Isham, Weston Solutions, Inc., Natural Resources. Identification and measurement of ionic strength as a causative agent of toxicity is difficult due to site-specific, species-specific, and ion-specific responses by freshwater biota. Concentration and composition of ionic strength are influenced by the localized topography and geology of the drainage, atmospheric deposition, changes in land use, storm water management, irrigation, agricultural activities, industrial effluents, salting of roads, and other anthropogenic activities which can alter the associated hydrology of the watershed. For example, researchers have documented that if untreated, increased TDS concentrations of oilfield produced waters, hydraulic frack fluids, and mine drainages were the causative agent of toxicity to downstream biota and a primary source of benthic community impairment. Ionic strength will increasingly influence biotic diversity in sensitive arid and semi-arid regions as climate patterns continue to shift our regional water balances. Recently, several states (e.g., Florida and West Virginia) have adopted water quality criteria which address the importance of monitoring ionic strength for the protection of freshwater biota. The objective of these experiments was to measure potential effects of total dissolved solids (TDS) concentrations of Tecolote Creek (an urbanized watershed in San Diego, CA) during dry weather on both native and sentinel laboratory species that represent the macroinvertebrate diversity and sensitivity residing within the Tecolote Creek Watershed. Serial dilutions (i.e., six concentrations) were prepared with high conductivity water (> 5,000 to 11,000 µS/cm) collected from Tecolote Creek tributaries and diluted with water from an un-urbanized reference creek (approximately 300 µS/cm). Toxicity bioassays with sentinel laboratory species included *Ceriodaphnia dubia* (48-h survival and 7-d reproduction), *Hyalella azteca* (48-h survival), *Chironomus tentans* (48-h survival), *Rhapidocelis subcapitata* (96-h growth), and an Isonychia spp. (48-h survival) and native test organisms including both an Ephemeroptera (mayfly) and Plecoptera (i.e., stonefly) species (48-h survival). *C. dubia* reproduction was the most sensitive endpoint to increased ionic strength compared to *H. azteca* and *C. tentans* survival which was not observed to be affected in this high TDS water. Preliminary results of water chemistry and benthic community assessment will also be discussed as part of this presentation.

279 Potential Impacts from Short-duration Exposures to Storm Water Runoff on the Rocky Intertidal Community of a Marine Preserve S. Gruber, Weston Solutions, Inc., Weston Solutions; D. McCoy, Weston Solutions, Inc.; B.J. Mastin, Weston Solutions, Inc., Natural Resources; R. Kolb, City of San Diego. As part of a larger study for the City of San Diego, Weston Solutions assessed the impacts of storm water on the rocky intertidal biological community in the La Jolla Area of Special Biological Significance (ASBS), a designated marine preserve. The assessment used a triad approach: water chemistry, toxicity to native marine species, and algal and biological surveys. Conditions during a storm event at the La Jolla ASBS were compared to a coastal reference site (Cabrillo National Monument), which is not influenced directly by storm water runoff. Water samples were collected for chemical and toxicological analyses at the La Jolla site over the course of a storm event (i.e., pollutograph) directly from a storm drain outfall as well as from the ocean receiving waters in the ASBS rocky intertidal habitat. Storm water samples were used in the laboratory to mimic the exposure to storm water that marine test species (e.g., abalone, sea urchins, diatoms, bivalves, and mysid shrimp) would experience over a tidal cycle (i.e., 6-h storm water exposure followed by a seawater flush for the duration of the test). Chemistry results showed that, during low tide, concentrations of pyrethroid pesticides and some metals at the La Jolla site were similar to those in storm water runoff and greater than LC50s of native marine organisms. Salinity at the La Jolla site was less than 3 ppt in the receiving waters during low tide, but never fell below 32 ppt at the reference site during the same storm event. Toxicity results indicate that short-term exposure (6 hours) to storm water runoff is toxic to marine organisms and exposure to fresh water during a storm may have more of an impact than exposure to pesticides and metals associated with the storm water outfall. Biological surveys showed distinct differences between the La Jolla ASBS and reference sites, possibly reflecting the long-term exposure to storm water runoff over several decades. The results have important implications for managing storm water discharges to ocean receiving waters and the ASBS with respect to new regulations designed to protect the beneficial uses of this important coastal habitat.

280 Short-term and Long-term Exposure Impacts of Diluted Desalination Brine Discharge to Various Biological Receptors S. Bodensteiner, Weston Solutions, Inc., Weston Solutions. Available disposal options for the high-salinity sidestream generated during the desalination process (i.e., brine) is a key limiting factor with construction of seawater desalination plants. If there is not a nearby or co-located wastewater treatment plant generating fresh water effluent available to blend with a high salinity brine stream, then a desalination plant must rely on ambient seawater to dilute the brine to an ecologically innocuous salinity level. This is commonly accomplished by blending brine with either receiving water intake or cooling water discharge from a co-located power plant. Seawater reverse osmosis desalination plants are typically designed for recovery of 45% to 55% as fresh water, leaving a brine discharge salinity of approximately twice that of marine receiving waters. The operational costs for seawater desalination plants is therefore influenced by the volume of ambient seawater necessary to dilute the brine to a level that does not pose any significant threat to marine life within the discharge environment. Although it has been demonstrated that salinity levels up to 57 parts per thousand have not caused statistically significant changes to the overall function and quality of the aquatic environment in the discharge area, most desalination plants are restricted by discharge permit criteria that are based on toxicological impacts to single sensitive receptors. This study evaluates the impacts of varying brine discharge dilutions to critical life stages of several biological receptors in both short-term and long-term exposure scenarios. The suite of receptors was a mix of species accustomed to either hard surface or sandy bottom substrates in order to represent the two most common marine discharge environments. In addition to a comprehensive assessment of short and long-term exposure impacts to brine diluted with ambient seawater, the study also investigated potential effects of different ion ratios within the standard suite of Total Dissolved Solids (Ca, Mg, Na, Cl and SO_4). This component was included to assess the differences in ecological impact between brine discharges diluted with ambient seawater and those diluted with effluent from wastewater treatment plants. In general, the occurrence of significant impacts was driven primarily by the type of life stage evaluated.

281 Case Study of Effluent Discharged in Transition Zone of Freshwater and Estuaries W.L. Goodfellow, EA Engineering Science & Technology, Inc.; W. McCulloch, EA Engineering, Science & Technology, Inc., Dept of Ecotoxicology; M.K. Chanov, EA Engineering, Science and Technology, Inc., Dept of Ecotoxicology. Industrial wastewater containing total disolved solids that are discharged to estuaries or rivers are often conplicated by the regulatory classification of the ecosystem. In situations that are in this transition from freshwater to estuarine systems, the organisms that are used for the whole effluent toxicity assessment are typically not organisms that are found in this system and the WET test is not always an indicator of the effluent's risk to the environment. Through the presentation of this case study, this paper will present the potential impacts of a TDS discharge to a large river in an upper estuary and provide recommendations and observations for these effluent discharge situations.

282 Linking Science and Policy to Inform Global Mercury Negotiations N.E. Selin, Massachusetts Institute of Technology, Engineering Systems Division. Global negotiations to address the risks posed by mercury are informed by scientific input of different forms, from peer-reviewed scientific papers to structured scientific assessments to informal science-policy dialogue. Recent insights from global-scale mercury modeling are highlighted in the context of ongoing negotiations towards an international, legally-binding mercury instrument. In particular, the role of historical versus present-day sources is highlighted, focusing on the long-term prospects for mercury exposure reductions. Additionally, the process by which science informs international mercury negotiations is examined and illustrated. Results from multiple iterations of a role-playing simulation focused on mercury are used to draw lessons about the uses and effectiveness of the provision of scientific information to international negotiators. Results are used to suggest potential avenues for scientific participation in the final two sessions of the global mercury negotiations.

283 Climate Change as a Driver for Mercury Bioaccumulation in Aquatic Ecosystems: Implications for Mercury Emission Control Under a Changing Climate F. Wang, Univ of Manitoba, Centre for Earth Observation Science, Dept of Environment and Geography. The stubbornly high and spatiotemporally variable concentrations of mercury (Hg) in Arctic

marine mammals have been a major subject of scientific research and policy debate. There is no doubt that Hg emission from anthropogenic activities in southern latitudes has played a major role in Hg contamination in Arctic marine ecosystems. What makes the Hg contamination phenomenon in the Arctic especially puzzling is, however, the apparent lack of an atmospheric-biological dose-response relationship in recent decades. Based on extensive research in the Arctic Ocean, we recently published a hypothesis that, under a rapidly changing climate, internal post-depositional processes within the system can overtake external emission sources in controlling Hg bioaccumulation in aquatic ecosystems. This hypothesis is further supported by new data from the Arctic Ocean and the Equatorial Pacific Ocean where climate-induced changes in the cryosphere and marine primary productivity, respectively, are shown to significantly modify the atmospheric Hg loadings. This shift in the paradigms in driving Hg bioaccumulation suggests that during a rapidly changing climate, emission control of Hg will be followed by long delays before ensuing reduction is seen in food-web Hg levels. The response lag makes it all the more urgent for the UNEP treaty to control further loading of Hg (and potentially other types of contaminants) into key environmental reservoirs. It also highlights the need of partnerships among scientists, policy-makers and local communities to develop short- and long-term adaptation and remediation strategies before the effectiveness of Hg emission control is realized.

284 Global Mercury Trends and Local Ecosystem Recovery L. Levin, Electric Power Research Institute, Air Toxics Health & Risk Assessment; K. Lohman, Environ Corp. As national steps are taken to reduce mercury emissions to the atmosphere, one issue remains unresolved: how much and how quickly will domestic ecosystems respond to reduced emissions from distant and nearby sources and the resulting changes in atmospheric deposition. Aquatic fish populations act as band-pass filters for mercury deposition and methylation over time, serving as interannual transfer systems for methylmercury mass within the system. Local and regional emission changes may be overlain by longer-range opposing trends in emissions and complex responses in water bodies and ecosystem receptors. Recent work by the HTAP (Hemispheric Transport of Air Pollutants) conference and other researchers shows how sensitive and with what rate local ecosystems may respond to global and local changes.

285 Integrating Knowledge to Inform Mercury Policy: The IKIMP Initiative J. Holmes, M.N. Gardner, T.A. Mather, D.M. Pyle, M.L. Witt, Univ of Oxford, Dept of Earth Sciences. It is essential that national and international initiatives to reduce the risks posed by mercury in the environment are informed by the best scientific knowledge of the sources of mercury in the environment and the options for reducing future human exposure to mercury. This paper will summarise the outputs of a project undertaken over the last three years at the Univ of Oxford to develop, integrate and present this knowledge to inform policy making at UK, European and global levels. Effective action to address anthropogenic emissions of mercury requires an understanding of the relative contributions of anthropogenic and natural sources, in particular from primary emissions to the environment such as crustal degassing. An updated national inventory has therefore been developed for the UK, identifying mercury sources and waste streams, and evaluating the adequacy of current monitoring arrangements. At a global level, an improved understanding of natural reservoirs of mercury, exchange fluxes between them, and the impact of climate change has been sought. Following evaluation of uncertainties in anthropogenic emissions of mercury, the project has focused on a review of mercury arising from the oil and gas industries. Policies are being developed nationally and internationally to withdraw mercury from the socio-economic system, requiring options to be developed for mercury storage and disposal. The current state of development of these storage/disposal technologies has been reviewed, and a decision framework has been developed which has informed discussions associated with the United Nations Environment Programme's initiative to develop a global instrument on mercury. A key aim of the project has been to enhance the availability of relevant information and understanding to policy processes at national and international levels. The paper will reflect on our experience of policy engagement over the last three years.

286 Mercury Remediation in Kazakhstan: Exploring Interactions Between Nanoscale Zero-valent Iron and Sulfate-reducing Bacteria A. Kajenthira, Harvard Univ, Harvard Kennedy School; I. Thompson, Oxford Univ, Dept of Engineering Science; A. Crossley, Univ of Oxford, Dept of Materials; M.N. Gardner, Univ of Oxford, Dept of Earth Sciences. The ecological and human health risks posed by the volatility of mercury in the environment are undeniable. Although UNEP's internationally binding treaty on the use of mercury is anticipated in early 2013, the global legacy of mercury contamination has necessitated continued research into efficient and cost-effective remediation technologies. This study focused on the remediation of a groundwater mercury plume associated with the Khimprom Plant in Kazakhstan, and evaluated the potential of nanoscale zero-valent iron (nZVI) particles for the immobilization of Hg(II) in aqueous media. Although nZVI has shown substantial potential for the remediation of chlorinated organic solvents and heavy metals, its possible adverse effects on the bioavailability of other toxins or nutrients, as well as other indirect ecosystem effects, are largely unknown. More specifically, nZVI has been reported to have the potential for cell membrane disruption in *E. coli*, but its possible influence on obligate anaerobes – such as the sulfate-reducing bacteria that form the largest biological component of the global mercury cycle – remain unclear. Further, as the proliferation of sulfate-reducing bacteria can be highly sensitive to the bioavailability of iron, the application of nZVI could impact both mercury and iron concentrations within the environment. This study evaluates the impact of nZVI on the growth of a model sulfate-reducing bacterium: *Desulfovibrio desulfuricans* subsp. *desulfuricans* (DSM 6949), and measures aqueous iron concentrations following nZVI amendment with the goal of establishing the utility of nZVI as a Hg(II) remediation technology. It was found that nZVI had little or no significant detectable impact on bacterial growth kinetics when applied at concentrations of up to 100 mg/L. In addition, although aqueous Fe(II) ions resulted from the Hg(II)-nZVI sorption process, total Fe concentrations in solution returned to pre-amendment concentrations following the growth of DSM 6949 to maximum culture capacity. It was consequently hypothesized that aqueous Fe(II) ions were metabolized during the growth of DSM 6949. A complementary remediation approach for the Khimprom Plant that utilizes both nanoscale Fe(0) and sulfate-reducing bacteria could therefore enhance the overall potential for mercury immobilization while minimizing environmental impact.

287 Methylmercury as a Brain Drainer P. Grandjean, Univ of Southern Denmark, Environmental Medicine. The fetus and the child are particularly vulnerable to pollution. The fetus shares the mother's exposure and accumulated body burdens of pollutants, and many chemicals are transferred to the infant via human milk. In addition, during early life, cell differentiation and organ development must happen in a particular sequence and at particular times to create optimal functions of the mature organism. The brain is uniquely sensitive to toxicity during development, and adverse effects can have serious consequences, as we depend on the integrity of the complete organ for optimal functioning. Because there is only one chance to develop a brain, even doses that are safe for adults may, if occurring during early development, cause permanent IQ loss. Research on neurobehavioral deficits in humans relies on 'natural' experiments and faces many obstacles, in part because the best evidence requires prospective studies of birth cohorts lasting at least until school age. Because of the paucity of data, there has been a tendency to ignore risks of developmental neurotoxicity caused by methylmercury and other chemicals known to be hazardous to the human nervous system. However, during the last 10 years or so, methylmercury exposures previously thought to be safe have been reliably linked to adverse effects on brain development in children. As the children grow, the full impact of the toxicity is becoming apparent. We have now followed a Faroese birth cohort up to age 22 years and demonstrated that the methylmercury-associated effects do not disappear. So the neurodevelopmental delay must now be recognized as a permanent brain drain. The methylmercury experience is a reminder that research is unlikely to provide a sufficient basis for decision-making in regard to pollutants, especially since chemical substances are not systematically screened for neurotoxicity. As optimal brain function is crucial to each individual as well as to society, new and precautionary approaches are required both for research and for decision-making on chemical testing and control.

288 US State Mercury Initiatives Demonstrate Need For Global Action To Reduce Mercury Pollution And Highlight Successful Strategies C.M. Smith, Massachusetts Dept of Environmental Protection, Office of Reseacrh and Standards. Mercury (Hg) total maximum daily load (TMDL) analyses for New England (NE), NY, NJ and MN indicate that anthropogenic Hg inputs to freshwaters may need to be reduced up to 98% to achieve statewide targets for freshwater fish consumption. Due to air transport,

reductions in regional, national and global sources are needed. Many states are pursuing aggressive Hg reduction strategies and coordinate activities through the Environmental Council of States Quicksilver Caucus (QSC), a consortium of interstate organizations, and regional initiatives such as the New England Governors and Eastern Canadian Premiers Hg Action Plan (MAP). States have considerable flexibility to address environmental issues and have taken many steps to address Hg sources that exceed federal requirements. For example, the MAP, adopted in 1998, established a long-term goal of virtually eliminating Hg pollution sources in the region. The MAP uses an adaptive management approach and includes emission reduction milestones of 50% by 2003 and 75% by 2010 vs. a mid-1990s baseline (achieved); and, by 2010, use of amalgam separator pollution controls by 95% of dental offices (achieved by most jurisdictions). The MAP also includes pollution prevention, outreach and monitoring elements. A regional Hg Task Force (MTF) was established to coordinate MAP implementation, adjust elements of the MAP and report on progress to senior political and environmental leaders. Under the MAP stringent emission limits have been adopted for many sources including coal-fired power plants (e.g., MA regulations will require 95% control by 2012). NE states also adopted Hg products legislation requiring manufacturers to label Hg-added products and to: phase-out unnecessary uses; notify of ongoing sales; and, enhance recycling, of Hg-added products. Monitoring of Hg levels in freshwater fish in MA demonstrates improvement coincident with reduced local and regional emissions but levels remain too high. To address global sources that contribute significantly to Hg deposition the MTF and QSC are providing input to the USEPA and State Dept on the global Hg agreement negotiations. States have advocated for improved inventories of Hg releases and uses; improved monitoring; comprehensive multimedia planning that crosses traditional discipline and agency boundaries; adaptive management approaches; overarching stretch goals with measureable milestones; and reporting mechanisms to track progress.

289 Wetlands – Implication on the Global Mercury Pollution J. Canario, IPIMAR, Aquatic Environment Dept, INRB IP/IPIMAR, Aquatic Environment and Biodiversity; C. Vale, INRB IP/IPIMAR. The overall goal of the UNEP Global Mercury Partnership is to protect human health and the global environment from the release of mercury and its compounds by minimizing and, where feasible, ultimately eliminating global, anthropogenic mercury releases to air, water and land. Besides the decrease on mercury emissions in the northern hemisphere in the last decade, the amount of mercury circulating in the environment is still of great concern. This issue assumes a major problem in ecosystems, which due to their physical/chemical/biological characteristics, exchange mercury species mainly Hg^o (mercury volatile) and MeHg (methylmercury) with the atmosphere and food web, respectively. Wetlands, particularly salt-marshes, are among these key ecosystems where these Hg transformations and Hg escape occur. Mercury studies in Portuguese salt-marshes showed that salt-marsh plants and the surrounding rizhosphere environment are important areas of mercury retention and methylation. Levels of up to 30% of MeHg in salt-marsh sediments contrasting to the 0.01% of MeHg in non-vegetated ones and higher concentrations of both Hg and MeHg in root biomass poses a serious debate about whether salt-marshes are efficient for Hg phytoremediation. Additional studies in Portuguese salt-marsh plants in contaminated areas also showed that macrophytes are important sources of Hg^o to the atmosphere. Mercury vegetation-air fluxes measured in two salt-marsh plant species showed Hg^o emissions during three consecutive days, indicating that these ecosystems can act also as an important natural mercury source. The export nature of these ecosystems for mercury has been shown. These findings have serious implications on mercury pollution especially concerning mercury fate and speciation in wetland contaminated areas. Based on our work we believe that the definition of a global mercury policy must take into account wetland areas which occupied up to 9 million km^2 of earth surface therefore incorporating these ecosystems in the UNEP monitoring and assessment mercury programs. Two types of measures should be envisaged. Encourage better understanding of mercury transformation and fluxes in key areas of the world, namely wetlands and areas where mercury is used in industrial processes. Improve technologies to reduce the mercury emissions and to sequestrate mercury in inorganic forms.

290 Terrestrial Ecological Risk Assessment to Support RCRA Facility Management Decisions at the Hanford Nuclear Reservation L. Williams, Integral Consulting Inc.; B. Tiller, Environmental Assessment Services; M. Connelly, Washington River Protection Solutions. The Inner Area of the Hanford Nuclear Reservation's Central Plateau is a 10-square mile mosaic of industrialized areas and highly fragmented and often disturbed sagebrush-steppe habitat. The Inner Area has been used for nuclear fuel processing and waste management and waste disposal activities, including several tank farms that collectively had received 53 million gallons of radioactive waste. Past spills and leakages at the tank farms are suspected of releasing up to 1 million gallons of mixed radioactive and non-radioactive materials to surface and subsurface soils. Waste Management Area C is an 8.5-acre tank farm that is undergoing a RCRA facility investigation and cleanup pursuant to closure within the next few years. An ecological risk assessment is being undertaken for Waste Management Area C to evaluate threats to terrestrial habitat that may be associated with past releases of chemicals and radionuclides under a no-action cleanup alternative. The ecological risk assessment uses a site and receptor-specific approach that integrated requirements in EPA, DOE, and Washington State regulations or guidance. Plant, invertebrate and wildlife species that are indigenous to the Columbia Plateau were selected as receptors of interest. Risk will initially be evaluated by comparison of ecotoxicity thresholds with contaminant concentrations in soils. A secondary line of evidence based on tissue chemistry for small mammals collected in the vicinity of the tank farm will be used to assess risk to higher trophic level predators. The terrestrial ecological risk assessment approach will also be used to help define site-specific cleanup goals, to facilitate selection of corrective action alternatives and to assist in evaluating post-closure conditions associated with an engineered soil cover.

291 Evaluation of Biointrusion in Support of Remedial Planning for the Central Plateau of the US Dept of Energy Hanford Site B. Sample, Ecological Risk Inc.; P. Seeley, Cenibark International, Inc.; J. Lowe, CH2M HILL Plateau Remediation Company; M. Markin, CH2M Hill. Remediation of the Central Plateau of the Hanford Site requires definition of the remedial depth (i.e., the point of compliance). Under the State of Washington Model Toxic Control Act (MTCA), the point of compliance for terrestrial ecological considerations can be adjusted based on site specific conditions, the assumed biologically active zone (6 ft) or at the standard point of compliance assuming no institutional controls (15 ft). This study was undertaken to identify and bound the biologically active soil zone as an appropriate point of compliance. Literature on animal burrowing and plant rooting depths was identified. Considerable primary data are available for depths to which ants, mammals, and plants may exploit the surface soil column at the Hanford Site and other comparable locations. The maximum depth observed for harvester ants (*Pogonomyrmex* spp.) was 270 cm (8.9 ft), with only trivial excavation below 244 cm (8 ft). Badgers (*Taxidea taxus*) are the deepest burrowing mammal at the Hanford Site, with maximum burrow depths of 230 cm (7.6 ft); all other mammals did not burrow below 122 cm (4 ft). Shrubs are the deepest rooting plants with rooting depths to 300 cm (9.8 ft) for antelope bitterbrush (*Purshia tridentata*). Two of the most abundant shrub species did not have roots deeper than 250 cm (8.2 ft). The deepest rooted forb had a maximum root depth of 240 cm (7.9 ft). All other forbs and grasses had rooting depths of 200 cm (6.6 ft) or less. Spatial distribution and density of roots over depths were also evaluated. These data indicate that the biologically active soil zone in the Central Plateau does not exceed 300 cm (9.8 ft), the maximum rooting depth for the deepest rooting plant. The maximum depth at which most other plant and animal species occur is substantially shallower. No mammals burrow to depths greater than 230 cm (7.6 ft). Although the maximum excavation by harvester ants is 270 cm (8.9 ft), trivial volume of soil is excavated from depths below 150 cm (~5 ft). Most root biomass (>50-80%) is concentrated in the top 100 cm (3.3 ft), and at the maximum depth, only trace root biomass is present. Based on these data, a site-specific depth of 305 cm (10 ft) is proposed for the Central Plateau at Hanford Site as the depth in soil below which it may be reasonably expected that contaminants do not pose a threat to terrestrial plants or animals.

292 Risk Based Soil Concentrations for the Protection of Wildlife at the US Dept of Energy Hanford Site C. McCarthy, CH2M Hill, Environmental Services; B. Sample, Ecological Risk, Inc.; J. Lowe, CH2M HILL Plateau Remediation Company; M. Markin, D. Wright, H. Awata, CH2M Hill. Risk-based soil concentrations for wildlife were developed as part of a tiered framework for derivation and application of values to support risk management for the US Dept of Energy Hanford Site. Generic values were initially identified from published sources (EPA, MTCA, ORNL,

DOE) that correspond to the no-effect based thresholds generally used in screening-level ecological risk assessments (SLERAs) with applicability across North America or the State of Washington. Tier 1 values were derived, still as literature-based values, by employing the exposure dose models used in the EPA's EcoSSLs and DOE's A Graded Approach for Evaluating Radiation Doses to Aquatic and Terrestrial Biota but specifically for bird and mammal species present at the Hanford Site. Tier 1 values generally correspond to the effect thresholds that would be employed in SLERAs, Step 3b of EPA's Risk Assessment Guidance for Superfund, or Site-specific Terrestrial Ecological Evaluations under MTCA. Tier 1 values are intended to differentiate between COPECs, receptors, and locations for which a conclusion of no unacceptable risk can be made and those for which risk may exist but current data are insufficient to support a definitive conclusion. Tier 2 values were also developed for non-radionuclides by updating the exposure assumptions of the Tier 1 models through integration of available Hanford specific bioaccumulation data with that from existing data sets. Data for soil paired with plants, terrestrial arthropods, and small mammals from the data sets that supported existing bioaccumulation models (i.e., those from OSWER Directive 9285.7 55 used to develop the EcoSSLs) or from other published sources were combined with Hanford Site data to develop a set of partially site specific bioaccumulation models. For estimating exposure from consumption of invertebrates, only arthropod tissues were included to be more representative of the terrestrial environments found at the Hanford site where insects and other arthropods (e.g., spiders, etc.) are more likely to be consumed. Use of the Tier 2 values is intended to improve risk management decisions through the reduction of uncertainty associated with assumptions in the development of Tier 1 values. Tier 2 values correspond to effect thresholds to be used in a baseline risk assessment or as preliminary remediation goals (PRGs). Tier 3 values can be developed for specific localized application but have not been developed to date.

293 Statistical Methods to Evaluate Soil Bioassay Results from Heterogeneous Soils and Multiple Collection Events W. Swanson, R. Ryti, Neptune and Company, Inc.; D. Jacques, Washington Closure Hanford. Among the lines of evidence evaluated in ecological risk assessments, bioassays performed with site-specific soils can be one of the most relevant and diagnostic of the potential for adverse effects on specific receptors. However, the results of the bioassays vary as a result of laboratory conditions (moisture, light, test organism, etc) as well as various confounding factors related to soil properties and characteristics. This paper reviews soil bioassays performed to support ecological risk assessment of upland and riparian habitat in the River Corridor portion of the Hanford Site in Washington State. Seedling germination tests using a local native species, Sandberg's Bluegrass (*Poa sandbergii*), were conducted on surface-soil samples collected from over 50 study sites in the River Corridor. The soil samples were collected from 2005 to 2008 from a variety of study sites having a wide range of contamination levels and soil characteristics. In total there were 362 different bioassay tests evaluated for over 70 contaminants and confounding factors. Statistical methods were used to evaluate overall bioassay trends, the impact of confounding factors, and draw conclusions regarding adverse effect levels of contaminants. Results for the seedling germination tests are presented to illustrate these statistical methods and the challenges related to interpreting results from this type of test.

294 Approach for Development of Plant and Invertebrate Preliminary Remedial Goals for the US Dept of Energy Hanford Site B. Sample, Ecological Risk, Inc.; C. McCarthy, CH2M Hill, Environmental Services; A. Aly, Interra; J. Hansen, United States Dept of Energy. Available literature-based soil screening values may not reflect Hanford Site specific conditions that affect analyte specific exposure/response relationships for plants and invertebrates. Use of these screening levels to guide remedial decision-making introduces uncertainty that warrants further study. A site-specific bioassay program, using Sandberg bluegrass (Poa secunda) 14 day post germination and 28 day growth bioassays and springtail (Folsomia candida) 28-day reproduction and survival bioassays was conducted to address this uncertainty. Bioassay results and paired chemistry data were collected for 70 samples (11 field controls and 59 target locations) representing a range of concentrations of selected contaminants. A step-wise approach for evaluating these data and deriving site-specific effect thresholds was employed. First, the distribution of analytical chemistry was compared to existing screening benchmarks and Hanford background concentrations to a) ensure field control samples were less than background and b) identify analytes that may have an association with effects. Second, specific samples were identified as toxic using statistical analysis (parametric and non-parametric ANOVA) to identify differences in responses among laboratory controls, field controls, and target samples and through the development of a 'reference envelope' based on background concentrations. Third, chemistry data were integrated with bioassay results. Correlation analyses were performed to identify analytes most associated with observed responses. Site-specific NOECs (highest concentration at which no effects were observed) and Apparent Effect Thresholds (lowest concentration at which effects were observed in all samples) were developed using the ANOVA and Reference Envelope results. Fourth, regression analyses (linear and nonlinear) were performed to quantify dose-response relationships and to identify 20 and 50 percent effects levels. Finally, principal components analysis was conducted to identify sets of analytes associated with observed bioassay response. The results of these analyses will be used establish preliminary remediation goals (PRGs) that will have applicability to soils within terrestrial environments across the Hanford Site, which include both upland and riparian habitats.

295 The Hanford Site: Ecological Risk Evaluation of the Columbia River J.E. Robinson, Woodard & Curran Inc.; L.C. Hulstrom, Washington Closure Hanford. As part of the on-going cleanup of DOE's Hanford Site in Washington State, approximately 100 miles of the Columbia River adjacent to and downriver of the Hanford Site is being investigated and evaluated in accordance with the RI/FS process of Superfund. Although not technically part of the Hanford Site, the Columbia River lies adjacent to the facility and was a source of cooling water for nuclear reactors during the decades when the Site was operating. This presentation describes the process used to conduct a screening level ecological risk assessment of the main channel of the Columbia River. The study was based on both historical data and additional surface water, porewater, sediment, island soil, and fish tissue data collected during the recent remedial investigation. The fish sampling program included the collection of composite samples of fish tissue (fillets, kidney, liver, and carcass) from six species of resident fish. Statistical evaluation of sediment and surface water data was used to divide the River into four Sub-Areas, which were evaluated independently. Contaminants of potential ecological concern (COPECs) were selected statistically and evaluated against no-observed-effect-level (NOEC) benchmarks. Compounds exceeding NOECs were further evaluated as part of a Refinement that considered a variety of additional factors, including LOEC values and the number, magnitude, location, and date of LOEC exceedances. Potential effects on fish were evaluated by histopathological examinations, plus comparisons of fish weight, length, condition factors, and hepatosomatic indices.

296 Overview of Biological Metrics Evaluated in the Near Shore Environment R. Ryti, Neptune and Company, Inc.; B. Tiller, Environmental Assessment Services; J. Markwiese, Neptune and Company, Inc., Environmental Assessment Dept; D. Jacques, Washington Closure Hanford. The baseline ecological risk assessment for the River Corridor portion of the Hanford Site in Washington State employed field-, laboratory-, and literature-based lines of evidence to evaluate the potential for adverse effects related to historical releases from plutonium production operations on biota in the near-shore aquatic environment. This paper presents the study design and results for one of the field measures – rock baskets that served as artificial substrates to sample the aquatic community. Clean cobbles were deployed in shallow water (~ 2 meters) at 41 locations along more than 100 km of the Hanford Reach of the Columbia River. This included reference sites upstream of the Hanford Site and study sites along the Hanford Site shoreline. Benthic macroinvertebrates that had colonized the rock baskets were collected after approximately 6 months of deployment and sorted to family, genus, or species level. Because mollusks were of special concern, they were identified to species. Biological information was summarized into 56 total attributes. In addition to characterizing the biota obtained from these rock baskets, habitat and contaminant information was also obtained for the deployment sites. Univariate and multivariate statistical tools were used to determine if there were any overall trends in diversity and abundance and if these trends could be related to habitat, contamination, or some combination of these factors.

297 Relationships Between Heavy Metals and PCBs in Sediment and Fish Tissue from the Hanford Reach in the Columbia River L.M. McIntosh, Woodard & Curran, Risk Assessment Services; S. McCarthy, Woodard & Curran; L. Campe, Woodard & Curran, Risk Assessment; C. Trapp,

Woodard & Curran, Risk Assessment Services; L. Hulstrom, Washington Closure Hanford. An approximately 150 mile stretch of the Columbia River in Washington State, upstream, adjacent to and downstream of the Hanford Site (a largely decommissioned nuclear production facility operated by the United States Dept of Energy), has been the subject of environmental investigations for decades. Recently, as part of a remedial investigation of the Columbia River, numerous environmental samples consisting of surface water, sediment, island soils, and different tissue types from several different species of fish, were collected along this river reach. The objective of the study reported here is to ascertain patterns in and relationships among environmental media—specifically, sediment and fish tissue-- for a variety of chemical constituents. In particular, in-depth multivariate statistical evaluation was conducted to determine the relationships of select heavy metals (e.g., Hg, Cd, Cu, Mn, Sr and Zn) and polychlorinated biphenyls within sediment as well as relationships of these constituents between sediment and different tissue types of six different fish species. The implications of this approach for using sediment data as an indicator of the uptake of these constituents into fish tissue is also discussed.

298 An Investigation into the Extent and Biological Impacts of Endocrine Disrupting Chemicals (EDCs) in a Highly Effluent-Dominated River in New England D. McDonald, K. Kipp, B. Hoskins, T. Faber, USEPA, New England Regional Laboratory; A.L. Batt, USEPA Office of Research and Development, National Exposure Research Laboratory; M.A. Mills, USEPA, National Risk Management Research Laboratory; L. Zintek, USEPA, Region 5; J.M. Lazorchak, US Environmental Protection Agency, Office of Research and Development, USEPA Office of Research and Development, National Exposure Research Laboratory, USEPA, Molecular Ecology Research Branch; H. Haring, The McConnell Group, c/o USEPA ORD; S.F. Nakayama, National Institute for Environmental Studies, Center for Environmental Health Sciences. The Assabet River in central Massachusetts is a heavily effluent-dominated river and, during low-flow conditions, is composed almost entirely of wastewater effluent (i.e., up to 95%). The USEPA Regional New England Laboratory and the USEPA Office of Research and Development Cincinnati Laboratory have been conducting a two-year study to investigate endocrine disrupting chemicals (EDCs) in the effluents and their potential impacts on fish in the river. During the first year of the study, effluents from four wastewater treatment plants were analyzed for a suite of EDCs, steroid compounds, perfluorinated chemicals (PFCs) and other pharmaceuticals and personal care products (PPCPs). Forage fish were collected from the river and analyzed for indicators of EDC exposure, including histopathology and vitellogenin (i.e., egg yolk protein) induction in male fish. Larval whole effluent toxicity exposure tests were conducted using effluents from the plants. Of the 54 pharmaceutical analytes, 29 were found across all four effluents, with six of those having concentrations near 1 ug/L. For the eight steroids measured, one effluent had a concentration of ethinylestradiol at concentrations known to cause effects on fathead minnow fecundity (@2 ng/L). Two plants had PFCs (PFOS/PFOA) at levels near the Minnesota Pollution Control Agency Aquatic Life Criteria. Nonyl Phenols were found at concentrations of at least 5 ug/L in all effluents. Additional results of the first year of research will be presented.

299 Endocrine Disrupting Compounds in Wyoming Surface Waters: Assessment of Presence, Suspected Sources and Possible Consequences for Wyoming Fisheries E.O. Johnson, Univ of Wyoming, Dept of Zoology and Physiology; D.T. Pham, Univ of Wyoming, Dept of Zoology and Physiology (3166); J.M. Morris, Stratus Consulting; H.L. Bergman, Univ of Wyoming, Dept of Zoology & Physiology. We initiated this project because of widespread reports from Europe and North America on intersex condition and other reproductive abnormalities in fish related to presence of measured or suspected endocrine disrupting compounds (EDCs) in surface waters (e.g., Joebling et al. (1998) in England on wild roach, Vajda et al. (2008) in Colorado on white sucker, and Hinck et al. (2009) on bass in many US surface waters). These studies often point to discharges from wastewater treatment plants (WWTPs) as the principal sources of natural and synthetic steroids and other chemicals that can affect fish reproduction and fish populations. But WWTP discharges are not the only sources of EDCs. A recent report on trout from remote, high-elevation lakes in the western US point to long-range atmospheric transport and deposition of industrial chemicals such as PCBs as the putative cause of intersex male trout (Schwindt et al. 2009). Possibly a potential issue for Wyoming and other rural agricultural areas are recent studies of livestock manure, including those associated with rangeland grazing, as a source of steroid hormones apparently causing elevated incidence of intersex male fish (Kolodziej and Sedlak 2007). There appears to be little information about the presence of EDCs from Wyoming surface waters or the possible presence of intersex male fish. But our recent measurement of 11.7 ng/L (parts per trillion) 17-beta-estradiol in the Laramie River above the Laramie WWTP discharge is a particularly concern, given the predicted-no-effect-concentration (PNEC) of 1 ng/L 17-beta-estradiol for protection of aquatic life, as established by the British Environment Agency (Young et al. 2004). Because of this concern, we collected white suckers from the Laramie River approximately 10 miles upstream from Laramie and above any WWTP discharges in this watershed and examined gonadal tissue using H&E stain and light microscopy and observed both oocytes and spermatogenic tissues in the same sections of male fish gonads indicating an intersex condition. We have now expanded this study and will report results on gonadal tissue histology and plasma vitellogenin levels in fish and chemical analyses for EDCs in water samples from four sites along the Laramie River, including (1) a pristine up-river site, (2) a site downstream from potential agricultural runoff, (3) a site downstream from potential septic system releases, and (4) a site downstream from the Laramie WWTP discharge.

300 Biological and Photochemical Fate of Pharmaceuticals and Their Metabolites in WWTPs, Wetlands, UV and UV/H2O2 Process E. Lee, Gwangju Institute of Science and Technology, Dept of Environmental Science, GIST, Dept of Environmental Science and Engineering; J. Cho, Gwangju Institue of Science and Technology, Environmental Engineering. As pharmaceuticals have been an emerging concern for several decades, pharmaceutical metabolites are also getting attention due to their potential of ecotoxicological effect. Even though pharmaceutical metabolites have been metabolized in body, some metabolites (10, 11-epoxycarbamazepine, paraxanthine) are still pharmaceutically active and more stable than parent compounds. However, the fate of pharmaceutical metabolites has been rarely known compared to the parent compounds. The purpose of this study is to provide scientific information of behavior of both pharmaceuticals and their metabolites in various water treatment processes. In this study, overall fate of pharmaceuticals and their metabolites was investigated in both biological (WWTPs, and wetlands) and photochemical (UV and UV/H2O2) process. Firstly, transformation of pharmaceuticals into their metabolites was investigated in both WWTPs and constructed wetlands process to understand the environmental fate of pharmaceuticals and their metabolites. Various micropollutant compounds, including 12 pharmaceuticals and 11 metabolites were selected for this study. Whole analytes were measured using Water 2695 Separations Module coupled with a Micromass Quattro Micro triple-quadrupole tandem mass spectrometer in electrospray ionization mode (ESI). Research revealed that most pharmaceutical compounds were substantially eliminated by WWTP process except for atenolol (removal efficiency at 50%) and iopromide (60%). And most of the metabolites (4-OH-diclofenac, hydroxyl-ibuprofen, O-desmethyl-naproxen and CBZ-10OH) were more stable than the parent compounds in both WWTP and wetlands treatment. Well-known pharmaceutically active metabolites (paraxanthine, CBZ-EP and N-acetyl-SMZ) were also detected in treated water. In addition, photochemical fate of pharmaceuticals and metabolites was studied using UV and UV/H2O2 process. Among various pharmaceuticals, diclofenac and sulfamethoxazole showed the highest photodegradation rate. And their pharmaceutical metabolites showed different photodegradation rate compared to parent compounds. 4-hydroxy-diclofenac was more susceptible to the photodegradation than the parent compound, diclofenac. However, N-acetyl-sulfamethoxazole had conservative behaviors during photolysis process in contrast to its parent compound, sulfamethoxazole. This study is expected to be helpful to understand the complex behaviors of pharmaceuticals and their metabolites in aquatic environment.

301 Endocrine Disrupting Chemicals in a US National Effluent Sampling M.A. Mills, USEPA, National Risk Management Research Laboratory; S.F. Nakayama, National Institute for Environmental Studies, Center for Environmental Health Sciences; K. Tadele, US Environmental Protection Agency, Student Contractor to National Risk Management Research Laboratory, Student Service Contractor; A.L. Batt, USEPA Office of Research and Development, National Exposure Research Laboratory; J.M. Lazorchak, US Environmental Protection Agency, Office of Research and Development, USEPA Office of Research and Development, National Exposure Research Laboratory, USEPA, Molecular Ecology Research

Branch; M. Kostich, USEPA Office of Research and Development, EERD. Wastewater treatment plant (WWTP) discharges (both aquatic and solids) are known to contain endocrine disrupting chemicals (EDCs). The long term nature of the discharges and the linkages to in stream effects has been a focus of research in recent years. There have been limited studies to evaluate the scale of the issue and the relationships to the type of treatment received within the WWTP. In, 2010-2011, USEPA ORD conducted sampling and analyses for selected EDCS, pharmaceuticals, and fluorinated chemicals at 50 WWTPs through the United States. The largest municipal wastewater plants in the United States were identified from the 2004 Clean Watershed Needs Survey. These plants produce about 16% of all the municipal wastewater in the US. A one-time grab or 24-h composite sample (total of 9 liters) of finished aqueous effluent from each plant were collected by EPA Regional or WWTP personnel. For each effluent sample, the concentration of steroid hormones, alkylphenolic compounds, and Bisphenol A along perfluorinated compounds and pharmaceuticals, and the estrogenic potential in a fish assay. The EDCs measured were found to have a great range of concentrations and were commonly found in many effluents tested. The result from the study will be discussed in the presentation.

302 Estrogenic Activity – A Frame of Reference for Some Foods, Agricultural Wastewaters, and Animal Feedstuffs N.W. Shappell, USDA-ARS-RRVARC, Biosciences Research Lab, USDA-ARS. In the last decade, several in vitro estrogenic activity assays have been used to assess municipal and agricultural wastewaters and surface waters. Some work has been published to provide context by measuring activity from waters collected in pristine or "control" sites, but the relative estrogenic activity of "healthful" foods such as milk, or rice prepared in microwavable bags had yet to be determined. Using the E-Screen – a proliferation assay using untransfected human mammary epithelial cells, estradiol equivalents (E2Eq) were determined for extracts of milk, rice, defatted soybean meal (animal feed), water used to clean chicken eggs from a commercial processing facility (egg wash wastewater) and a 1.25 mg pill of Premarin (used for human hormone replacement therapy). On a serving basis, E2Eq were: skim milk 31 -317 pg (8 oz, 5 different weeks of supermarket collection), vitamin D 4 pg (as fortified in 8 oz of milk), rice 0 – 7303 pg (48 g dry rice, 6 extracts from 4 lots), folic acid 220 pg (as fortified in 48 g rice); with no activity detected from vitamin A, niacin or thiamin (other fortifications in milk or rice). The microwavable bags used to prepare the rice contained 2 – 18 pg of E2Eq per serving (n = 6);, no estrogenic activity was found in 3 of 6 rice samples prepared in bags, and in 2 of 6 rice samples prepared without bags. The variability in E2Eq of both milk and rice is to be expected. Milk is a composite product coming from animals at various stages of lactation with variable estrogen secretion. The estrogenic activity in rice is most likely the result of trace mycotoxin contamination, such as zearalenone, and therefore highly variable. To put these values in context, Premarin contained ~300,000 pg/pill of E2Eq and defatted soybean meal used as an animal feed contained ~ 120,000 pg/g dry matter. The highest untreated egg wash wastewater contained 10 ng/L of E2Eq, approximating the proposed lowest observable effect concentration for E2 in fish. Analysis of egg wash wastewater from the holding lagoon indicated a 66% reduction in E2Eq. These data provide a broader context in which to frame past, present and future measures of estrogenic activity.

303 Fate of Triclosan and Methyltriclosan in Soil from Biosolids Application N. Lozano, Univ of Maryland, Faculty Research Assistant; A. Torrents, Univ of Maryland, Civil and Environmental Eng.; C. Rice, US Dept of Agriculture, Environmental Management and Byproduct Utilization Laboratory; M. Ramirez, District of Columbia Water and Sewer Authority. Biosolids contain synthetic chemicals that have the potential to alter soil microbial communities and disrupt endocrine functions if they move offsite. In this study, the persistence of triclosan (TCS), an antibacterial compound normally found in biosolids and in soils after biosolids applications was evaluated. The fate of its biodegradation product, Methyltriclosan (MeTCS), was also examined. TCS and MeTCS concentrations were analyzed in biosolids samples collected every two months from a large waste water treatment plant (WWTP) over 4 years. An experimental agricultural plot was treated with a single biosolid application from this plant (average TCS and MeTCS concentrations of 15.6 ± 0.6 and 0.12 ± 0.01 μg g-1 dry wt.) and surface soil samples were collected several times afterward, over a three years period. In the experimental plot, for the first 8 months, concentration of TCS in the soil gradually increased with maximum levels of 63.7 ± 14.1 ng g-1 dry wt., far below the predicted maximum concentration of 307.5 ng g-1 dry wt. After one year, TCS disappearance corresponded with MeTCS appearance, suggesting in situ biodegradation. The results suggest that soil incorporation and degradation processes are taking place simultaneously and thus soil concentrations are always far below the predicted maximum concentration. In this study, TCS background levels are achieved within two years. TCS half-life was determined as 104 d and MeTCS half life was estimated to be more than 4 times this value.

304 Pharmaceuticals, Perfluorinated Compounds and Other Organic Wastewater Compounds in Private Drinking Water Wells on Cape Cod, Massachusetts L.A. Schaider, Harvard School of Public Health, Dept of Environmental Health, Silent Spring Institute, Dept of Environmental Health; R.A. Rudel, J.M. Ackerman, S.C. Dunagan, J.G. Brody, Silent Spring Institute. The shallow aquifers of Cape Cod, Massachusetts, USA, are vulnerable to contamination from septic systems, the area's predominant form of wastewater treatment, because of the porous nature of the sandy soils and close proximity between septic leach fields and groundwater levels. Such contamination is of concern because groundwater is the sole source of drinking water on Cape Cod. Private wells, which serve 20% of Cape Cod residents, may be more vulnerable to wastewater contamination than public wells because they are located in residential areas without large buffer zones to separate them from septic systems or other sources of groundwater pollution. We tested for 121 organic wastewater compounds (OWCs) in 20 private drinking water wells on Cape Cod. Wells were selected through a two-step screening process. We used GIS land use data to analyze the extent of residential development in a zone near each of 130 wells that were volunteered by local homeowners. Of these, 50 wells were selected for a second round of screening, with the goal of including wells with a range of nearby residential development and geographic locations. Water samples from these 50 wells were tested for two inorganic markers of wastewater, nitrate and boron, and these results were used to a select a final list of 20 wells that encompassed a range of concentrations, with an emphasis on wells with high nitrate and boron. We compared the results of OWC testing in these 20 wells to those found in our recent study of Cape Cod public wells and other US source waters. We also evaluated the ability of land use information, well depth and concentrations of nitrate, boron, and acesulfame (an artificial sweetener) to predict overall OWC occurrence. Findings were reported to participating well owners, including supplemental information for interpreting results, and to the general public. Our results provide some of the first results documenting septic system impacts on drinking water supplies and have implications for wastewater management planning and protection of similarly vulnerable water supplies.

305 Seasonal Variation of Surface Water Veterinary Pharmaceutical Levels in an Agricultural Watershed D. Snow, Univ of Nebraska-Lincoln, Water Sciences Laboratory, School of Natural Resources, Univ of Nebraska, Associate Professor; D. Rus, US Geological Survey; S. Bartelt-Hunt, Univ of Nebraska, Civil Engineering. Traces of veterinary pharmaceutical compounds can be introduced directly to surface water through illicit or unintentional discharge of livestock wastewater, and indirectly through storm run-off from field receiving wastewater or biosolids application. In areas with a high density of animal feeding operations it is difficult to distinguish between sources and relative importance of these routes. This study investigated the seasonal occurrence of 17 veterinary antibiotics and growth promoters in river and tributaries draining approximately 300,000 acres of cropland with roughly 140 large livestock operations. Polar organic contaminant integrative samplers were used to measure variation of pharmaceutical levels in the watershed at eight locations during spring, summer, and fall in 2008 and 2009. Time-weighted estimated average concentrations of pharmaceuticals were estimated using uptake rates determined in a previous study. Sites with passive samplers were also equipped with continuous monitoring equipment for water levels, conductivity, temperature, and dissolved oxygen. Twelve of the seventeen pharmaceutical compounds were detected in the passive samplers during the monitoring periods. Compounds regularly detected in POCIS extracts include lincomycin, monensin, sulfamethazine, tiamulin, and oxytetracycline. Compounds detected infrequently and at concentrations less than 1 ng/L include ractopamine, sulfachloropyridazine, sulfamethazole, sulfamethoxazole, sulfathiazole, and tylosin. Previous evidence had suggested a spill or direct discharge to surface water, though there was little evidence of a point source release of pharmaceuticals during this study. Run-off from fields fertilized with animal manure is thought to be the major contributor of pharmaceuticals to surface water.

306 Great Lakes, Great Laboratory: Achievements in Environmental Chemistry D. Swackhamer, Univ of Minnesota, Environmental Health Sciences. Environmental chemistry was largely motivated by the environmental disasters of the 1950s – 1960s, including air pollution problems in the Ohio Valley, the burning of the Cuyahoga River, and the "death" of Lake Erie. The first account of DDT and PCBs in North America was from fish from the Great Lakes. Many of the visible environmental problems were concentrated in the Great Lakes basin, and much of the research that has helped solve the problems and led to the enactment of many of our federal environmental laws has been done in the Great Lakes. The successes include large scale water quality modeling of phosphorus; analytical advances in POPs measurements; POPs fate and transport, especially the discovery of long-range transport; greater understanding of bioaccumulation; development of large-scale, long term monitoring programs; and more. Each of the problems will be presented along with a case study of how Great Lakes environmental chemistry research has made significant contributions to our understanding of the problems.

307 Women in Environmental Chemistry: Past Accomplishments, Present Challenges D. Delach, Clemson Univ, Environmental Toxicology; C.M. Lee, Clemson Univ, Environmental. Engineering and Earth Sciences Dept. Women have been among the pioneers of Environmental Chemistry since its inception. Many women were able to overcome major challenges to make significant contributions that continue to be important to this day. The contributions of scientists such as Ellen Swallow Richard, Alice Hamilton, Rachel Carson, Kathleen Taylor, Rosalyn Yallow, and Susan Solomon will be discussed. Each of the scientists featured contributed to the theory and technology that we use today. These women share some similar characteristics such as passion for science and compassion for humanity that enabled them to overcome challenges and contribute. We will discuss the characteristics and accomplishments of women from the earliest days of environmental chemistry to the present day. We seek to answer how to inspire future chemists to continue the progress in understanding the behavior of contaminants in environmental systems by considering the lives of these women.

308 Environmental Chemistry: The View From the Cupboard Under the Stairs A. Jones, Clemson Univ, Institute of Environmental Toxicology, Clemson Univ, Institute of Environmental Toxicolo; E. Carraway, Clemson Univ, Environmental Engineering & Earth Sciences, Clemson Institute of Environmental Toxicology. What is environmental chemistry? Why is it worth poking my head out from behind the cupboard door? From important chemists of yesteryear, to movers and shakers of today and the budding chemists of tomorrow, this presentation takes a look at how we got here, and where we are going in environmental chemistry from a student's point of view. Stuart Baird and Scott Cann described environmental chemistry as being concerned with the chemical aspects of problems that humankind has created in the natural environment. While that may be a succinct, though pessimistic description, this presentation will explore the origins of environmental chemistry as a reactionary scientific discipline. Our initial lack of understanding of environmental processes has been replaced with advancements in knowledge of the natural world around us. In a short time we have come from 'the environment will take care of it,' to 'dilution is the solution to pollution,' to the seemingly never-ending search for the limit of our detection capabilities. But where do we go from here? Fortunately, our relentless pursuit of a better understanding of the environment has led to potential remedies to many of our environmental problems. However, as is often the case, issues with economics and applicability at large scales still exist. We still have much work to complete to further our understanding of current and developing environmental problems, to make implementation of solutions less costly, and to better communicate our science to the policy makers and general public.

309 Equilibrium Partitioning in a Multimedia World: Past, Present and Future D. Mackay, Trent Univ. Looking back, the author devoted three decades to exploring the feasibility of using the equilibrium criterion of fugacity to complement and help interpret various multimedia concentrations that are measured and used by environmental chemists. Insights that can be obtained by viewing the world of multimedia contamination through the lens of fugacity are outlined, notably fascinating excursions into bioconcentration, air-water exchange, global transport, and the ability to compile very simple and intuitive mass balance models. Coming from a petrochemical engineering background the author grew to love the fugacity concept but others are understandably less enthusiastic because it is concentrations that are measured and it is doses and body burdens that induce toxic effects: not fugacity. The author was slow to appreciate that the closely related equilibrium criterion of activity has toxicological significance, especially for narcotics, namely Ferguson's "activity hypothesis". Fugacity can thus describe not only multimedia environmental fate, it can also contribute to assessing effects and risk of effects. Looking forward, there is an opportunity for progress in four areas: improving the determination of equilibrium parameters for a diversity of chemicals experimentally and by computation from molecular structure: testing and improving multimedia models of fate, transport and exposure: testing the "activity hypothesis": and refining passive sampling methods of determining fugacity and activity directly in the environment and especially within organisms.

310 The History of Environmental Chemistry – The Mackay Era and Beyond M.L. Diamond, Univ of Toronto, Dept of Geography and program in planning, Univ of Toronto, Dept of Geography. SETAC was founded 1979, the year Don Mackay started the fugacity legacy with "Finding Fugacity Feasible" (ES&T). The context for the burgeoning field of environmental chemistry was dire reports of global environmental catastrophe from Barry Commoner, and Meadows et al. ("Limits to Growth" 1972) and others. The degraded state of the lower Great Lakes, catalyzed interdisciplinary, problem-solving research amongst chemists, chemical engineers and biologists under the aegis of the International Joint Commission. In this atmosphere Don Mackay, with SETAC colleagues Yalkowsky, DiToro, Eisenreich et al., marshaled the fundamental principles of chemical engineering and chemistry, together with knowledge from other fields such as pharmaceutical sciences and toxicology, to give birth to a new integrated thinking about environmental pollution. The prime innovations by Mackay and SETAC colleagues, which I suggest formed a new paradigm, were explaining that the fate and effects of organic chemicals were predictable, based on knowledge of fundamental physical-chemical properties of the chemical together with an understanding of the environment. I suggest that this was a paradigm shift because this explanation moved the field beyond the phenomenological and towards a consistent, mechanistically-based and unifying theory. Mackay also advocated taking a multi-media approach since, in this new paradigm, organic chemicals were transported and caused effects far from their point of emission – the message introduced by Rachel Carson ("Silent Spring" 1962). It was also a time of the burgeoning of North American universities, with some faculty members hired "sight unseen" and who had time to think and explore science, without the "publish or perish" dictum. In the intervening time, many of us have contributed to fleshing out the "fugacity" paradigm as we do our "normal science" (T Kuhn "The Structure of Scientific Revolutions"). As with any paradigm, inconsistencies mount which, due to our scientific culture, we tend to sweep under the carpet or use to embellish rather than change the paradigm. As dire predictions of global environmental catastrophe mount from the next generation of prognosticators, let's hope that we can give birth to the next paradigm that will meet the challenges that we face!

311 The Early Days of Environmental Chemistry R.A. Hites, Indiana Univ, School of Public & Environmental Affairs. Environmental chemistry as a discipline developed from two directions: air pollution and water pollution. As sanitation in urban centers developed in the 19th century, a type of civil engineer evolved; their goal was to understand the processes of treating sewage and drinking water (and keeping the two apart). These folks became known as sanitary engineers and had skills in both hydrology and in microbiology. At the same time, people realized that air pollution was a significant problem, particularly in highly industrialized cities, and dealing with these problems lead to some fundamental work on gas-phase chemical kinetics. In parallel and crystalized by Rachel Carson's 1962 book Silent Spring, interest also developed in what were at the time called "pesticide residues." The work from these three rather diverse groups was being published in different journals. The sanitation engineers were typically publishing in water treatment journals and presenting papers at civil engineering meetings. The atmospheric scientists were publishing and presenting at earth sciences meetings. The pesticide chemists were publishing in agricultural journals and presenting at food science meetings. In many ways, this was reasonable given that the intellectual and measurement tools used by these three populations were quite different. In the 1960s, the American Chemical Society had a division called Air, Water, and Waste Chemistry – an accurate but unappealing title. By

the time of the first Earth Day in 1970, this division had changed its name to Environmental Chemistry with the goal of being inclusive. About the same time the American Chemical Society's journal Environmental Science and Technology was founded. These two initiatives solidified environmental chemistry as a real discipline, at least among chemists. The Society for Environmental Toxicology and Chemistry (SETAC) was founded in 1979, and again the goal was to be inclusive and to reach out to applied aquatic toxicologists (on the one hand) and environmental chemists (on the other). Initially this inclusiveness was less that fully realized; for example, the first SETAC meeting I attended in 1984 had one half-day session devoted to all aspects of environmental chemistry. Eventually, through the hard work of SETAC's Board of Directors, the annual meeting began to attract more chemists, and it is now one of the annual highlights of the scientific conference calendar.

312 Proteomic Analysis of Colorful Oysters from Metal Contaminated Estuary F. Liu, The Hong Kong Univ of Science & Technology; W. Wang, Hong Kong Univ of Science and Technology. Proteomic analysis of ecologically and economically important organisms is a promising novel approach for environmental toxicology. Few proteomic studies have been applied to natural contaminated ecosystems. We collected three populations of oysters along a metal-contaminated estuary together with one population as the control from a nearby pristine site. Strikingly, tissue color changed markedly from white (control) to yellow, green and blue, and the increasingly darken colors were in good agreement with a steady increase in measured metal concentrations (Cd, Cu and Zn) in the gills. Proteomic analysis of the gills as one of major metal targets suggested that metal overload led to systemic dysfunctions in metabolisms of reactive oxygen species, amino acid and protein, lipid peroxidation, cytoskeleton, and energy production. These molecular alterations were responsible for the visible population abnormity (e.g., tissue coloration). Meanwhile, we found a unique protein expression signature composed of 11 altered proteins, and the signature could successfully distinguish the population from clean and contaminated areas and achieve perfect classification of the contaminated animals with different levels of metals mixture exposure. More importantly, the expression abundances of 8 proteins, i.e., 26S protease regulatory subunit 6A, actin, CRE-PGK-1, elongation factor 2, enolase, gelsolin, mitochondrial H^+ ATPase a subunit and an unnamed protein, were significantly related to gill Cu, Zn or Cd concentration. These proteins could be very useful as novel biomarkers in environmental pollution assessment.

313 Metabolic Profiling of Calanus Finmarchicus to Study the Impact of Waterborne Diethanolamine Exposure K.F. Degnes, SINTEF, Materials and Chemistry; T.R. Stoerseth, SINTEF, Fisheries and Aquaculture; D. Altin, BioTrix; H. Sletta, K. Zahlsen, S.F. Borgos, B. Hansen, SINTEF, Materials and Chemistry. The metabolic impact of exposure to different concentrations of the alkanoamine diethanolamine (DEA) on the microcrustacean Calanus finmarchicus was evaluated. C. finmarchicus is one of the most important organisms in the North Atlantic Ocean due to its significant position in the food web. This crustacean has therefore been used as a relevant model for a numerous eco-toxicity tests performed at SINTEF/NTNU. Thus a large database of eco-toxicological data exists for this species. DEA has low acute toxicity (96 hrs-LC50=380mg/L), but due to the widely use of this solvent in a considerable number of industrial applications, it is relevant to elucidate potential sub-lethal aquatic eco-toxicological effects of this amine. DEA is therefore a suited model chemical for metabolic fingerprinting and metabolic profiling of C. finmarchicus. We have previously published that DEA has an effect on the C. finmarchicus metabolome using 1H nuclear magnetic resonance spectroscopy (NMR). In the present study we wanted to further investigate if liquid chromatography mass spectroscopy (LC-MS) based metabolomics could uncover sub-lethal stress responses in C. finmarchicus that would not have been observed with classical toxicological tests. LC-TOF and Mass Profiler Professional software were used as diagnostic tools in order to evaluate molecular stress responses in the test species. Metabolic fingerprinting with PCA analysis revealed changes in metabolite profiles at concentrations fare below LC50, and these results were confirmed by NMR. Putative metabolites were identified and metabolites related to biosynthetic pathways that are likely to be significant for important physiological responses were subject for further investigations. We have in particular investigated metabolites related to the glycerophospholipid metabolism. Preliminary data indicate that the metabolic profiles of several classes of glycerophospholipids are altered in response to DEA exposure, but work remains in order to investigate if these changes have biological relevance for C. finmarchicus.

314 Assessment of Cadmium Toxicity in the Liver and Gonads of Adult Largemouth Bass (*Micropterus salmoides*) Using Microarrays A.C. Mehinto, K.J. Kroll, D.S. Barber, N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology. Cadmium is one of the most common pollutants found in Superfund sites. This heavy metal can accumulate in the aquatic environment and interfere with fish reproduction. Research in mammals also demonstrated that cadmium can induce hepatotoxicity. This study examined the acute physiological changes induced by a low dose of cadmium (20 μg/kg) in the liver and gonads of adult male largemouth bass. A 15K largemouth bass microarray was used to examine the genes differentially regulated in both tissues. Microarray analyses revealed that the genomic responses identified were tissue-specific with more genes being affected in the liver than in the gonads of the male fish. In the liver many genes related to DNA repair and transcription were down-regulated. Oxidative stress response and a disruption of carbohydrate metabolism were also observed in the liver. Fewer genes were differentially expressed in the gonads. Gene Ontology analysis showed that lipid metabolism and steroid biosynthesis were significantly altered. in this tissue Transcription-related processes were disturbed in the gonads but the genes identified were dissimilar to those found in the liver. Although the main biological processes disturbed by cadmium exposure can equally be affected by other environmental toxicants, some of the genes identified in this study have been consistently affected by cadmium and they could be considered as potential biomarkers of cadmium exposure.

315 The Cytochrome P450 Superfamily in the Rotifer, *Brachionus orientalis*: Annotation and Their Transcript Expression Analysis R. Kim, Hanyang Univ, Dept of Chemistry; J. Lee, Hanyang Univ, Dept of Chemistry, Hanyang Univ Graduate School, Dept of Chemistry. Cytochrome P450 (CYP) genes, a large and most versatile gene family, translates essential enzymes for the detoxification of xenobiotic chemicals and the metabolism of drugs. To date, CYPs and those of specific activities have been characterized in numerous invertebrates. However, CYPs showed a considerable sequence divergence in allied species and little information is available about their innate functions. For these reasons, a study on CYPs may provide us with an opportunity to elucidate specifc functions and regulation mechanisms of particular CYP genes. Since the rotifer *Brachionus* sp. represents an underived metazoan species we expect it to provide evolutionarily primitive forms of the whole CYP complement genes. This also makes it a suitable model species for marine toxicity testing. To annotate *Brachionus* sp. CYPs, we constructed phylogeny trees using Mr.Bayes v3.1.2 program. CYPs from *Brachionus* sp. were divided into five distinct clans (clan 2, 3, 4, 46) and mitochondrial groups (8 families, 8 subfamiles, and 28 isoforms). Clan 2, 3, and the mitochondrial groups showed close similarity with those of other invertebrates, whereas Clan 4 and 46 more similar to vertebrates. To analyze the effect of B[α]P as a strong inducer of cytotoxic stress, we exposed 10, 100, and 1000 μg/L B[α]P for 24 h and measured transcript profiles by quantitative real-time RT-PCR. Upon B[α]P exposure, CYP isoforms including Clan 4, 46, and mitochondrial groups showed no significant mRNA expression. However, other isoforms of Clan 2 and 3, showed a significant up-regulation in a concentration-dependent manner. These results indicate that these two isoforms may have an important role on the metabolism of xenobiotics like B[α]P in *Brachionus* sp. For further investigation of CYP genes we measured the mRNA expression of CYP isoforms (Clan 2 and 4) after exposure to a WAF (Water Accommodated Fraction) that was mainly composed of PAH from heavy oil spillage in the Yellow Sea of Korea. We also obtained the relationship of those CYP genes in the AhR-CYP transduction pathway. The present study may provide comprehensively annotation of the rotifer cytochrome superfamily and indicates their putative role in the mechanism of detoxification of environmental toxicants.

316 Use of Genome and Proteome Analysis to Reveal Toxicity Pathways in Rainbow Trout Exposed to the Brominated Flame Retardant TBBPA-DBPE A. Muttray, D. Simmons, T. Neheli, S. Clarence, J. Miller, J. Sherry, Environment Canada, Water Science & Technology Directorate. Fluorescent RNA Arbitrarily Primed (FRAP)-PCR is an open-ended exploratory tool that identifies gene expression differences without prior knowledge of the affected genes. We employed FRAP-PCR to select genes that clearly responded to Tetrabromobisphenol A bis(2,3-dibromopropyl

ether) (TBBPA-DBPE) in rainbow trout (*Oncorhynchus mykiss*) liver. The flame retardant TBBPA-DBPE was introduced as a replacement for other high-volume brominated flame retardants that showed clear evidence of carcinogenicity. Although little toxicity data is available for TBBPA-DBPE, related chemicals have been found to be endocrine-disrupting, geno-, hepato-, immuno- and neuro-toxic in some tests. For risk assessment purposes, it is important to learn if genetic pathways linked to adverse outcomes are affected by this flame retardant. About 100 FRAP-PCR amplification products were identified as differentially expressed, extracted from the differential display gels, and sequenced. Approximately half of the FRAP-PCR products were positively identified using the BLAST algorithm. The sequenced and identified products were entered into Ingenuity Pathway Analysis software (IPA) to categorize them into biochemical pathways. Key pathways and network nodes affected by TBBPA-DBPE were confirmed by qPCR. Affected pathways included the acute phase response, cell cycle, protein metabolism, and genes for serum albumins. qPCR confirmation of the remaining network nodes and differentially expressed genes is in progress. Similar real-time PCR analysis of hepatocyte cultures exposed to TBBPA-DBPE allowed us to compare in vitro to in vivo gene expression signatures. To juxtapose genome-level responses with responses at the proteome level we performed a qualitative protein profile of hepatocyte and plasma samples by liquid chromatography quadrupole time-of-flight (LC-Q-TOF) mass spectrometry. Approximately 12% of filtered Q-TOF spectral data were positively identified as peptides from proteins in hepatocyte lysates using the Agilent Technologies SpectrumMill protein database search software. IPA indicated that proteins involved in cellular development, function, maintenance, assembly and organization were found in all treatments and controls. TBBPA-DBPE-treated hepatocytes, but not controls, also expressed proteins significantly linked to protein networks involved in endocrine system disorders, molecular transport, and nucleic acid metabolism.

317 Benzene and Trichloroethylene Induce Common Mechanisms of Toxicity in Largemouth Bass R.C. Colli-Dula, A. Alvina Mehinto, Univ of Florida, Center of Environmental and Humand Toxicology; A. Cuenca Navarro, IBMB-CSIC, Dept of Molecular Biology; K.J. Kroll, D. Barber, Univ of Florida, Center of Environmental and Humand Toxicology; N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology. Benzene and trichloroethylene (TCE), known environmental pollutants, have been detected in aquatic systems causing adverse effects in fish. In recent years genomic tools, like microarrays, have been useful to quantify gene expression, allowing the exploration of mechanisms of toxicity and the identification of biomarkers of exposure and effect. The object was to use microarrays to investigate changes in gene expression caused by exposure to benzene and TCE in largemouth bass. Forty eight fish were individually weighed and injected IP with a single dose of benzene and TCE (10 mg/kg b/w). After injection, the fish were sacrificed at 48h. Livers and gonads were obtained and analyzed for gene expression changes using microarrays. The hypothesis was that concentrations of 10 mg/kg of benzene and TCE would produce changes in sensitive genes. In the liver 1332 and 1236 genes were significantly affected (*p*

318 Connecting Triclosan's Impact on the Swimming Behavior of Larval Fathead Minnow (*Pimephales promelas*) with Altered Ryanodine Receptor Pathways E.B. Holland Fritsch, Univ of California- Davis, Molecular Biosciences; R.E. Connon, Univ of California – Davis, School of Veterinary Medicine, Aquatic Toxicology Laboratory; I. Werner, Swiss Centre for Applied Ecotoxicology, Eawag/EPFL; I.N. Pessah, Univ of California, Davis, Molecular Biosciences. The antibacterial agent triclosan is commonly found in consumer products including toothpaste, hand soap, and textiles. As an emerging contaminant of concern found in countless environmental samples around the world, including wild caught fish tissue and dolphin plasma, more and more research is beginning to address its impacts in vertebrate species. Notably, recent research in mammalian cells has shown that triclosan alters Ca^{2+} signaling through the ryanodine receptor (RyR), important for muscle function. Altered RyR functioning, due to triclosan, has not been investigated in teleost species but could have vast effects on the overall health and behavior of an organism. To address these effects we evaluated time-dependent and dose-dependent impacts of triclosan on survival and swimming behavior in correlation with altered RyR related gene expression, protein levels and protein functional states. The nominal 7d median lethal concentration (LC50) $_{w}$as 193µg.L-1. Triclosan had a significant impact on swimming behavior and ability after 1d that was consistent after 4d and 7d of exposure. There was a time-dependent and dose-dependent gene expression response to the antibacterial agent, which significantly altered the expression of the three RyR isoforms (*RyR1*, *RyR2*, and *RyR3*), as well as, several genes that tightly regulate RyR activity; *Dihydropyridine receptor, Selenoprotein-N* and *Glutathione-Sulfur-Transferase*. Interestingly, triclosan did not increase RyR activity in whole fish homogenates suggesting that RyR related impacts are not direct actions on the receptor. Our research increases the understanding of triclosan's mode of toxicity across vertebrate species and begins to address RyR dysfunction in fish due to environmental contaminants, which to date has only been investigated in mammals.

319 A Stress-Responsive Whole-Cell Array for Comprehensive Ecotoxicity Analysis C. Gao, N. Gou, A. Onnis-Hayden, A. Gu, Northeastern Univ, Civil and Environmental Engineering. Current toxicity evaluation methods like whole effluent toxicity testing (WET) and toxicity identification evaluation (TIE) require sophisticated and laborious procedures, as well as long time for the test. It is desirable to develop fast and reliable assessment methods to detect the presence and effects of toxicants. In this study, we utilized a whole-cell array in the development of methodology in the quantitative measurement of the toxicological effects caused by toxicants, and in the differentiation of toxicants by their toxicological mechanisms through bioinformatic analysis. The array consists of a library of *Escherichia coli* K12 strains carrying gene promoters with transcriptional *gfp* fusions, covering 10 categories of known stress responses. We selected 11 potential toxicants ranging from model chemicals such as Mitomycin C (MMC) and 4-Nonylphenol (4-NNP), to newly emerging nanomaterials such as nano-silver (nAg) and single-walled nanotube (SWNT). The real-time gene expression levels under the exposure of these chemicals were monitored over a period of 2 hours, and transformed into a newly developed Transcriptional Effect Level Index (TELI) to reflect the toxicological impacts. The results shows the TELI values follow a dose-response pattern and fit logistic regression model well (R^2 values near 0.9). Thus we derived endpoints such $TELI_{50}$ and $TELI_{NOTEL}$ analogous to EC50 and NOTEL, finding close relationship among some of them. It also shows that the contributions from different categories of genes to overall TELI value are not equal, namely the pattern of gene expression distribution is distinct among chemicals. These results indicate a possibility to differentiate chemicals according to their TELI patterns. We applied clustering methods such as Hierarchical Clustering (HCL) and Self-Organizing Maps (SOM) to the samples of different chemicals with changing concentrations, and found that 1) the samples with extreme low or high concentrations of chemicals could be clustered together, without distinguishing the chemical species, implying two ends of toxic effects; 2) the other samples tend to group into subsets containing similar chemicals, 3) the subsets with similar toxicological mechanisms tend to group together. In conclusion, our whole-cell array could be used to measure the toxic effect of toxicants and explore their mechanisms accordingly.

320 Growth and Bioaccumulation of Copper in Barley (*Hordeum vulgare*) Exposed to Copper Oxide Nanomaterials H. McShane, McGill Univ, Natural Resource Sciences, McGill Univ, Dept of Natural Resource Sciences; J.K. Whalen, McGill Univ; G.I. Sunahara, NRC-Biotechnology Research Institute, NRC-Biotechnology Research Institute; W.H. Hendershot, McGill Univ, Dept of Natural Resource Sciences. The replacement of micron-sized materials with nano-sized materials in commercial applications can increase product efficiency and reduce manufacturing costs. However, it is necessary to ensure that the subsequent release of these novel materials into the environment, either intentionally or unintentionally, has no negative impact on exposed organisms. The current study will present results of tests in which barley seedlings are exposed to copper oxide materials in agricultural field soil. Commercially-available copper oxide materials with different primary particle sizes, ranging from nano- to micron-size, and variable specific surface area, are used to spike the soils. We report the effects of primary particle size and specific surface area on barley root and shoot length, total biomass and bio-accumulation of copper. We also report the effect of the copper oxide on selected soil chemical properties relevant to model copper transformations in the plant-soil system. These results will be discussed in the context of current guidelines that regulate copper concentrations in agricultural soils.

321 Nanomaterial Contamination of Agricultural Plants J.C. White, C. Musante, J. Hawthorne, Connecticut Agricultural Experiment Station, Dept of Analytical Chemistry. Although the use of nanomaterials (NM)

has increased dramatically in the past decade, the potential risks posed to humans and the environment have been investigated only recently. A number of studies evaluating nanomaterial exposure to a range of receptors have been published but there is little information about the effects on agricultural plants. We have previously shown that standard phytotoxicity tests such as germination and root elongation are not sensitive enough or appropriate when evaluating NM toxicity to terrestrial plant species and that plant growth assays are preferred. Different Cucurbita pepo subspecies were exposed to 100-1000 mg/L elemental (Ag, Cu, Si, Au) or carbon-based nanomaterials (fullerenes, single and multi-walled nanotubes), as well as corresponding bulk material controls, in Hoagland's solution amended with or without humic acid (100 mg/L). Plant biomass, transpiration, solution content, and particle accumulation were determined. Nanoparticle Ag and Si reduced plant biomass and transpiration by 30-91% compared to equivalent bulk materials. In addition, the accumulation of Ag and Si was significantly greater for nanoparticles than for the corresponding bulk particles. Au had no effect on plant growth, regardless of particle size. Fullerenes had no impact on plant growth in Hoagland's solution but the presence of humic acid in solution resulted in significant reductions in transpiration volume. Our data clearly demonstrates differential toxicity and accumulation of several nanomaterials relative to respective bulk particles. The finding solution chemistry differentially impacts bulk and nanomaterial behavior highlights the importance of evaluating NM fate and effects under environmentally relevant conditions.

322 Effects of Metal Oxide Nanomaterials on Soil Microbial Populations and Communities: Observations and Explanations P. Holden, Y. Ge, J. Priester, R. Vukanti, A. Horst, O. Brun, J. Schimel, Univ of California. With their widespread manufacture and use, engineered nanomaterials (ENMs) are increasingly expected to be transported into soils where they may accumulate and affect soil bacterial communities that importantly catalyze critical reactions in nutrient cycling. Questions regard the potential for ENMs to negatively affect soil microbes, and the degree to which effects originate in either indirect changes to soil properties or direct effects on cells. In this study, we exposed California grassland ecosystem surface soils to varying concentrations of nanoTiO_2 and nanoZnO. We assessed the potential for direct effects to cells under controlled, well-mixed, conditions where ENMs are fully bioavailable. We assessed the potential for altered soil water characteristics as a measure for indirect effects of ENM addition related to water retention. We used community profiling of genes encoding 16S rRNA to observe shifts in diversity and composition after 15 and 60 days. Taxa that shifted were identified by pyrosequencing. Through this study, specific taxa, many of which are functionally important, were decreased in abundance with increasing ENM exposure and over time. Water characteristics in TiO_2-amended soil were examined, as well as ENM effects on cell growth, to inform the relative importance of direct, versus indirect, effects of ENMs on soil bacterial community structure and function. Additional possible indirect effects of ENMs to soil bacterial communities are discussed, as well as their relative importance to altering microbial communities.

323 Toxicity Testing of ZnO Nanoparticles with Soil Organisms: The Case-studies in NanoFATE, a FP7 EU Project S. Loureiro, Universidade de Aveiro, Dept of Biology & CESAM; P. Tourinho, A.M. Soares, Univ of Aveiro, Dept of Biology & CESAM; W. Tyne, L. Heggelund, M. Diez-Ortiz, D. Spurgeon, C. Svendsen, NERC-Centre for Ecology and Hydrology; K. Jurkschat, Oxford Univ, Dept of Materials; P.L. Kool, C.A. Van Gestel, Vrije Universiteit, Dept of Animal Ecology. Application of Engineered nanoparticles (ENP) in certain products means they have a route into the environment. In case of metal based ENP, like the ones studied in NanoFATE (EU FP7 project), interaction with natural components, dissolution and agglomeration will be important factors affecting their bioavailability and possible effects. While nano-dependent behaviours of ENP may be desirable for several commercial and industrial purposes, it remains difficult to foresee their potential implications for how the fate and effects of ENP in the environment may differ from those expected from metals in ionic form. Metal oxide-based ENPs, such as ZnO, used in personal care or cleaning products will enter waste water treatment plants (WWTP), and pass to soil systems upon land application of sewage sludge. Hence, knowledge on how to assess ENP toxicity to soil organisms is crucial for developing the environmental hazard assessment of these emerging substances. In this work we are presenting some case-studies of ZnO-NP exposures to different soil organisms with different life traits in natural soil. Modifications needed to dosing procedures and exposure validation to work confidently with nanoparticles will be covered. These include inclusion of different "control treatments" so ZnO-NP toxicity could be compared with the correspondent non-nano equivalent ZnO and with $ZnCl_2$. In initial tests with *Eisenia fetida*, the reproduction EC50 for ZnO-NP was observed around 700mg Zn/kg, while the ionic Zn form ($ZnCl_2$) EC50 was found at 500mg/kg. Also for the collembolan *Folsomia candida*, 28-d EC50 values based on Zn concentrations in soil were lower for $ZnCl_2$ exposures compared to ZnO-NP, but EC50 values based on free Zn in the soil pore water were in the same range for both ZnO-NP and $ZnCl_2$ (10-16 mg Zn/l), suggesting that toxicity is mainly due to free zinc. For the isopod *Porcellionides pruinosus*, oxidative stress biomarkers responded to ZnO-NP exposures in soil. Although there is a lack of information on the predicted environmental concentrations for ZnO-NP, the case-studies with these three relevant soil organisms provide useful information for future hazard assessment of ZnO-NP. However, other studies undertaken in the NanoFATE project prove that once testing moves beyond strict standard conditions and short time frames (such as pH ranges and ageing) unforeseen and hard to explain patterns may be found in ENP fate and effects within soil systems.

324 1H NMR Metabolomics as a Non-targeted, Molecular Level Technique to Detect Sub-lethal Earthworm Responses to Titanium Dioxide Nanoparticles in Soil M. Whitfield Aslund, Univ of Toronto, Physical and Environmental Sciences; H. McShane, McGill Univ, Natural Resource Sciences, McGill Univ, Dept of Natural Resource Sciences; M.J. Simpson, A.J. Simpson, Univ of Toronto, Physical and Environmental Sciences; J.K. Whalen, McGill Univ, Natural Resource Sciences; W.H. Hendershot, McGill Univ, Dept of Natural Resource Sciences; G.I. Sunahara, NRC-Biotechnology Research Institute, NRC-Biotechnology Research Institute. Traditional ecotoxicity tests rely on organism-level endpoints (i.e., survival, growth, or reproduction) but may be insufficient to predict long-term population level toxicity (e.g., immune system impairment or accumulation of DNA damage over multiple generations). Therefore, various molecular- and/or cellular-level toxicity tests have been developed to provide sensitive measures of sub-lethal organism responses to contaminants. One such emerging technique is environmental metabolomics, which provides insight into the biochemical response of an organism to an environmental stressor by comparing the concentrations of endogenous metabolites in a tissue or biofluid. Changes in the metabolic profile can reveal information about the organism's response to contaminant exposure at the metabolic level as well as the contaminant's toxic mode of action. In this study, ^{1}H NMR-based metabolomics was used to examine the response of *Eisenia fetida* earthworms raised from juveniles to sexual maturity (20-23 weeks) in soil spiked with either 20 or 200 mg/kg of a commercially available uncoated TiO_2 nanomaterial (nominal diameter, 5 nm). To distinguish responses specific to particle size, soil treatments spiked with a micron-sized TiO_2 material (nominal diameter, < 45 μm) at the same concentrations (20 and 200 mg/kg) were also included in addition to an unspiked control. Multivariate statistical analysis of the ^{1}H NMR spectra for *E. fetida* tissue extracts suggested that earthworms exhibited significant changes in their metabolic profile following TiO_2 exposure for both particle sizes and that this response was less variable when the TiO_2 concentration increased from 20 to 200 mg/kg. In general, the observed earthworm metabolic response to both materials was compatible with oxidative stress, which has been proposed as a mechanism of toxicity related to nanoparticle exposure. In contrast, a parallel study observed no differences in earthworm survival, reproduction, or growth following exposure to the same nano-sized TiO_2 spiked soil. This suggests that metabolomics may be more sensitive than traditional ecotoxicity endpoints for detecting earthworm sub-lethal responses to TiO_2 nanoparticles in soil and that further molecular or cellular level assays (e.g., DNA damage, immune function) should be considered to better assess organism responses to TiO_2 nanoparticle exposure.

325 Ecotoxicity of Silver Nanoparticles on Stress Response Gene Expression in *Chironomus riparius* P.G. Nair, S. Park, Univ. of Seoul; J. Choi, Univ of Seoul, School of Environmental Engineering. The increased use of silver nanoparticles (AgNPs) in various products makes it likely to result in the release of AgNPs into the aquatic environment, which finally leads to their accumulation in sediment. *Chironomus riparius*, an aquatic midge (Chironomidae, Diptera), is extensively used as a model organism in sediment toxicity. In this study, toxicity of AgNPs was investigated in *C. riparius* using expression of stress response genes, identified from Expressed

Sequence Tags developed by 454 pyrosequencing. The selected genes were Heat Shock Protein 70, Transferrin, Heme oxygenase-1, Cytochrome P4501A1, Quinone Oxidoreductase, Glutathione S-Transferase, Superoxide Dismutase, Catalase, Glutathione Peroxidase, and Start1 genes. The responses of these genes to AgNPs exposure were compared with higher level effects, such as, development and reproduction. Overall results suggest that AgNPs lead significant alteration on genes of various biological functions, and some of them were found to be correlated with alteration on population level effects. This work was supported by the Ministry of Education, Science and Technology of Korea [2010-0027722].

326 Toxicity of Fullerenes (C_{60}) in Sediments E.J. Petersen, NIST, Biochemical Sciences, National Institute of Standards & Technology; K. Pakarinen, G. Leinonen, Univ of Eastern Finland; M.T. Leppanen, J. Akkanen, J. Kukkonen, Univ of Eastern Finland, Dept of Biology. Effects of fullerene-spiked sediment on two benthic organisms, *Lumbriculus variegatus* (Oligochaeta) and *Chironomus riparius* larvae, were investigated. Fullerene agglomerates were prepared using a water stirring method. *L. variegatus* were exposed to 10 and 50 mg fullerenes/kg sediment dry mass for 28 d. These concentrations did not impact worm survival or reproduction compared to the control. Feeding rates were also slightly decreased for both concentrations indicating fullerenes' disruptive effect on feeding. *Chironums riparius* were exposed after allowing suspended fullerenes to settle down creating a layer of nC_{60} on top of the sediment, another environmentally realistic exposure method. Two food concentrations were tested (0.5 % and 0.8 % *Urtica* sp.) in sediment containing fullerene masses of 0.36 to 0.55 mg/cm^2 using a 10-d chronic test. In the 0.5 % food level treatment, there were significant differences in all growth-related endpoints for fullerene exposed organisms compared to controls. Fewer effects were observed for the higher food treatment. Fullerene agglomerates were observed by electron microscopy in the gut but no absorption into the gut epithelial cells was detected in either organism. Electron micrographs of *L. variegatus* also indicated that 16 % of the epidermal cuticle fibers of the worms were destroyed in the 50 mg/kg exposures. For *C. riparius*, gut microvilli were damaged and significantly shorter.

327 Method Development for Detecting Ag Nanoparticles in a Soil Using AF4 and ICP-MS A. Whitley, Univ of South Carolina- Aiken, Chemistry and Physics, Univ of Kentucky, Plant and Soil Sciences; J.M. Unrine, Univ of Kentucky, Dept of Plant and Soil Sciences, Univ of Kentucky, Dept of Plant & Soil Sciences; P. Bertsch, Univ of Kentucky, Plant and Soil Sciences. Products containing manufactured nanoparticles continue to increase in use with silver as a main product choice, largely due to its antimicrobial properties. Normal use of silver nanoparticle containing products may lead to release of silver nanomaterials into wastewater streams. Due to the partitioning of particles during wastewater treatment, sewage sludge is proposed to be a main reservoir of Ag NPs. Therefore, land application of sewage sludge biosolids creates increased concentrations of Ag NPs on agricultural soils, leading to increased exposure to soil dwelling organisms. Unfortunately, few techniques are available for the in situ detection and characterization of manufactured nanomaterials in soils. We have developed a method for detecting Ag NPs in a sandy loam soil which includes pore water extraction techniques as well as optimizing parameters for particle size separation and analysis. Asymmetrical flow field flow fractionation (AF4) was used to separate different size particles extracted from the soil pore water, then coupled to UV-vis diode array detection, multi-angle/dynamic light scattering (MALLS/DLS) and inductively coupled plasma mass spectrometry (ICP-MS) in order to characterize Ag containing colloids based on size. Various pore water extraction techniques have been investigated to ensure Ag NP aggregation state is not altered when extracted from the complex soil matrix. Investigations have also been underway to ensure that AF4 parameters including membrane type, external field and carrier composition do not alter the aggregation state of the colloids. Development of methods for detection and characterization of Ag NP partitioning between solid phases and soil pore water is a stepping stone to understanding Ag NP behavior and transformation within soils.

328 Modernizing Requirements for the Ecological Assessment of Chemicals: The Move to Intelligent Testing Strategies M. Bonnell, Environment Canada, New Substances Division, Environment Canada, Science and Risk Assessment Directorate. The generation of data for the regulatory assessment of chemicals is undergoing a paradigm shift. Traditional toxicological methods that use a large number of animals is being replaced with alternative test methods. Mostly, this has been driven by the fact that government and industry are now required to examine large numbers of chemicals in their inventories for hazard properties using a relatively rapid assessment approach. Fewer chemicals undergo the long assessment cycles traditionally associated with legacy chemicals such as PCBs, mercury and dioxins. The focus of regulatory assessors today is on lesser studied practically unknown chemicals with little or no data, let alone toxicological data. One can imagine then the animal usage, cost and time required to test thousands of chemicals in an inventory in order to satisfy traditional data requirements for hazard or risk assessment. Animal rights activists, particularly in Europe, have petitioned the European Commission to severely reduce or even abandon animal testing for the data requirements under REACH (Registration, Evaluation, Authorization and Restriction of Chemicals). Intelligent or integrated testing strategies (ITS) have therefore evolved to help fulfill data needs for modern regulatory assessment with the intent of reducing animal usage. The focus of these strategies has been on toxicity testing, but strategies also exist for other endpoints in risk assessment (e.g., bioaccumulation and biodegradation). This presentation will examine the critical tiers of an ITS and discuss how elements within each tier, such as in silico and in vitro methods interact to help satisfy data requirements for chemical assessment yet also provide a weight of evidence. ITS concepts shall be presented using bioaccumulation assessment as an example.

329 Revisiting the Relationships Between the Fish Embryo Toxicity Test and the Acute Fish Toxicity Test (OECD 203) – New Data, New Insights S.E. Belanger, The Procter & Gamble Company, Environmental Stewardship Organization, The Procter & Gamble Company, Central Product Safety Dept; F. Busquet, European Commission JRC/ IHCP/ ECVAM; T. Braunbeck, Univ of Heidelberg, Dept of Zoology; G. Carr, Procter & Gamble; M. Halder, European Commission JRC/IHCP/ECVAM; A. Lillicrap, NIVA; J. Rawlings, Procter & Gamble; R. Strecker, Univ of Heidelberg, Dept of Zoology; S. Walter-Rhode, UBA, German Federal Environmental Agency; A. Gourmelon, P. Amcoff, OECD. The OECD 203 Acute Fish Toxicity Test Guideline (TG 203) is used as a basis for chemical safety assessments worldwide. In 2005, the German Federal Environment Agency submitted a draft TG on "Fish embryo toxicity (FET) test" to the OECD Test Guideline Program and a supportive Background Paper. Subsequently, OECD established the ad hoc Expert Group on the FET Test. The Expert Group concluded that critical components to establish the utility of the Fish Embryo Toxicity Test (FET) as an alternative to the (OECD 203) included better understanding of inter- and intra-laboratory variability of the method, the ease of method transfer, and the relationship between the FET and acute fish toxicity (OECD 203). The FET-acute fish relationship was previously examined by Lammer et al. (2009); however, additional information on the domain of applicability was needed as well as the influences of FET inter-laboratory variability. The OECD established a Validation Management Group for the FET, coordinated by ECVAM, to oversee a comprehensive international validation involving several laboratories. Significant advances in knowledge in the key areas have been gained along with a burgeoning data base of new FET results for additional chemicals. We revisit the FET-acute fish toxicity relationships incorporating results from the first of this two-phase validation program. FET Inter-lab variability measured as coefficient of variation for seven organic compounds that ranged in toxicity between 0.3 mg/L to 12 g/L (4+ orders of magnitude) was demonstrated to be between ~5 to 50%. Reproducibility was fairly independent of toxicity, but driven by chemical properties. In revising the FET-acute Fish relationship we investigate the influence of 48-hr FET data (much of the historical studies) versus 96-hr FET data (more recent). An increase in the chemical coverage from the historic relationship (n= 77 chemicals) to the current update (~ 100 chemicals) reflects a broad change in the applicability domain. The new data results in marginal change to the older FET-fish regressions while addressing concerns about a lack of knowledge in the FET axis. Example of species-specific relationships (e.g., zebrafish only data) versus pooled species relationships will be also be reviewed. "Disclaimer: The opinions expressed and the arguments employed herein are those of the authors and do not necessarily reflect the official views of the OECD or of the governments of its member countries".

330 Assessment of In Silico Methods to Estimate Aquatic Species Sensitivity M.G. Barron, USEPA, Gulf Ecology Division; C.R. Jackson, J. Awkerman, USEPA. Determining the sensitivity of a diversity of species to environmental contaminants continues to be a significant challenge in

ecological risk assessment because toxicity data are generally limited to a few standard species. In many cases, QSAR models are used to estimate toxicity in the absence of measured toxicity values. We developed species sensitivity distributions (SSDs) and fifth percentile hazard levels (HC5) for aquatic species using three USEPA QSAR tools: ECOSAR (Ecological Structure Activity Relationships; www.epa.gov/oppt/newchems/tools/21ecosar.htm), ASTER (Assessment Tools for the Evaluation of Risk; www.epa.gov/med/Prods_Pubs/aster.htm), and T.E.S.T. (Toxicity Estimation Software Tool; http://www.epa.gov/nrmrl/std/cppb/qsar/). QSAR estimates were used as input into the SSD module of the internet-based toxicity estimation program Web-ICE (http://www.epa.gov/ceampubl/fchain/webice/). In silico estimated HC5s were compared to HC5s developed from a dataset of over 14,000 toxicity records extracted from Ecotox and other sources. Preliminary results indicated that the input LC50 values generated by the three QSAR tools produced variable and often substantially higher estimates of acute toxicity than measured values. In general, chemicals with narcosis-based MOAs had the best agreement between measured and in silico estimated HC5s. Additional research will determine if in silico methods can be used to generate SSDs and accurate HC5s.

331 Embryotoxicity of Pulp Mill Effluent Extracts in Japanese Medaka (*Oryzias latipes*) R. Orrego, Univ of Ontario Institute of Technology, Faculty of Science, Univ of Ontario Institute of Technology, post doctoral fellow; J. Guchardi, D. Holdway, Univ of Ontario Institute of Technology. Effects of Chilean pulp mill effluent extracts (solid phase extraction of untreated, primary and secondary treated pulp mill effluents), along with steroid standards (testosterone and 17β-estradiol) and a wood extractive standard (beta-sitosterol) were evaluated on developing post-fertilized medaka fish embryos. Our research has included a waterborne semi-chronic exposure experiment using 24hpf (unknown sex) d-rR (orange-red) mutant strain medaka embryos and two waterborne exposure experiments using 24hpf (unknown sex) FLFII (female leucophore free) and 72hpf FLFII (phenotypic sex-identified) mutant strain medaka embryos. Chronic exposure of both 24hpf d-rR and FLFII strain embryos showed similar delay in time to hatch and decreased hatchability with no significant egg and larvae mortality observed in all pulp mill extract exposed embryos. In contrast, significant early hatching and increased hatchability were observed in beta-sitosterol d-rR exposed embryos. High mortality was observed in all testosterone exposed embryos. Severe teratogenic responses were observed in medaka d-rR embryos in all treatments. Abnormalities included optical deformities (micro-opthalmia, 1 or 2 eyes) and lack of development of forebrains and hearts. Teratogenic responses such as axis malformation and pericardial edema were observed in all treatments using 24hpf FLFII with a high percentage related to males identified by fluorescent leucophore under microscope. Sex-related high mortality associated with severe malformations was observed in male and female embryos exposed to testosterone and pulp mill. Furthermore, signs of later masculinisation were observed in females exposed to testosterone where a slightly fluorescence of leucophores were detected before death. Differences in the severity of teratogenic effects seem to be related with the unique phenotype of each medaka mutant strains (d-rR and FLFII). Overall, our research has indicated that Chilean pulp and paper mill extractives caused medaka embryotoxicity (post-fertilized embryos) irrespective of the effluent treatment and different mutant strain used. The effects were mainly associated with delayed time to hatch, decreased hatchability, and sex-related teratogenesis and mortality.

332 Linking High-Throughput In Vitro Screens with EDSP Assays: The Casual Relationship Dilemma E. Mihaich, Environmental and Regulatory Resources, LLC; C. Borgert, Applied Pharmacology and Toxicology, Inc.; L. Ortego, Bayer CropScience; B. Neal, Exponent; S. Gehen, Dow Agrosciences; W. Jones, CropLife America. One step in complying with Test Orders under the USEPA's Endocrine Disruptor Screening Program was compilation of Other Scientifically Relevant Information (OSRI). The extent and quality of OSRI was evaluated to determine what requirements were met by existing data, and hence, which of the 11 Tier 1 Endocrine Screening Battery (ESB) assays were needed. Many of the List 1 chemicals under ESB Test Orders were analyzed in the EPA's ToxCast Program, hence ToxCast data were submitted as OSRI in lieu of conducting many similar ESB in vitro assays, and to help support waivers for some in vivo assays. ToxCast seeks to predict human toxicity by measuring the activity of chemicals in a suite of some 500 cellular, biochemical and molecular assays conducted in high-throughput mode. The concept presumes that these assays can identify a chemical's ability to activate so-called 'toxicity pathways.' In evaluating acceptability of OSRI, EPA rejected ToxCast results claiming that the reliability, responsiveness and relevance of ToxCast were undetermined and that ToxCast does not evaluate all known endocrine targets. In rejecting ToxCast data, EPA claimed its validation status was inferior to that of the individual ESB assays. However, the predictive value of the in vitro ESB assays for in vivo endocrine activity is also unknown at this time. Although EPA rejected ToxCast data as OSRI for the ESB, it used ToxCast data to assess and deem acceptable the risks of oil dispersants used for the Deep Water Horizon spill. These decisions have significant implications for the use of screening assays in regulatory programs, yet inconsistencies in application confound what those implications might be. Both the ESB and ToxCast programs appear to rely on correlative analyses rather than dispositive evidence that assays individually or in combination measure precursor events or frank toxicity. Clear and transparent criteria have yet to be defined for conducting weight of evidence evaluations of the ESB data. Although clearly defined biological activity is measured by most endpoints in the ESB, the 'toxicity pathways' ostensibly addressed by ToxCast assays are hypothetical. Despite potential advantages offered by ToxCast methods, it will be necessary to elucidate aspects of biological and physiological function as well as causal relationships between biochemical events and adverse effects before these data can offer improvements in the assessment of endocrine-mediated toxicity.

333 The DanTox-Project – Identification of Specific Toxicity and Molecular Modes of Action of Sediment-bound Pollutants in Zebrafish H. Hollert, RWTH Aachen Univ, Institute for Environmental Research, Dept of Ecosystem Analysis, Institute for Environmental Research, RWTH Aachen Univ, Deptartment of Ecosystem Analysis, RWTH Aachen Univ, Inst. for Envrionmental Research; S. Peddinghaus, J. Braunig, RWTH Univ; U. Feiler, 2German Federal Institute for Hydrology; c. Hafner, Hydrotox GmbH; M. Hammers-Wirtz, GAIAC; N. Ho, 5Karlsruhe Institute of Technology; B. Kais, Aquatic Ecology and Toxicology Group; J. Otte, Karlsruhe Institute of Technology; R. Ottermanns, RWTH Univ; S. Rastegar, Karlsruhe Institute of Technology; G. Reifferscheid, German Federal Institute for Hydrology; T. Braunbeck, Aquatic Ecology and Toxicology Group; U. Straehle, Karlsruhe Institute of Technology; S. Keiter, RWTH Univ. The aims of the DanTox project are a) to develop a suitable testing strategy for the assessment of bioavailable toxicants in sediments, b) to investigate the molecular and cellular mechanisms of sediment toxicity, and c) to elucidate the causality of biological effects. The long-term objective will be the development of a targeted cDNA-microarray which will be a useful tool for environmental screening. Sediment samples were collected from the Rhine River (Altrip and Ehrenbreitstein) and from the Vering Canal in Hamburg. For the testing of model chemicals methylmercury(II)-chloride, chlorpyrifos, Aroclor 1254 and bisphenol A were selected. The different methods of the project are categorized into four modules: a) bioassays – selected biomarkers and endpoints; b) gene expression – microarrays and qRT-PCR; c) data assessment – statistical evaluation of the data; d) practical transfer – comparison of the results from sediment contact tests and guideline tests. At the present stage of the project, results from the fish embryo test, EROD assay, live-imaging of EROD induction and qRT-PCR analysis are available. The highest embryotoxic potential was measured for the sample from Vering Canal after 48 h of exposure (EC50 = 2.6 and 3.6 mg/ml for extract and native sediments, respectively). EC50s for the extracts from Ehrenbreitstein (EC50 = 21.7 mg/ml) and Altrip (EC50 = 18.1 mg/ml) suggest that there is a comparable embryotoxic hazard potential. Only minor EROD induction was measured for TCDD suggesting that the barrier function of the chorion prevents TCDD from harming the embryo. In contrast, sediment extracts showed a clear dose-response-depending EROD induction. Live-imaging of EROD induction with β-naphtoflavone as a positive control documented CYP1 induction at any time of inspection. Due to their molecular structure, methylmercury(II)chloride and chlorpyrifos showed no EROD induction. qRT-PCR revealed clear changes in the transcript abundance of CYP1A1, GST and UGT1A1 genes for the sediment extracts. Up to 600-fold changes in CYP1A1 could be seen for the extract from Vering Canal. First results from the biotest systems indicate that measurement of specific endpoints is a suitable strategy to identify and detect the bioavailable hazard potential of sediments. In addition, a comparison of the results from the EROD assay and qRT-PCR showed similar tendencies for the sediments indicating that the EROD assay with zebrafish could be a useful tool for routine testing.

334 Transcriptomics and Transgenics – Novel Endpoints for the Fish Embryo Toxicity Test (FET) to Infer Adverse Outcomes M. Fenske, E. Muth-Koehne, Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Dept of Ecotoxicology; V. Delov, RWTH Aachen Univ, Institute of Molecular Biotechnology (BioVII) , Fraunhofer IME, Ecotoxicology; V. Schiller, RWTH Aachen Univ, Institute for Molecular Biotechnology (Biology VII), Fraunhofer Institute for Molecular Biology and Applied Ecology, Dept of Ecotoxicology; A. Wichmann, RWTH Aachen Univ, Institute for Environmental Research (BioV); R. Kriehuber, Forschungszentrum Jülich GmbH, Dept of Safety and Radiation Protection; C. Schaefers, Fraunhofer Institute for Molecular Biology and Applied Ecology IME, Dept of Ecotoxicology. In aquatic ecotoxicology, the fish embryo toxicity test FET can be considered as one of the most promising animal alternative methods, and internationally considerable endeavors are being made to validate the FET as an alternative to the fish acute toxicity test (OECD203). In the US, zebrafish embryos are also used in the context of the ToxCast™ program of the EPA to screen for developmental toxicity. However, proof-of-principle studies have repeatedly shown that the FET can deliver more than just acute toxicity data, in particular when new and especially molecular endpoints are incleded in the test. Notably postgenomic approaches, like transcriptomics using microarrays, are well suited to evaluate subacute or teratogenic effects mechanistically, due to their high sensitivity and information rich data. They are also excellent tools for the identification of effect-specific markers, which prove very beneficial for (pre-)screening applications or for the prioritization of chemicals according to their hazard potential. We conducted gene expression studies with zebrafish and medaka embryos after exposure (for 48h and 7 days, respectively) to different chemicals. Effects of estrogenic and anti-androgenic compounds (genistein, BPA, linuron, prochloraz) were studied in both species; effects of insecticide were evaluated in zebrafish only. Functional analysis of regulated genes revealed that compounds suspected of endocrine activity in fish were able to disrupt endocrine system related pathways already in the embryos. Often, even the mode of endocrine disruption could be inferred from the transcriptome response. Insecticides like cartap or fenazaquin, affected the transcriptome very specifically, and the intersection of regulated genes was comparably larger for insecticides of similar than of dissimilar MOA. The use of GFP-expressing transgenic zebrafish lines is a novel and useful approach to enhance the mechanistic characterization of teratogenic effects in the FET. We use e.g., the transgenic line Tg(*fli1a*:EGFP)^{y1}, which expresses the enhanced green fluorescent protein in all blood vessels. This enables the assessment of vascular malformations at an early stage in the live embryo, and the effects are quantifiable, which is another advantage of this method over subjective morphological assessments.

335 What Reductions in Fish Use Can be Made Employing Alternatives for Wastewater Effluent Assessment? P. Dorn, Shell Health, Ecotoxicology & Ecological Risk Ass; S.E. Belanger, The Procter & Gamble Company, Environmental Stewardship Organization, The Procter & Gamble Company, Central Product Safety Dept; T.J. Norberg-King, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; M.R. Embry, ILSI Health and Environmental Sciences Institute , ILSI Health & Environmental Sciences Institute (HESI), Senior Scientific Program Manager; P. Guiney, S.C. Johnson & Son, Inc., Global Safety, Regulatory & Environmental Assessme; M. Lampi, ExxonMobil Biomedical Sciences, Inc. Fish testing has many applications which may include new chemicals screening, product safety assessment, and water supply safety. The majority of fish testing use can be attributed to compliance and investigational testing of treated wastewaters throughout the world. Permitted wastewater discharges to surface waters are routinely tested in North America for effluent toxicity to determine compliance to state and national water quality standards. Similar mechanisms or goals exist in certain parts of Europe and Asia. Larval, juvenile and adult fish are employed for acute and/or chronic toxicity determinations. A major advantage of effluent toxicity testing is the integration of mixture toxicity and bioavailability. This is unlike chemical-specific analysis which identifies only individual constituents and can make it difficult to determine if receiving waters are protected. We suggest that a 3R approach for effluent testing will lead to adequate or new alternative solutions that are fit better designed for their purpose and enable fast, cost-effective equivalents. Alternatives for fish effluent testing include streamlining existing tests to use fewer fish, in vitro methodologies and fish embryo testing. We will review several options to reduce numbers of fish using techniques such as: combining control treatments, test designs using fewer effluent concentrations and possible development of fish embryo tests yielding equivalent results to standard assays using swim-up/ and larval forms and chronic toxicity endpoints. A program has been initiated to test assumptions and assay conditions using fathead minnow and zebrafish. Comparisons of embryo tests and classical effluent survival and growth assays for both species are planned using chemicals and representative effluents. Successful results in the pilot experiment would prompt a more extensive program. Lastly, these assays may have additional utility to develop fish toxicity perspectives on complex mixtures and metabolites using benchtop wastewater treatment plant models (e.g., CAS units) during the development of new or existing chemical assessments.

336 Neurochemical Biomarkers and Mercury Levels in Three Brain Regions of Wisconsin River Otters (*Lontra canadensis*) P.W. Dornbos, Univ of Michigan, Environmental Health Sciences; D. Nam, Univ of Michigan, Environmental Health Sciences; S. Strom, Wisconsin Dept of Natural Resources, Bureau of Wildlife Management; N. Basu, Univ of Michigan, Environmental Health Sciences, 1512 Plymouth Road Apartment 64 Fish-eating wildlife, such as River otters (*Lontra canadensis*), bioaccumulate concerning levels of mercury (Hg) which is a potent and ubiquitous environmental neurotoxicant. Despite such exposures, little is known about Hg-associated neurotoxic effects in this species and whether certain physiologically-important brain regions are particularly at risk. By studying river otter carcasses (N=40) from Wisconsin, we hypothesize that: A) brain total Hg levels will associate several neurochemical biomarkers, such as the N-methyl-D-aspartic acid receptor (NMDA) and benzodiazepine g-aminobutyric acid receptor ($GABA_a$), as shown in previous investigations; and B) that associations will vary across three brain regions of physiological importance: Occipital cortex (Ox), Cerebellum (Cb), and the Brain Stem (Bs). In order to assess Hg exposure, a Direct Mercury Analyzer was used to measure total dry weight Hg concentrations within the three brain regions as well as fur, muscle, and liver. Mean Hg levels indicated the highest concentrations in Cb (0.95±0.76 ug/g), followed by Ox (0.89±0.69 ug/g), and lowest concentrations resided in Bs (0.66±0.36 ug/g). Statistical analysis indicated mean Hg concentration of Cb was significantly higher than Bs ($P=0.037$) while no significant differences were present among the remaining regions. Hg levels of fur (8.72±4.90 ug/g), muscle (1.98±1.35 ug/g), and liver (4.92±5.71 ug/g) were found to be significantly higher than the three brain regions ($P < 0.01$). Preliminary neurochemical assays (N=13) indicated no significant associations among total Hg and NMDA and $GABA_a$ receptor binding in the three brain regions. Additional samples and other biomarkers, such as glutamic acid decarboxylase and glutamine synthetase, will be analyzed to increase the power of this study. It is expected that these results will provide insight into the localization of Hg within the brain and the potential neurochemical effects associated with differing Hg concentrations within river otters and other mammalian wildlife.

337 The Effects of Polychlorinated Biphenyls (PCBs) on Song Sparrow (*Melospiza melodia*) Songs S. DeLeon, R. Halitschke, A. Dhondt, Cornell Univ, Dept of Ecology and Evolutionary Biology. During the last century, polychlorinated biphenyls (PCBs) have emerged as harmful, worldwide chemical pollutants. Most research on the biological effects of PCBs on wildlife has emphasized the lethal effects of PCBs, such as embryo and juvenile mortality, and adult survival. However, it is well known that PCBs have long lasting developmental, reproductive and endocrine effects at sublethal exposures. The brain areas that produce song in birds are complex and highly vulnerable to both internal (i.e., developmental stress) and external (i.e., habitat fragmentation and parasitism) environmental stressors. Recent research shows that key areas in the learning and production pathways in the avian brain song system decrease in size when young birds are exposed to PCBs. Therefore, the goal of this research is to study consequences of sublethal exposures to PCBs on song production and quality in free-ranging song sparrows. During the breeding seasons (April-June) of 2006-2009 we studied Song Sparrows residing along the Hudson River, in northeastern New York. General Electric plants on the Hudson River discharged up to 1.3 million pounds of PCBs into the river between 1914 and 1977, resulting in the Hudson River being listed as a National Priorities List Superfund Site in 1984. Male Song Sparrow songs were recorded along the Hudson River, at locations above the point source pollution, and along a gradient downstream from the pollution source. Individual Song Sparrows were also captured at a subset of the recording locations in 2008 and 2009, and a whole blood sample and five feathers were collected from each individual along this PCB-gradient. PCBs were extracted according to established protocols after

addition of a stable isotope-labeled $^{13}C_{12}$-PCB mixture as an internal standard. A Solid Phase Extraction (SPE) cleanup produced the final extracts, which were analyzed by gas chromatography-mass spectrometry. We report quantitative PCB values from blood and feather samples, correlated with song data of males from the same regions, to test the hypothesis that there exists a direct link between PCB exposure and song in Song Sparrows.

338 The Neurotoxic Potential of Emerging Perfluoroalkyl Acids (PFAAs) in Developing Chicken Embryos C.G. Cassone, V. Vongphachan, Univ of Ottawa, Dept of Biology; S. Chiu, E. Pelletier, Environment Canada, Wildlife Toxicology; R.J. Letcher, Carleton Univ, Dept of Chemistry, Environment Canada, Science and Technology Branch, Ecotoxicology and Wildlife Health Division, Science and Technology Branch, Environment Canada, Great Lakes Institute for Environme, Canadian Wildlife Service; C.L. Yauk, Health Canada, Environmental Health Centre, Carleton Univ, Dept of Biology; D. Crump, Environment Canada, National Wildlife Research Centre; S.W. Kennedy, Univ of Ottawa, Dept of Biology, Univerisity of Ottawa, Dept of Biology, Environment Canada, National Wildlife Research Centre. Perfluoroalkyl acids (PFAAs) are synthetic substances known for their chemical stability, resistance to degradation and potential to biomagnify in food chains. The toxicological and biological effects of PFAAs are not well characterized, although there is some evidence to suggest that they can impact neurodevelopment. Recent studies conducted in our laboratory have reported significant in vitro effects of two "replacement" PFAAs, perfluorohexane sulfonate (PFHxS) and perfluorohexanoic acid (PFHxA), on mRNA levels of thyroid hormone (TH)-responsive genes, including type II 5'-deiodinase (D2) and neurogranin (RC3), in chicken embryonic neuronal (CEN) cells. The present study attempts to confirm the in vitro effects of PFHxS and PFHxA in whole chicken embryos and to evaluate embryotoxicity, developmental endpoints and global gene expression profiles. PFHxS or PFHxA was injected into the air cell of 16-20 embryos per dose group at nominal concentrations of 0 (DMSO control), 10, 100, 1,000, 10,000 and 50,000 ng/g egg. Chicken embryos were incubated until pipping, at which point hatching parameters including pipping success, embryo and liver mass and tarsus length were recorded. Cerebral cortices were collected from eight embryos for chemical residue analysis and total RNA was extracted for subsequent real-time RT-PCR and microarray analysis. Pipping success decreased to 69% and 78% in the 50,000 ng PFHxS/g and 10,000 ng PFHxA/g dose groups, respectively. Embryo mass and tarsus length were significantly decreased, while liver somatic index was significantly increased in the 50,000 ng PFHxS/g dose group (n=16-20, $p< 0.05$). No significant morphological changes were observed in the PFHxA-dosed embryos. Octamer motif binding factor 1 (OCT1), D2 and RC3 mRNA levels were significantly up-regulated in the cortex of embryos exposed to 10,000 and 50,000 ng PFHxS/g (n=4-8, $p< 0.001$). D2 mRNA levels were significantly up-regulated in embryos exposed to 100 and 10,000 ng PFHxA/g (n=8, $p< 0.05$). The present study successfully validates in vitro results concerning the modulation of key TH-responsive genes in an in vivo system and identifies adverse phenotypes in response to PFHxS treatment. Future microarray analysis of genome-wide expression patterns in developing chicken cortex will provide insight into the effects and mechanisms of action of PFHxS during neurodevelopment.

339 Mercury Inhibits Brain Synaptosomal Glutamate Uptake Across Fish, Birds, and Mammals – Evidence from In Vitro, Laboratory, and Field Studies D. Nam, Univ of Michigan, Dept of Environmental Health Sciences; N. Basu, Univ of Michigan, Dept of Environmental Health Sciences, Univ of Michigan, Dept of Environmental Health. Mercury (Hg) is a potent neurotoxicant that affects essential brain functions related to animal behavior and reproduction. While rodent studies have documented that a major mechanism underlying the neurotoxicity of Hg is inhibition of sodium-dependent transporters modulating glutamate uptake by astrocytes, such studies have not been studied in wildlife species. Here we explore the inhibitory effects of inorganic mercury ($HgCl_2$) and organic mercury (MeHg) on glutamate uptake in brain synaptosomes from fish (seatrout, zebrafish, lemon shark, mako shark), birds (chicken, bald eagle), and mammals (mouse, mink, otter, seal). We use both in vitro and in vivo methods. Through in vitro screening assays, MeHg and $HgCl_2$ inhibited the glutamate uptake in synaptosomes in a dose-dependent manner across species (IC_{50}: 0.39–2.3 μM of $HgCl_2$; 0.15–19.6 μM of MeHg). Based on IC_{50} values, species sensitivities to glutamate uptake inhibition by $HgCl_2$ can be generally ranked as: seatrout, zebrafish, mink (< 0.5 μM) > otter, mouse, lemon shark, chicken (< 2 μM) > seal, bald eagle, mako shark (>2.0 μM). Following in vitro MeHg exposure, seatrout (< 0.5 μM) was the most sensitive to glutamate uptake, followed by other 7 species (< 2.0 μM), and mink and seal (6.4–19.6 μM). Following in vivo studies on laboratory-exposed mink and chicken embryos and field-exposed bald eagles and lemon sharks, similar MeHg-related effects were observed. MeHg-exposed minks (n=12; 2ppm MeHg in diet) had 40 times more MeHg in their brain and 35% less glutamate uptake compared to non-exposed controls ($p< 0.001$). Glutamate uptake was significantly reduced (30–35%) in chicken embryos exposed to MeHg (2, 3.2, 6.4 μg MeHg/g egg) compared to control groups (n=11-18 each; $p< 0.05$). Field studies on bald eagles also showed a negative correlation between brain total Hg (range: 0.29 – 13.5 ppm) and glutamate uptake (n=7; rp=-0.871 p=0.011), while such a relationship was not observed in lemon sharks (n=27; rs=-0.327; p=0.096) probably due to relatively low brain Hg levels (0.05–0.34 ppm). Collectively, ecologically relevant levels of Hg can modulate glutamatergic pathways as demonstrated in series of in vitro, field work, and laboratory bioassay across fish, birds, and mammals. These comparative approaches may provide a framework for evaluating neurotoxic risks in the environment.

340 Decreased Swimming Performance in Juvenile Rainbow Trout (*Oncorhynchus mykiss*) Associated to the Pyrethroid Pesticide Deltamethrin A. Goulding, L. Shelley, Simon Fraser Univ; P.S. Ross, Fisheries and Oceans Canada, Institute of Ocean Sciences; C.J. Kennedy, Simon Fraser Univ, Dept of Biological Sciences. Deltamethrin and permethrin are neurotoxic pyrethroid insecticides commonly used both agriculturally and domestically, and have been identified as contaminants in sensitive aquatic environments. While pyrethroids are generally considered to present minimal risk of toxicity to terrestrial vertebrates, these chemicals have high lethal toxicity to fish. Except under rare conditions such as spills, the concentrations of pyrethroids in the environment are generally below levels expected to cause immediate lethality; however, these pesticides may lead to sub-lethal effects in exposed fish. Pesticide-associated changes to neuro-muscular function may translate into decreased swim performance and increased risk of predation, thereby increasing mortality rates and contributing to population-level declines. Since there are no readily available biochemical indicators of pyrethroid-induced neurotoxicity, swimming behaviour represents an integrated means of assessing toxicological injury in a manner that is ecologically relevant. Juvenile rainbow trout, *Oncorhynchus mykiss*, were exposed to either deltamethrin (0, 100, 200 or 300 ng/L) or permethrin (0, 0.5, 1, and 1.5 μg/L) for four days and subsequently assessed for swimming performance. Swim performance was reduced at the 200 and 300 ng/L doses of deltamethrin; however, permethrin did not affect swim performance at the concentrations tested and was therefore not investigated further. Subsequently, *O. mykiss* were exposed to deltamethrin (300 ng/L) for up to seven days and then allowed to recover in clean water, with assessment of swim performance on days 1, 4 and 7 of both exposure and recovery periods. Additional experiments will assess the ability of deltamethrin-exposed fish to avoid predation. This study suggests that sublethal exposures to deltamethrin leads to risks that are ecologically relevant, a finding that should be of value for regulators as they seek to protect fish and fish habitat from unintended impacts.

341 Evolving Swimming Performance Endpoints in Fish for Water Quality/Toxicity Assessment B. Berli, Univ of Basel, Man-Society-Environment Program; A. Ralph, L. Wiwchar, Univ of Alberta, Dept of Biological Sciences; P. Holm, Univ of Basel, Man-Society-Environment Program; K. Tierney, Univ of Alberta, Biological Sciences. Fish swim in waters increasingly impacted by human activities. Studies have found contaminants, temperature change, disease and flow rates can affect swimming performance. The majority of these studies have tested fish individually, in spite of many species tendency to school. We found the swimming performance of two juvenile salmonids, rainbow trout (*Oncorhynchus mykiss*) and brown trout (Salmo trutta), and adult zebrafish (*Danio rerio*) increased by as much as 2 fold when tested in schools. With acute exposure to low concentrations of calcium carbonate, a common constituent of sediment, rainbow trout swam considerably slower, but only when tested in schools. An interesting finding with zebrafish was that swimming performance became more variable with increased school size, and that a small proportion of fish consistently outperformed the school. Individual swimming performance is notoriously variable, but repeatable. We were able to associate some of the performance variation with increased mRNA and activity of two enzymes critical to aerobic and anaerobic metabolism (citrate synthase and

lactate dehydrogenase). We take three things from our experiments: testing fish in schools captures more realistic and greater performances; changes in swimming performance depend on whether fish are tested individually or in schools; and innate differences in enzyme activity may help explain performance variation. These findings will be useful in determining how environmental contaminants, such as the neuromodulatory pharmaceuticals we are currently testing, differentially impair the athletic phenotypes apparent in schooling fish.

342 Sub-network Enrichment Analysis Reveals Sexually Dimorphic Responses in the Largemouth Bass Hypothalamus After Dieldrin Exposure C.J. Martyniuk, Univ of New Brunswick, Dept of Biology/Canadian Rivers Institute, Univ of New Brunswick, Biology; N.J. Doperalski, Univ of Florida, Dept of Physiological Sciences; K.J. Kroll, Univ of Florida, Physiological Sciences; D.S. Barber, Univ of Florida, Dept of Physiological Sciences; N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology. Organochlorine pesticides (OCPs) are a persistent class of environmental contaminant found in aquatic ecosystems worldwide. Studies demonstrate that the OCP dieldrin induces both neurotoxic and adverse reproductive effects in fish and mammals. The objective of this study was to characterize the effect of dieldrin in both female and male sexually regressed largemouth bass (*Micropterus salmoides*) (LMB) in a sub-chronic feeding exposure to 1) determine if the transcriptomic responses to dieldrin in the hypothalamus are conserved between the sexes and to 2) identify cell processes and signaling cascades underlying dieldrin neurotoxicity. Few studies address mechanisms of sexually dimorphic responses in the vertebrate CNS. Despite being a weak estrogen receptor agonist, we observed no adverse effects on reproductive endpoints that included GSI, plasma E2, and vitellogenin in males or females. Gene expression profiling and hierarchical cluster analysis revealed that the expression signature of dieldrin fed females and males grouped separately from control LMB but not from each other, suggesting that treatment influenced gene expression profiles more than the sex of the individual. However, male and female LMB showed marked differences in gene expression responses (only 11% transcripts were in common between the sexes). Functional enrichment analysis identified common biological processes and molecular functions affected by dieldrin that were related to steroid activity, stress, and protein folding (i.e., ubiquitin-proteasome pathway). Novel mechanistic insight was gained by performing sub-network enrichment analysis (SNEA), which revealed that in the female hypothalamus, dieldrin affected expression targets of GnRH, androgen, and GABA-A signaling whereas dieldrin affected expression targets of GnRH, somatostatin, and dopamine receptor signaling in males. This study demonstrates that there are sexually dimorphic responses to dieldrin in the vertebrate hypothalamus. This has implications for characterizing molecular responses and modes of action of aquatic pollutants in brain regions, as the neuroendocrine transcriptome of the sexes can respond quite differently at the genomic level to aquatic pollutants.

343 Using Magnetic Resonance Imaging to Determine the Effects of Thyroid Hormone Disruption on Brain Development E. Montie, M. Powell, Univ of South Carolina Beaufort; T. Zoeller, Univ of Massachusetts Amherst; M. Parekh, T. Mareci, Univ of Florida. Humans, terrestrial wildlife, and aquatic animals are exposed to environmental chemicals that have been shown to interfere with the thyroid hormone system at various levels. This hormone system is especially important in white matter development. Volume data acquired from magnetic resonance images can be used as endpoints to assess white matter defects. A first step in this line of investigation is to determine how a goitrogen (i.e., a substance that suppresses the function of the thyroid gland) administered to pregnant rats affects brain volumes and white matter integrity in offspring. We exposed pregnant Sprague Dawley rat dams to propylthiouracil (PTU) from gestational day 6 until postnatal day (PD) 25 with 3 and 10 ppm PTU but continued the life of some offspring to P90. Exposure to 10 ppm PTU caused lowered levels of triiodothyronine (T3) and thyroxine (T4) in the serum of PD 25 pups, while the levels of P90 rats returned to normal. We performed 3D isotropic imaging *ex vivo* at P25 and P90 using a 750 MHz Wide Bore Spectrometer (17.6 T). Our preliminary analysis of these images shows a global loss of white matter that is visible at postnatal day 25. These early results suggest that MRI will provide a sensitive tool for the study of thyroid disrupting chemicals on brain development that can be used to quantify volume changes in white matter and potentially changes to the axonal structure of the brain.

344 Passive Sampling as Tool for Monitoring the Quality of Source Waters for Drinking Water Supplies D. Alvarez, US Geological Survey, USGS Columbia Environmental Research Center; K. McCarthy, USGS; W. Cranor, USGS Columbia Environmental Researh Center. Determining the quality of drinking water sources, especially with respect to anthropogenic organic chemicals, can be problematic using standard sampling techniques. Many contaminants, including emerging contaminants related to wastewater treatment discharges, are present at trace, but potentially biologically significant concentrations. The Eugene Water and Electric Board in Oregon has taken a proactive approach to monitoring for regulated and unregulated organic contaminants using the semipermeable membrane device (SPMD) and polar organic chemical integrative sampler (POCIS) passive samplers. The use of passive samplers for monitoring drinking water sources is a relatively untested concept in the United States. These samplers were deployed in 2007 and again in 2010 in source waters and the finished water targeting a suite of legacy and emerging organic contaminants. Few chemicals were identified, generally at concentrations in the subnanogram to nanogram per liter range. Among the chemicals commonly identified were several PAHs and the pesticides chlorpyrifos, dacthal, and the degradation products of endosulfan and DDT. Chemicals related to wastewater treatment discharges were generally not detected. A screen for estrogens and estrogen-mimicking chemicals, the yeast estrogen screen (YES), measured detectable levels of estrogenicity in tributaries to the McKenzie River; however, no estrogenicity was measured in the river itself. This pilot study demonstrated the ability to use SPMDs and POCIS to monitor the water quality of drinking water sources.

345 Integrated Water-Quality Assessment using Conventional Sampling, Passive Sampling, and Assay Techniques: Toward a More Holistic Understanding of Risk K. McCarthy, V. Kelly, USGS; D. Alvarez, US Geological Survey, USGS Columbia Environmental Research Center. A combination of conventional point-in-time discrete water sampling, time-integrated passive sampling, and a bioassay are being used to assess the quality of the McKenzie River, which provides drinking water for nearly 200,000 water consumers in the vicinity of Eugene OR. The synergy of this three-pronged approach is allowing a more robust understanding than would be available from any one of the methods alone. Discrete water samples are being collected to provide information about how chemical concentrations vary with flow conditions (e.g., over the course of a storm). Semipermeable membrane device (SPMD) and polar organic chemical integrative sampler (POCIS) passive samplers are being used for time-integrated sampling and to allow measurements of chemicals present at concentrations below the limits of conventional point-in-time sampling and analysis techniques. Finally, the yeast estrogen screen (YES) is being used to provide insight into the biological effects of the mixture of compounds present in the water, including some that may not be targeted by the other two approaches. So far, during three separate sampling periods, we have detected 5 to 20 times more compounds with passive samplers than with conventional methods. In addition, positive results from the YES assay were associated with several potential endocrine disrupting compounds detected by passive samplers and indicate that estrogen activity is associated with urban land use in the basin. No compounds associated with endocrine disruption were detected using conventional sampling techniques.

346 USEPA/USGS Study of CECs in Source Water and Finished Drinking Water: Pharmaceuticals and Anthropogenic Indicator Compounds E.T. Furlong, M. Noriega, US Geological Survey, National Water Quality Laboratory; S.T. Glassmeyer, USEPA, Office of Research and Development, USEPA, NERL/MCEARD/CERB; D. Kolpin, US Geological Survey. For more than 10 years, the presence and distribution of contaminants of emerging concern (CECs) in water supplies has been a subject of substantial scientific and public interest. The US Environmental Protection Agency and the US Geological Survey jointly designed and implemented a study of concentrations of CECs in source and finished drinking waters across the United States, sampling ground- and surface-water sources prior to and after treatment by various processes typically used to produce finished drinking water. The timing of collection of source and finished drinking water samples from each plant was adjusted by the hydraulic residence time in the plant to determine relative removal of CECs during treatment. An extensive quality assurance/quality control design was applied to this study to assess precision and accuracy of CEC determinations at ambient environmental concentrations. More than 185 pharmaceuticals and

anthropogenic indicator compounds were determined by high-performance liquid chromatography/tandem mass spectrometry (LC/MS/MS) and by gas chromatography/mass spectrometry. Provisional results from a new direct aqueous injection LC/MS/MS method indicate that pharmaceuticals were detected in both untreated source water and finished drinking water samples, generally ranging in concentration from 2.5 to 400 ng/L. Precision at these ambient environmental concentrations was estimated from duplicate samples by calculating the relative percent difference (RPD). The median RPD ranged between 10 and 14 percent, with maximum RPDs of 74 and 83 percent in source and finished water, respectively. After correcting for ambient concentrations, median recovery of all pharmaceuticals from multiple matrix-spike experiments was 86 and meanrecoveries of individual pharmaceuticals ranged between 59 and 116 percent. The relative standard deviations of spiked pharmaceuticals ranged between 7 and 22 percent. The median method detection limit (MDL) for 113 pharmaceuticals was 5.4 ng/L, with greater than 75 percent of individual compound MDLs less than 17 ng/L, indicating that method sensitivity is sufficient for evaluating pharmaceuticals in water sources used for domestic consumption.

347 Pharmaceuticals and Endocrine Disrupting Compounds in Drinking Water: Occurrence, Treatment, and Transformation M.J. Benotti, Battelle, Analytical and Environmental Chemistry. The presence of pharmaceuticals and endocrine disrupting compounds (EDCs) in drinking waters has generated a lot of discussion about what, if any, toxicological significance they pose. To compliment this ongoing discussion, this talk will present results from several studies to highlight 1) pharmaceutical and EDC occurrence in drinking water, 2) the efficacy of conventional and advanced forms of water treatment, and 3) novel approaches for elucidating the transformation products that are formed from some of these treatment technologies. Low nanogram-per liter concentrations of pharmaceuticals and EDCs are found in source and finished drinking waters throughout the United States, and the suites of compounds that are detected are a function of the type of chemical oxidation used during the treatment process. Advanced oxidation processes (AOPs) have been shown in pilot-scale studies or in water reuse applications to be particularly effective at reducing concentrations of these compounds and total estrogenic activity, though the energy costs incurred by these processes are very high compared to conventional processes. Scientists and regulators have recently begun to investigate the presence of transformation products of certain pharmaceuticals and EDCs. Identifying transformation products produced following chemical or photolytic oxidation is important given that they may also bear some toxicological significance. To illustrate this approach, the transformation of four compounds commonly detected in drinking water (atrazine, carbamazepine, diclofenac, and sulfamethoxazole) by low- and medium-pressure UV and UV-H2O2 will be discussed. Experiments were conducted with a collimated beam apparatus and samples were analyzed by both LC-MS/MS and QToF-MS approaches. In each case, disappearance of the target analyte occurred concomitantly with the appearance of transformation products. The relative abundance of transformation products as a function of treatment can be used to hypothesize whether a transformation pathway is sequential (i.e., transformation products appear in a distinct sequence as a function of treatment) or non-sequential (i.e., transformation products appear with the same relative abundance as a function of treatment).

348 Comparison of Toxicity Measures and Disinfection Byproduct Analyses for Evaluating Drinking Water Quality After Disinfection B.A. Lyon, Univ of North Carolina at Chapel Hill, Environmental Sciences & Engineering; R.Y. Milsk, H.S. Weinberg, Univ of North Carolina at Chapel Hill, Environmental Sciences and Engineering. As drinking water sources become increasingly impacted by anthropogenic activities, utilities are looking to alternative disinfection techniques to meet regulations and deliver quality drinking water to consumers. UV irradiation is one such process being used in some drinking water treatment plants as a primary disinfectant prior to terminal disinfection by chlorination or chloramination. It is important to understand the potential impacts of these processes and to evaluate the balance between microbial and chemical byproduct risk. Trihalomethanes (THMs) and haloacetic acids (HAAs) are two widely-occurring classes of disinfection byproducts (DBPs) whose quantity and speciation are sometimes used as indicators for formation of other DBPs. However, past research has demonstrated that while some alternative treatment processes may reduce the formation of THMs and HAAs, they can increase the formation of other DBPs which could potentially be of more concern to human health. This paper demonstrates the value of measures other than THM and HAA formation as better representing DBP formation and overall finished water quality during UV treatment combined with chlorine or chloramines and includes both chemical and toxicity analyses. Water samples collected at the intake of a drinking water treatment plant were treated with chlorine or chloramine following UV irradiation in the presence and absence of nitrate, bromide and iodide, and compared to the same samples without UV but with a disinfectant dose adjusted for a similar target chlorine residual. Differences across treatments were investigated through analysis of total organic halogens (TOX) and TOX speciation (total organic chlorine, bromine and iodine), which was compared to individually measured DBPs (10 THMs, haloacetonitriles, halonitromethanes and haloketones). For toxicological assays, organic matter was concentrated by reverse osmosis (RO) and treated with different combinations of UV followed by chlorine/chloramine. RO concentration allowed for direct application of the disinfected samples to cells used for evaluating toxicity without the need for further treatment. Chronic cytotoxicity assays were performed using normal human colonocytes. This presentation will discuss the effects of UV treatment combined with chlorination/chloramination on the formation of DBPs, the overall incorporation of halogens into DBPs and indicate strategies for reducing drinking water toxicity associated with their presence.

349 The Fate and Cellular Toxicity of Silver, Zinc Oxide, Titanium Dioxide Engineered Nanoparticles in Water T.E. Abbott Chalew, Johns Hopkins Bloomberg School of Public Health, EHS; H. Huang, Johns Hopkins Bloomberg School of Public Health; K. Chen, Johns Hopkins Univ; K. Schwab, Johns Hopkins Bloomberg School of Public Health. Engineered nanoparticles (NP) widely used in consumer products may end up in the aquatic environment with potential impacts on aquatic organisms and humans. This project investigated NP stability in synthetic surface waters and the toxicity of aqueous NPs to human gut cell lines. We purchased unmodified, commercially available nanoparticles including silver (Ag), titanium dioxide (TiO_2), and zinc oxide (ZnO) with similar sizes as specified by the manufacturers. Average particle sizes measured by transmission electron microscopy were 34 nm, 36 nm, and 84 nm for TiO_2, ZnO, and Ag, respectively. Over 90% of particles were aggregated in ultrapure water. NP size was monitored over 48 hours in synthetic freshwaters (SFW) without and with natural organic matter (SFWN) (n=12 for both) using dynamic light scattering. After 48 hours, NPs in SFWN were the smallest (248 nm, 287 nm, and 201nm for TiO_2, ZnO, and Ag) compared to SFW (4970 nm, 9050 nm, and 255 nm for TiO_2, ZnO, and Ag). Human gut epithelial Caco-2 cells were exposed to NPs in media from 0-1000 ppm for 24 and 48 hours. Cell viability and cell stress are being evaluated. Significant cell death was observed at 50 ppm ZnO NPs (60%). No significant death in TiO_2 or Ag exposed cells was observed. NPs in SFWN are less than 300nm and remain in suspension, which suggests they will persist in surface and drinking waters. Therefore, it is critical to understand the effects of ingested nanoparticles to protect human health.

350 Presence of Arsenic in the Environment in Southwestern USA and Northern Mexico L.M. Camacho, Univ of Texas at El Paso, Center for Inland Desalination Systems; M. Gutierrez, Missouri State Univ, Dept of Geography; M.T. Alarcon-Herrera, Advanced Materials Research Center; M.d. Villalba, Chihuahua Autonoma Univ; S. Deng, New Mexico State Uiversity, Chemical engineering Dept. The presence of arsenic in the arid region of northern Mexico (states of Chihuahua and Coahuila) and the bordering states of the southwestern US (New Mexico, Arizona, and western Texas) were reviewed in this article. Main sources of arsenic in the study area were found to be primarily of natural origin. However, sources of non-naturally occurring arsenic included pesticides, sewages and smelting plants. Potential future Arsenic release from sediments of the Rio Concho Basin in northern México into the water column is a cause of concern. Exposure to arsenic contamination has shown to be detrimental to the central nervous system and for cognitive development in children, independent of socio-demographic variables, nutritional status, and levels of blood lead. Even though a variety of methods to treat contaminated water and soil are available, in the area of study, enhanced and emerging technologies have been applied in most of the cases only at laboratory or bench scale. Phytoremediation stands out as a promising technology for removal or arsenic in this region.

351 Arsenic Adsorption Influences Safe Drinking Water Options in Bangladesh K.A. Radloff, LDEO, Columbia Univ; Y. Zheng, LDEO, Columbia Univ, Queens College, CUNY; H.A. Michael, Univ of Delaware; M. Stute, LDEO, Columbia Univ, Barnard College; K. Ahmed, Dhaka Univ; A. van Geen, LDEO, Columbia Univ. An estimated 100 million people are exposed to elevated levels of As by drinking untreated groundwater tapped by manually operated tube wells in South Asia. In Bangladesh, the high spatial variability of dissolved As in the shallow aquifer makes predicting the location of safe, low-As groundwater difficult. The same spatial variability, however, also creates an opportunity for reducing As exposure by targeting low-As wells. A major question remains: To what extent could low-As wells be contaminated by the intrusion of high-As groundwater, especially in areas with extensive municipal and agricultural pumping? The purpose of this study was to quantify the extent to which retardation and adsorption can protect low-As aquifers from contamination. Two field sites were chosen to investigate arsenic adsorption in a shallow and a deeper aquifer. At the shallow aquifer site, groundwater As concentrations increased from 30 L kg-1. The push-pull tests confirmed the differences between the shallow and deeper sands, however partitioning estimates were generally lower. The results of these experiments provide further evidence that groundwater As concentrations are controlled by As sorption on sediment and sorption reaches equilibrium rapidly compared to the time scale of groundwater flow. The implication of this work is that groundwater As concentrations in both shallow and aquifer are currently stable, as mobility is retarded by adsorption, but remain vulnerable as groundwater flow conditions are perturbed at a growing scale.

352 Bioaccumulation of Biosolids-borne Triclosan (TCS) in Terrestrial Organisms M. Waria, Univ of Florida, Soil and Water Science Dept, Univ of Florida, Soil of Water Science; G.A. OConnor, G.S. Toor, Univ of Florida, Soil and Water Science; C. Wilson, Univ of Florida. Triclosan (TCS) is a common antimicrobial agent found in many personal care products and subsequently detected in wastewater treatment effluents and biosolids. Land application of biosolids can transfer significant quantities of TCS to the terrestrial environment. Our objective was to quantify the accumulation of biosolids-borne TCS in multiple food crops and earthworms. A recent greenhouse study found significant TCS accumulation [bioconcentration factor (BCF) = 3 to 6.5) in plant parts of a single crop (soybean) grown in soil amended with TCS spiked liquid biosolids. However, accumulation can vary with the plant species and type of biosolids (liquid vs cake) utilized. Our study evaluated plant accumulation in lettuce (*Lactuca sativa*), radish (*Raphanus sativus*), and bahia grass (*Paspalum notatum*), representing monocotyledons (monocots), dicotyledons (dicots), above-ground (leaves), and below-ground (roots) biomass. We grew plants in a field collected soil that was amended with cake biosolids at a high application rate (228 Mg ha^{-1}) once and field equilibrated for 2 years. The resulting TCS concentration was ~1 mg TCS kg^{-1} amended soil. The plants were either grown under growth chamber or greenhouse conditions. The TCS concentration utilized in the study did not adversely affect crop growth (dry matter yields). Accumulation was negligible in radish [bioaccumulation factor (BAF) = < 0.001] and bahia grass leaves (BAF = < 0.001), minimal in lettuce leaves (BAF = 0.01), but greater in radish roots (BAF = 0.10). Dicots (radish, lettuce) accumulated more TCS than the monocot (bahia grass). The BAF values suggest some accumulation in below-ground biomass (roots), but minimal translocation to above-ground biomass (leaves). We also collected earthworms from the same biosolids amended field soil. The average TCS concentration measured in the earthworms was 4.3 ± 1.9 mg kg^{-1} corresponding to an average bioaccumulation factor (BAF) of 4.3 ± 0.7. Preliminary risk assessments suggest that the pathways of plant consumption by human, animals; and soil consumption by earthworms present minimal risk from biosolids-borne TCS.

353 Bioaccumulation of Perfluorochemicals in Earthworms C. Rich, A. Blaine, Colorado School of Mines; C. Higgins, Colorado School of Mines, Environmental Science and Engineering. Perfluorochemicals (PFCs) are found in a variety of household products used every day including everything from stain repellents to non-stick pans. Biosolids derived from wastewater treatment plants are commonly land-applied in the United States, and as a result, biosolids-amended soils often contain high levels of PFCs. Recently, concerns have arisen about potential impacts to soil ecosystems following the land application of biosolids. Specifically, bioaccumulation of PFCs in the earthworm is of great interest since it represents a direct link between the soil and higher trophic levels. Previous studies have found that PFCs from sediment can bioaccumulate in aquatic worms. This study examined PFC bioaccumulation in earthworms living in biosolids-amended soils using a standard 28-day exposure. Two different field soils amended with high and low biosolids loading rates were used. Results from this study have important implications with respect to the potential transfer of PFCs from biosolids into the terrestrial food chain.

354 Uptake and Transformation of Estrogenic Compounds by Corn M. Card, The Ohio State Univ, School of Earth Sciences; Y. Chin, The Ohio State Univ, Dept of Geological Sciences. Hormonally active compounds are emerging contaminants of concern, and runoff from manure-fertilized fields represents a major, uncontrolled source of natural and synthetic estrogens in the environment. Uptake and transformation by crop plants and associated microbes may significantly limit the environmental mobility and effects of manure-borne estrogens. We exposed maize (corn) seedlings to hydroponic solutions containing one natural estrogen (17beta-estradiol [17b-E2] and estrone [E1]) or a synthetic estrogen mimic (zeranol [α-ZAL] and zearalanone [ZAN]). At given time points, four replicates of each treatment, including estrogen-free blank controls and plant-free glassware controls, were collected and destructively sampled. Plant tissues were homogenized and extracted in methanol, and analyte concentrations in the aqueous phase and methanol extracts were quantified by reverse-phase high pressure liquid chromatography (RP-HPLC). Transformation products were qualitatively identified by gas chromatography with mass spectrometry (GC-MS). After 22 d of exposure to maize seedlings, aqueous α-ZAL concentrations decreased 99% and ZAN concentrations decreased 96%. 17b-E2 and E1 were undetectable in the aqueous phase after 12 and 18 d of exposure, respectively. The seedlings performed reversible transformations between 17b-E2 and E1 and between α-ZAL and ZAN, whereas the plant-associated microbes only completed the oxidation step. Taking into account the relative estrogenicity of these natural and synthetic hormones, and the rate at which each was produced as transformation products, the observed transformations generally led to an overall reduction in the estrogenicity of the solutions. Further, exposure to these estrogens did not elicit significant changes in germination, growth, or enzyme activities of maize seeds. Although significant increases in all of these measures have been previously reported in corn exposed to 17b-E2, we did not observe changes in germination rates; root and shoot lengths; or activities of amylase, peroxidase, polyphenol oxidase, or catalase. Taken together, these results indicate that maize seedlings may have a significant impact on the environmental fate of manure-borne natural and synthetic estrogens, while exposure to these hormones likely has no detrimental effect on the plants.

355 In Situ Aquatic Flame-retardant Exposure and Trophic Transfer M.J. La Guardia, Virginia Institute of Marine Science, Environmental & Aquatic Animal Health, Virginia Institute of Marine Science, Environmental Science; R.C. Hale, E. Harvey, Virginia Institute of Marine Science, Environmental & Aquatic Animal Health. Based on concerns over potential health effects caused by some flame-retardants (FRs), two of the three-polybrominated diphenyl ether (PBDE) formulations (Penta- and Octa-BDE) were recently added to the Stockholm Convention's Persistent Organic Pollutants (POPs) list (Stockholm Convention, May 2009) and their usage and manufacture restricted. The third formulation, Deca-BDE is now banned in the EU and will be phased out of production in the U.S by the end of 2013. An additional FR, hexabromocyclododecane (HBCD) is also classified as persistent and bioaccumulative. It may cause reproductive developmental and neurological disorders. HBCD will be phased-out of European commerce by 2015. In the US, a USEPA review of HBCD is due by the end of 2011. To meet fire safety standards, consumer products still need to contain FRs. However, the environmental fate of several PBDE replacement products (i.e., 2-ethylhexyl 2,3,4,5-tetrabromobenzoate (TBB), 2-ethylhexyl 2,3,4,5-tretabromophalate (TBPH) and 1,2-bis (2,4,6-tribromophenoxy) ethane (BTBPE)) is largely unknown. We observed TBB, TBPH and BTBPE in sediments and to bioaccumulate in benthic organisms (Corbicula fluminea and Elimia proxima) collected downstream from a US textile manufacturer's outfall. The summed totaled body burden of these replacement products ranged from 152-to 2230 ng g-1 lipid weight (lw). These mollusks also exhibited ΣPBDEs 64,900 and 47,200 ng g-1 lw, and ΣHBCDs 363,000 and 151,000 ng g-1 lw, respectively. To further identify the aquatic fate of these alternative-FRs, critically needed for risk management evaluation, additional samples were collected at the aforementioned textile outfall. These included benthic predators and higher trophic

vertebrates. Samples were analyzed by liquid chromatography-atmospheric pressure photoionization (APPI) tandem mass spectrometry for α-, β- and γ-HBCD, TBB, TBPH and BTBPE including FRs routinely analyzed by gas chromatography mass spectrometry (i.e., PBDEs). Details of this in situ field study will be discussed including the aquatic trophodynamics of multiple FR exposure. Results using this novel ionization approach for FR analysis will also be introduced. A comparative analysis between the bioavailability of PBDEs, HBCD and alternative-FRs and their trophic transfer will be presented.

356 Bioaccumulation of Legacy POPs and Emerging Contaminants in Tropical Mangrove Food Webs B.C. Kelly, S. Bayen, H. Zhang, Y. Teo, National Univ of Singapore, Dept of Civil and Environmental Engineering. Tropical mangroves are important ecosystems in Southeast Asia, as well as other tropical and subtropical regions of the world. These unique ecosystems provide essential habitat for numerous species of aquatic and terrestrial organisms. Previous studies have demonstrated the occurrence and bioaccumulation of legacy persistent organic pollutants (POPs) such as PCBs, DDTs and PBDEs in Singapore mangroves. For example, SPCB concentrations were approximately 1 ng/g dry weight in sediments, 7 ng/L in sub-surface waters and between 0.5 to 100 ng/g wet weight in biota. The objectives of the present study are twofold: (i) conduct a field study to assess the occurrence, levels and bioaccumulation behavior of several emerging contaminants of concern in Singapore mangrove ecosystems and (ii) develop and evaluate a mechanistic model representing the bioaccumulation kinetics and trophodynamics of organic contaminants in tropical mangrove food webs. The field survey focused on detection of pharmaceuticals and personal care products (PPCPs), synthetic musks and current-use brominated flame retardants (BFRs) in samples of water, sediments and mangrove organisms (algae, zooplankton, worms, mollusks, crabs and fish) from two local mangroves. Following standard extraction and cleanup methods, identification and quantification of target compounds was performed using liquid chromatography-electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS) or gas chromatography triple-quadrupole tandem mass spectrometry (GC-MS/MS). Observed concentrations and bioaccumulation potential of target analytes were compiled and compared to those of legacy POPs. We further employed a mechanistic bioaccumulation model to predict steady-state chemical concentrations, species-specific bioaccumulation factors (BAFs) as well as trophic magnification factors (TMFs) based on ambient concentrations (air, water, sediments) and physical-chemical properties. The results indicate that chemical KOW greatly influences the chemical bioaccumulation in aquatic organisms such as zooplankton and fish, while chemical KOA is shown to be a key determinant for chemical biomagnification in air-breathing organisms inhabiting the mudflats and terrestrial zones. The model also highlights the significance of metabolic transformation rate, which undoubtedly plays a major role in the bioaccumulation potential of organic chemicals in the food webs.

357 Occurrence, Fate, and Biological Consequences of Antidepressants in Fish Living in Effluent-impacted Streams M.M. Schultz, College of Wooster, Dept of Chemistry; E.A. Sakach, The College of Wooster, Biochemistry and Molecular Biology; E.T. Furlong, US Geological Survey, National Water Quality Laboratory; D. Kolpin, P. Phillips, US Geological Survey; N. Chavez, The College of Wooster, Dept of Chemistry; H. Schoenfuss, St. Cloud State Univ, Aquatic Toxicology Laboratory, St. Cloud State Univ, Dept of Biological Sciences MS-273 Antidepressants are widely prescribed pharmaceuticals in the United States. As conventional treatment has limited removal of many pharmaceuticals, municipal wastewater treatment plants have been found to be an important source of antidepressants to the environment. Thus, fish residing in the effluent-impacted streams are receiving continuous exposure to antidepressants, causing a potential concern to non-target organisms A liquid chromatography/tandem mass spectrometry method was applied to measure antidepressants in aqueous samples and fish tissues from field and laboratory studies. A field study (2010) to measure antidepressants in brain tissues from native white suckers residing in effluent-impacted streams was conducted at points upstream and at points progressively downstream of select effluent outfalls in New York State (NY). Antidepressant profiles observed in the brains from this study substantially differed from the profiles previously observed at other geographic locations. Duloxetine was present at higher concentrations in the fish brains in the 2010 study as compared to the levels observed in previous studies conducted in 2005 and 2006, perhaps reflecting the increase in prescriptions dispensed over that time period. In addition, this NY field study reinforces the relation between effluent concentrations and corresponding fish brain concentrations. For example, a NY site with orders of magnitude higher effluent concentrations of bupropion than observed in previous studies also had parallel orders of magnitude higher fish brain bupropion concentrations. Complementary laboratory exposure studies were conducted on adult fathead minnows (*Pimephales promelas*) and adult bluegill (*Lepomis macrochirus).* Results from both laboratory exposures suggest that there is preferential uptake of select antidepressants, and that fish can metabolize fluoxetine to its biologically active metabolite, norfluoxetine, which, similarly to parent fluoxetine, can inhibit the presynaptic reuptake of serotonin.

358 The Role of Periphyton in the Removal of Trace Organic Compounds in an Engineered Treatment Wetland J.T. Jasper, Univ of California – Berkeley, Dept of Civil and Environmental Engineering; D.L. Sedlak, Univ of California – Berkeley, Dept of Civil & Environmental Engineering. Engineered treatment wetlands offer a cost-effective means of removing trace organic contaminants from municipal wastewater. Treatment wetlands designed to remove nutrients often employ dense vegetation and reducing condition to enhance rates of denitrification and particle settling. However, these systems are often inefficient and could actually accumulate organic contaminants. To enhance rates of removal of trace organic contaminants, a treatment system was designed with shallow water and a coating of periphyton on the bottom. This configuration yields enhanced rates of photolysis, opportunities for contaminant removal through sorption and contaminant transformation by a diverse microbial community. To better understand the role of periphyton in an unvegetated engineered treatment wetland, the removal efficiency of six compounds was studied in a pilot-scale system and under well-controlled laboratory conditions. All compounds had half-lives of less than two days in the aqueous phase, except carbamazepine, which behaved conservatively. Sorption to periphyton coupled with biotransformation was an important removal mechanism for compounds that were not amenable to photolysis, such as atenolol, metoprolol, and trimethoprim. Photolysis was important for the compounds propranolol and sulfamethoxazole and was enhanced at elevated pH values, caused by periphyton photosynthesis. Measurements of reactive oxygen species and other transients generated by photolysis indicated that indirect photolysis in the sunlit treatment wetland is attributable to the simultaneous production of several different oxidants.

359 Background PAHs in Urban Watersheds, Beneficial Use of Dredged Material, and the Case for Relative Risk Assessment for Urban Environment Restoration J.P. Kreitinger, AECOM Environment, US Army Engineer Research and Development Center, CEERD-EP-R; R.A. Price, A.J. Kennedy, US Army Engineer Research and Development Center. The US Army Corps of Engineers is responsible for the maintenance of 58 federal navigation channels in the Great Lakes. To maintain Cleveland, OH harbor, approximately 250,000 cubic yards of sediment must be dredged and managed each year. Complicating the management of dredged material is that most of the sediment is considered 'contaminated' and is managed by placement in confined disposal facilities (CDFs) constructed along the Lake Erie waterfront. The capacity in waterfront CDFs is limited and a comprehensive review of the suitability of the dredged material for various beneficial uses has been conducted. Sediment in the Cleveland Harbor navigation channel was determined that have Total PAHs (sum of 13) ranging in concentration from 8 to 21 mg/kg exceeding the consensus threshold effect concentration (TEC) but below the probable effect concentrations (PEC) considered to be protective of aquatic life. No toxicity was observed in sediment having 21 mg/kg Total PAHs using the aquatic invertebrates *Hyalella azteca* and *Chironomus dilutus* nor the terrestrial worm *Lumbriculus variegatus*. Characterization of the potential narcotic toxicity resulting from PAHs using ASTM Method D7363-07 demonstrated low PAH bioavailability and little contribution to narcotic toxicity (< 0.15 Toxic Units). Sediment previously dredged from the navigation channel from 1979 to 1999 (having similar or higher concentrations of PAHs) is currently managed as an 88-acre urban nature preserve that has numerous native plant and animal species. In contrast, recent data has been reported on the concentration of PAHs in an urban Cleveland neighborhood consisting of over 100 abandoned houses that is being considered for urban land rehabilitation. The average concentration of benzo[*a*]pyrene, the primary risk driver for human health, in neighborhood soils is approximately twice the average concentration observed in the navigation channel sediment. These data demonstrate

that that the risk to human health from beneficial use of dredged material for urban land restoration would be approximately ½ the risk that results from exposure to existing soil in some urban neighborhoods. From a public health and ecological perspective the beneficial use of dredged material as soil in Cleveland's highly urbanized environments could reduce exposure to PAHs. The assessment of relative risk must be considered for successful restoration of human and ecological habitat in urban environments.

360 Developing Menhaden as a Model Organism of Studying the DeepWater Horizon Oil Spill C. Bentivegna, Seton Hall Univ, Dept of Biological Sciences; J. Sowa, N. Snow, Seton Hall Univ, Dept of Chemistry/Biochemistry; K. Cooper, Rutgers, the State Univ of New Jersey; R. Portier, Louisiana State Univ. The DeepWater Horizon (DWH) oil spill is likely to have widespread and chronic effects on the Gulf of Mexico's ecosystems and fisheries. The release of petroleum from the BP's Macondo 252 well started on April 20, 2010 and continued for 87 days until the well was capped on August 3, 2010. A major goal of this research project was to determine the levels and types of polycyclic aromatic hydrocarbons (PAH) found in a common filter-feeding fish called menhaden. Menhaden is an oily, prey fish used commercially to produce omega-3. Due to their oily nature, it was anticipated that menhaden would accumulate oil contaminants and potentially transfer them to predatory fish. For this project, adult menhaden (28-35 cm) were collected in 2010 from the James River, VA, Delaware Bay, NJ and Grand Isle, LA. Grand Isle received heavy oiling of its shores and wetlands from the DWH spill. It was anticipated that collecting menhaden from VA and NJ as well as LA would allow discrimination of a BP oil spill signature from that of general urbanization. Studies have included 1) analyzing PAHs in DWH source oil and fish oil by headspace solid-phase microextraction (HS-SPME) in combination with gas chromatography-mass spectrometry (GC-MS), 2) analyzing fish liver for PAH metabolites using scanning fluorescence spectroscopy, 3) conducting trophic transfer studies by exposing mummichog and bluefish to fish oil by gavage and 4) conducting histopathology on "peanut" menhaden collected from the same sites. Preliminary data has indicated that HS-SPME GC-MS can detect PAHs in fish oil at part per billion levels and that LA fish show higher levels of naphthanol-like PAHs but lower levels of hyroxypyrene-like PAHs than VA and NJ fish. There also were characteristic patterns of naphthanol-like PAH accumulation. This project should help develop menhaden as a model organism for monitoring oil spills.

361 A Multi-Site Model to Estimate the Toxicity of PAH-Contaminated Sediments at MGP Sites M. Kierski, Exponent, Ecological and Biological Services Practice; A. Morrison, Exponent, Inc., EcoSciences; S. Kane Driscoll, Exponent Inc.; C. Menzie, Exponent, Inc., Exponent, Principal. Many manufactured gas plant (MGP) sites have left a legacy of polycyclic aromatic hydrocarbon (PAH)-contaminated sediments in adjacent waterways. At three MGP sites in the Midwest, the toxicity of PAH-contaminated sediments to benthic invertebrates was evaluated using 1) laboratory-based sediment toxicity test results for *Hyalella azteca*, and 2) predictions of toxicity using the US Environmental Protection Agency's equilibrium partitioning sediment benchmark (ESB) methodology. Site-specific toxicity-based concentration thresholds for total PAHs (based on 13 analytes) varied considerably among the three sites (i.e., 103 mg/kg to 712 mg/kg total PAHs). To evaluate whether the differences in these toxicity-based threshold concentrations was a function of sediment characteristics, the data for all three sites were analyzed collectively. Total PAH concentrations were normalized based on total organic carbon (TOC) content, black carbon content, a combination of TOC and black carbon, or with the ESB methodology to evaluate the consistency of PAH thresholds. Receiver operating characteristic (ROC) curve analysis was used to determine whether each indicator (e.g., TOC-normalized total 13 PAH concentrations) was a good predictor of sediment toxicity and to develop multi-site thresholds based on toxicity tests and ESB values. All indicators investigated were good predictors of survival. Very few adverse impacts on growth were observed. Thresholds estimated on the basis of concentrations of total 13-PAH or total 34-PAH (and the normalized equivalents) were equally good indicators of toxicity. Thresholds predicted using the multi-site data set were compared with thresholds calculated for individual sites. This modeling effort demonstrated that ROC analysis of normalized data from multiple sites can be used to develop sediment toxicity thresholds that are often higher than traditional sediment quality benchmarks, but still are protective of aquatic organisms.

362 PAH Distribution and Source Association in Sediments and Mussel Tissue the NH Great Bay Estuary A. Watts, S. Jones, Univ of New Hampshire. Polycyclic aromatic hydrocarbon concentrations have been monitored in sediment and mussel tissue in the NH Great Bay Estuary through the EPA National Coastal Condition Assessment program and the Gulfwatch program. Samples have been collected at 154 sites in the Great Bay and in Rye and Hampton harbors, from 2000 to 2006. PAH concentrations in mussel tissue in portions of the Great Bay have been increasing gradually since 1993. Spikes in concentration appear to be correlated with oil spills and dredging activities, the latter probably reflecting re-suspension of legacy contaminates, but all factors contributing to the trend have not been definitively identified. Potential sources include increased urban watershed runoff, atmospheric deposition, and sediment erosion. Characteristic compound patterns can be used to identify source categories, and source receptor models can be used to identify dominant sources of PAHs in sediments. Initial analysis of sediments samples collected in sections of the estuary are consistent with coal tar, and are probably associated with dredging or other disturbances in the vicinity of a former manufactured gas plant. Concentration distributions in sediments and tissue with respect to known and suspected source events will be discussed, and a more detailed source receptor model will be performed to determine if specific watershed characteristics and land use patterns are associated with elevated PAHs in sediment and tissue.

363 Genetic and Epigenetic Mechanisms of Environmental Injury by Benzo[*a*]pyrene and Related Polycyclic Aromatic Hydrocarbons K.S. Ramos, Univ of Louisville, Biochemistry and Molecular Biology. This presentation will highlight recent findings implicating L1 (Long Interspersed Nuclear Element-1) in the regulation of renal morphogenesis. Retroelements such as L1 are silenced epigenetically in terminally differentiated cells, and become highly active in embryonic, undifferentiated, and transformed cells. Using the mK4 murine embryonic kidney cell model we recently showed that somatic cells harbor retrotransposition events upon ectopic expression of L1RP (L1 from Retinitis Pigmentosa) and that overexpression of L1RP modulates differentiation programming in these cells through a feedback loop that involves L1, WT1 and AHR. These genetic alterations are recapitulated by exogenous activation of L1 by polycyclic benzo[*a*]pyrene and dioxin, suggesting that L1 represents a key molecular target in the modulation of genetic and epigenetic programs by environmental chemicals.

364 Proposed Increases in PAH Relative Potency Factors Will Greatly Increase Risks at All PAH Sites B. Magee, D. Chin, ARCADIS. The United States Protection Agency (USEPA) is proposing to modify the approach that it has been using since 1993 to evaluate polycyclic aromatic hydrocarbon (PAH) mixtures. While USEPA previously considered seven PAHs to have carcinogenic potential, the proposed approach increases to 26 the number of PAHs considered to be carcinogenic. In addition, according to the proposed approach, a number of the PAHs are being assigned a Relative Potency Factor (RPF) that is greater than 1 relative to benzo[*a*]pyrene. Several proposed RPFs are greater than 10 including benzo[*c*]fluorene (20), dibenzo[*a,l*]pyrene (30), and benz[*j*]aceanthrylene (60). If this approach is adopted, it will be necessary to quantify all 26 compounds in media at contaminated sites. Many of these additional constituents are not included in any standard analytical methods. In addition, it may be necessary to re-open and reassess sites that have already received regulatory closure. However, there are many scientific criticisms of the USEPA proposal. Most importantly, USEPA has not performed a Weight of Evidence Evaluation as called for in its Guidelines for Carcinogen Risk Assessment (EPA, 2005). Second, USEPA assumed that all PAHs act by a similar mode of action with no supporting evidence. USEPA also failed to validate the derived RPFs using cancer response data from real world complex mixtures. As noted in Supplemental Guidance for Conducting Health Risk Assessment of Chemical Mixtures (USEPA, 2000), data from whole mixtures are preferable to data from mixture components. We have performed several validation exercises that demonstrate that USEPA's RPFs overestimate the true carcinogenic risk observed when the interactions between components are inherently taken into account in mixture studies. Lastly, there were many technical problems associated with specific RPFs. For instance, many RPFs are based on a single study or "low confidence" studies; some RPFs are based on in vitro assays; some RPFs are derived from studies in which the chemical identity of the test substance was not confirmed; some RPFs are based on studies with unusual modes of administration, such as lung implantation in unusual

matrices; and many studies exceeded the Maximum Tolerated Dose. This presentation discusses the implications for human health risk assessment and presents key scientific criticisms presented in our recent comments to USEPA on the new guidelines.

365 Risk Evaluation of Polycyclic Aromatic Hydrocarbon Mixtures C. Liu, B. Krupka, CDM; C. Julias, CDM, CDM, Chemical Engineer; N. Luke, CDM. Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous organic chemicals that persist in the environment. PAHs are formed through an incomplete combustion of most organic material and also occur naturally at low levels of crude oil and coal. Currently, there are seven PAHs considered by the USEPA as probable human carcinogens (cPAHs) by a mutagenic mode of actions. Toxicity criteria are currently available only for benzo[*a*] pyrene. The remaining cPAHs are assessed using PAH-specific relative potency factors (RPFs) that express the potency of these cPAHs relative to benzo[*a*]pyrene. The California EPA (Cal/EPA) considers 24 PAHs to have carcinogenic potential and has developed potency equivalency factors (PEFs) for 23 PAHs by comparing the cancer activity of the chemicals relative to benzo[*a*]pyrene. The USEPA is proposing a RFP approach to assess cancer risks from whole mixtures of PAHs and to expand cPAHs from seven to 24 compounds. Nevertheless, cPAHs typically drive site risks and remediation because of their high cancer potencies and toxicity. This paper describes a human health risk assessment (HHRA) for residential properties where widespread soil PAH contaminations were found. The PAH contaminations were predominately in surface soil and high in areas along roadways, intersections and driveways. A HHRA is performed for residents to characterize potential health risks associated with PAH exposure via incidental ingestion of and dermal contact with soil and inhalation of particulates. In order to estimate a range of potential cancer risks for PAH mixtures, we have utilized RPFs developed by the USEPA in 1993 for the seven cPAHs, PEFs developed by the Cal/EPA for the 24 cPAHs, and the proposed RPFs for the 24 cPAHs by the USEPA. Comparisons of PAH cancer risks using different toxicological approaches have implications for future PAH risk assessment.

366 PAH Concentrations Associated with Use of Coal-Tar-Based Sealcoat and Relevance for Human Exposure Pathways B. Mahler, US Geological Survey, Water Resources Discipline; P. Van Metre, US Geological Survey; E.S. Williams, Baylor Univ, Bayor Univ. Coal-tar-based sealants applied to the asphalt pavement of many parking lots, driveways, and playgrounds contain 20 to 35% coal tar (CT) pitch, a known human carcinogen. CT-based sealants typically contain about 50,000-100,000 mg/kg PAH (sum of 16 PAH compounds); asphalt-based sealants, in comparison, contain about 50-100 mg/kg PAH. Pathways by which humans might be exposed to PAHs from CT-based sealants include dermal contact, inhalation, and non-dietary ingestion. This exposure might occur through contact with several media: the pavement surface (dermal), pavement dust (dermal, inhalation, ingestion), soil near sealed pavement (dermal, ingestion), settled/resuspended house dust (dermal, ingestion, inhalation), and air over sealed pavement (inhalation). Median T_{12}-PAH (sum of concentrations of 12 PAH compounds) in dried sealant scraped from CT-sealed pavement and in dust swept or vacuumed from the pavement were about 19,000 and 4,000 mg/kg, respectively; T_{12}-PAH in scrapings and dust from unsealed pavement were typically less than 50 mg/kg. The median T_{12}-PAH in soil near CT-sealed pavement was 80 mg/kg, about 8 times the median in soil near unsealed pavement (< 10 mg/kg). The median T_{12}-PAH concentrations in settled house dust from apartments adjacent to CT-sealed parking lots was about 130 mg/kg, compared to a median concentration of < 10 mg/kg from apartments adjacent to unsealed lots. The median concentrations of T_8-PAH (sum of eight PAH compounds) in the gas phase 1.3 meters above CT-sealed parking lots was 120 ng/m^3, about four times the median concentration above unsealed parking lots (29 ng/m^3). Because carcinogenic PAHs are considered non-threshold carcinogens (any additional exposure is associated with increased risk), these values indicate that potential exposure to PAHs by dermal contact, ingestion, and inhalation might be substantially greater in areas where pavement is sealed with CT-based sealants.

367 Assessing the Two-Year Change in Serum PFC Levels in an Exposed Community in Minnesota C. Huset, MN Dept of Health, Organic Chemistry Unit; J. Nelson, MN Dept of Health, Chronic Disease and Enviromental Epidemiology; P. Swedenborg, MN Dept of Health, Organic Chemistry Unit; J. Johnson, MN Dept of Health, Chronic Disease and Environmental Epidemiology. The Minnesota Dept of Health (MDH) conducted a human biomonitoring pilot project in 2008/2009 that measured serum levels of seven perfluorochemicals (PFCs) in 196 residents of the East Metro of Saint Paul, Minnesota known to have been exposed to drinking water contaminated with PFCs. Concentrations of PFCs in serum were found to be higher than the national average and strongly associated with the concentration of PFCs in drinking water. Since measures have been in place in these communities since 2005 to reduce exposure to PFCs through contaminated drinking water, it is expected that concentrations of PFCs in serum should be declining. In 2010/2011, MDH followed up with the same residents to determine the two-year change in serum levels of PFCs to assess whether efforts to reduce exposure from drinking water have been successful. The 186 participants from the 2008-2009 study who agreed to future contact were asked to participate; of these, 164 (88%) consented, filled out a questionnaire, and provided a second blood sample. Serum samples were analyzed by the MDH Public Health Laboratory for 7 PFCs by solid phase extraction and liquid chromatography tandem mass spectrometry. The concentrations of perfluorobutanoate, perfluoropentanoate, perfluorohexanoate, perfluorooctanoate, perfluorobutane sulfonate, perfluorohexane sulfonate and perfluorooctane sulfonate in serum samples were determined using matrix matched calibration curves and stable isotope labeled internal standards. The limit of detection for the method was 0.1 ppb. We will present results from this follow-up study and compare to the results from the 2008/2009 project.

368 Prenatal Exposure to Perfluorinated Compounds in China T. Zhang, Nankai Univ, China, and Wadsworth Center, USA, Key Laboratory of Pollution Processes and Environmental Criteria, Ministry of Education, Nankai Univ; H. Sun, Y. Lin, MOE Key Laboratory of Pollution Processes and Environmental Criteria, Nankai Univ; K. Kannan, Wadsworth Center, New York State Dept of Health, and Dept of Environmental Health Sciences, School of Public Health, State Univ of New York at Albany. Prenatal exposure to perfluorinated compounds in China Tao Zhang,1 Hongwen Sun,1,* Yan Lin,1 Kurunthachalam Kannan,2 1 MOE Key Laboratory of Pollution Processes and Environmental Criteria, Nankai Univ, Tianjin 300071, China 2 Wadsworth Center, New York State Dept of Health, and Dept of Environmental Health Sciences, School of Public Health, State Univ of New York at Albany, Albany, NY 12201, USA ABSTRACT Perfluorinated compounds (PFCs) are a group of chemicals widely used for many applications. In this study, PFCs were investigated in 30 paired maternal samples (i.e., maternal blood, maternal urine, cord blood, placenta, and amniotic fluid) from China. Perfluorooctane sulfonate (PFOS), perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA), perfluorodecanoic acid (PFDA), perfluoroundecanoic acid (PFUnDA), and perfluorododecanoic acid (PFDoDA) were detected in all cord blood samples, and maternal blood and placenta samples. The mean concentrations of PFOS and PFOA in cord blood were 3.09 and 1.95 ng/mL, respectively, accounting for 19% of PFOS, and 58% of PFOA in maternal blood. For fetus, the total intakes of PFOS and PFOA during perinatal period were 7176 and 3475 ng, respectively. Based on 280 days prenatal period, the daily intake for fetus were 25.6 ng PFOS/d and 12.4 ng PFOA/d. The potential for crossing the placental barrier were negatively correlated with carbon chain length of C8-C12 PFCAs. The efficiency for placental transfer of PFOA is higher than PFOS, similarly, the efficiency for placental transfer of branch PFOS is higher than linear PFOS. Cross all human urine, PFOS was found at the highest mean concentration with the range of 4.60-15.0 pg/mL, followed by PFOA (1.77-5.24 pg/mL); PFOA was the major PFC in amniotic fluid with the level of 14.8 pg/mL, followed by perfluorobutyric acid (PFBA) (7.02 pg/mL) and PFOS (6.78 pg/mL). Urinary excretion of PFOS and PFOA were 6.90, and 2.90 ng/d for newborn mother, respectively, which account for 7% of daily intake of PFOS, and 12% of PFOA intake. Our results suggested that urine is a potential excretion pathway for adults. Maternal loss of PFOS and PFOA during each childbearing were 15,400 and 5070 ng, respectively. This is the first time to report PFDoDA concentration in humans, and this is the first to assess human exposure to PFCs to Chinese fetus.

369 Analysis of Dialkyl Phosphate Metabolites of Organophosphate Pesticides in Human Urine D. Wang, California Dept of Public Health, Environmental Health Laboratry Branch; P. Behniwal, California Dept of Public Health, Environmental Health Laboratory Branch; R. Fan, Key Laboratory of Ecology and Environmental Science in Guangdong Higher Education, College of Life Science, South China Normal Univ, California

Dept of Public Health, Environmental Health Laboratory Branch; J. She, California Dept of Public Health, Environmental Health Laboratory Branch. Organophosphate (OP) pesticides continue to be used on crops in agriculture and for pest control in residential settings in the United States. Acute and chronic exposures to OP insecticides have been reported to cause adverse health effects. Most of the OP pesticides used are metabolized to upto six common urinary dialkyl phosphate metabolites (DAPs). Quantification of DAPs provides information on continuous exposure to most OP pesticides. In this study we have developed a novel method for the analysis of human urinary DAPs by using isotope dilution and gas chromatography/tandem mass spectrometer (GC/MS/MS). The sample preparation procedure included lyophilization, derivatization, and clean-up by a dual layer of solid phase extraction (SPE) cartridges, which effectively eliminated matrix interferences and yielded satisfactory results with lower limits of quantification (0.10 ng/mL) for the method. The relative standard deviations were lower than 16% from analysis of three concentrations (3.0, 15 and 30 ng/mL) of DAPs spiked in 2.0 mL urine. The measurement of DAPs in proficiency test samples generated results close to the certified values. The urine matrix might cause variations of analytical results of dimethyl phosphate (DMP), and further studies are being performed to eliminate such matrix effects. The method is being used in several projects in California Environmental Contaminant Biomonitoring Program.

370 PCBs and Their Hydroxylated Metabolites in Children and Their Mothers Living in Urban and Rural Communities R. Marek, Univ of Iowa, Civil & Environmental Engineering, The Univ of Iowa, Civil and Environmental Engineering; S.N. Spak, Univ of Iowa, Civil & Environmental Engineering; P.S. Thorne, The Univ of Iowa, Occupational and Environmental Health; J. DeWall, The Univ of Iowa, Occupation and Environmental Health; K.C. Hornbuckle, Univ of Iowa, Dept of Civil & Environmental Engineering. We have analyzed human blood serum collected since 2008 from adolescent children and their mothers in urban East Chicago, Indiana (n >100) and rural Columbus Junction, Iowa (n >100) for all 209 PCB congeners and 11 hydroxlyated PCBs (OH-PCBs). East Chicago is a heavily-industrialized residential community on the southwestern shore of Lake Michigan. Bisecting the area, and passing within 2 km of two schools, is the Indiana Harbor and Ship Canal from which about 7 kg PCBs per year volatilize. In contrast, residents of the rural Columbus Junction area have no known PCB exposure from current or past industrial sources. We used highly selective methods (EPA Method 1668 modified for GC/MS/MS) and a full suite of quality control measures (SRM, surrogate recoveries, laboratory blanks, internal standard method) to optimize the analytical method for our target compounds. Data of each sample population approximates a Poisson distribution with a long tail. Analysis of the first year of samples suggests that East Chicago residents have a higher baseline than Columbus Junction residents although the two communities exhibit similar median PCB concentrations. Residents of both communities had similar levels of OH-PCBs serum concentrations. Interestingly, though mothers almost always had approximately double the PCB body burden of their children, some children had equal to or double the OH-PCB body burden of their mothers. Differences in PCB and OH-PCB body burdens were discovered between male and female children. Following analysis of a second round of blood sampling one year later, these trends are examined for continuity within the second year of data. We present the results of this analysis and possible implications of our findings.

371 Assessment of Human Exposure to Chlorinated and Brominated Compounds in Ghana K.A. Asante, Ehime Univ, Center for Marine Environmental Studies (CMES), Ehime Univ, Center for Marine Environmental Studies; S. Takahashi, Ehime Univ, Center for Marine Environmental Studies (CMES); T. Isobe, Ehime Univ, Senior Research Fellow Center; T. Itai, G. Devanathan, Ehime Univ, Center for Marine Environmental Studies (CMES); O.D. AnsaAsare, CSIR, Water Research Institute; S. AduKumi, Environmental Protection Agency, Chemicals Management; S. Tanabe, Ehime Univ, Center for Marine Environmental Studies (CMES). Brominated flame retardants (BFRs) such as polybrominated diphenyl ethers (PBDEs) and hexabromocyclododecanes (HBCDs) are widely used in polymers and consumer products to slow down the combustion of these materials. Among BFRs, PBDEs have received the most attention because of their environmental ubiquity, persistence and also possess a notable potential of bioaccumulation. As a result, the Penta-BDE and Octa-BDE commercial mixtures have been banned by the European Union and voluntarily withdrawn from the marketplace in the United States. Polychlorinated biphenyls (PCBs) on the other hand were historically used in various applications such as hydraulic fluid additives, insulating oil for transformers, capacitors, plasticizers, etc. The widespread occurrence of flame retardants in the indoor and outdoor environment requires constant monitoring as human exposure to these chemicals is of particular concern. These contaminants were measured in human breast milk and tilapia fish samples collected from Ghana. Mean concentrations of PCBs (62 ng/g lw), PBDEs (4.5 ng/g lw) and HBCDs (0.54 ng/g lw) measured in breast milk samples using GC-MS and LC-MS/MS, were unexpectedly high, albeit Ghana is a non-industrialized country when compared with many of the European and Asian countries. The health risk of infants and adults were calculated through mothers' milk and fish consumption, respectively using hazard quotients (HQs). Estimated HQs showed that all the mothers had HQ values exceeding the threshold of 1 for PCBs, indicating potential health risk for their newborns. However, the HQs through fish were all below 1, suggesting less potential health risk of these contaminants to Ghanaians via fish consumption. Our fish findings indicate a moderate contamination level; however, continuous study of the temporal trends of PCBs and BFRs in Ghana is needed to evaluate long-term impacts to human health via fish consumption since fish is seen as the most important source of animal protein in Ghana. Ghana does not produce PCBs, however, there is illegal or uncontrolled usage of PCB oils and thus PCBs in dirty oils and obsolete equipment should be of concern as potential sources in Ghana. Furthermore, e-waste recycling with little or no experience in safe handling could be a threat to Ghana noted for unregulated disposal and incessant burning of e-waste. This is the first study to report BFRs in human breast milk and fish from Ghana and arguably from Africa.

372 Phthalate Metabolites in Human Urine from China and Potential Sources of Phthalate Exposure Y. Guo, Q. Wu, K. Kannan, Wadsworth Center, New York State Dept of Health. Urinary phthalate metabolites can be used as biomarkers to reflect recent human exposure to phthalates. In this study, 14 phthalate metabolites were analyzed in 183 urine samples collected in 2010 from Shanghai, Guangzhou, and Qiqihaer, China. To evaluate potential human exposure sources, 75 indoor dust samples collected from six cities in China were also collected and 9 phthalates were determined. Phthalate metabolites were detected in all urine samples, with a total concentration ranging from 18.6 to 3160 ng/mL (median: 331 ng/mL). Mono-n-butyl phthalate (mBP) and mono-2-isobutyl phthalate (miBP) were the major metabolites found in urine. In dust samples, bis(2-ethylhexyl) phthalate (DEHP), di-n-butyl phthalate (DBP) and di-iso-butyl phthalate (DIBP) were the predominant compounds found; concentrations of DEHP (median: 228 μg/g) were 10 times higher than the concentrations of DBP (20.1 μg/g) and DIBP (17.2 μg/g), and the concentrations of these three compounds were 1000 times higher than the concentrations of the other 6 phthalates analyzed. Based on the concentrations of phthalate metabolites in urine and of phthalates in house dust, our results indicated that indoor dust accounted for less than 0.2% of the total intakes reported for dimethyl phthalate (DMP) and DEP, less than 2.2% of the intakes for DIBP and DBP, and 2%-5% of the intakes for DEHP in China. Furthermore, dietary intake was the main source of exposure to all phthalate esters, especially for DEHP (> 95%).

373 One-box Population-level Pharmacokinetic Models for Interpretation of Biomonitoring Data for Persistent Pollutants M. MacLeod, Stockholm Univ, Dept of applied environmental science; R. Ritter, M. Scheringer, ETH Zurich; C. Moeckel, K.C. Jones, Lancaster Univ; K. Hungerbuhler, ETH Zurich. Analysis of persistent organic pollutants (POPs) in human blood and milk is a key component of the global monitoring plan that will assess the effectiveness of the Stockholm Convention. At the same time, there are an increasing number of biomonitoring programs underway at the national level in many jurisdictions. There is a need to develop quantitative modeling tools to extract as much meaningful information as possible from the levels and trends found in these biomonitoring data. Here, we present two novel applications of a one-box pharmacokinetic model applied at the population-level to interpret biomonitoring data. In the first case, we examine the significance of time-trends of POPs in human milk in a population that has lived entirely in a post-ban situation where exposures are falling exponentially. We use biomonitoring data for DDT and DDE from Sweden that represent this situation. Our modeling demonstrates that in this special case the time trend in the biomonitoring data directly corresponds to the

time trend for reduction of exposure to DDT and DDE. In the second case study we analyze biomonitoring data from a population with some members who have lived through increasing, peak and decreasing regimes of exposure. In this case study we use two sets of biomonitoring data for polychlorinated biphenyls (PCBs) from a broad cross-section of the UK population. We demonstrate that a one-box population-level pharmacokinetic model can be fit to such biomonitoring data in two dimensions simultaneously to describe both the time course of average bodyburden in the population, and the age – concentration relationship within each set of cross-sectional data. Applied in this way, the model reconstructs the time course of exposure of the population, and estimates the half-time for intrinsic elimination of POPs from the bodies of the members of the population at background exposure levels. Results from our case study for PCBs in the UK population indicate that the maximum intrinsic half-time for elimination of even the most persistent and hydrophobic PCBs is about 15 years. We hypothesize that this half-time corresponds to elimination by non-metabolic processes, and that it represents a baseline human elimination rate for POPs.

374 Organohalogenated Contaminants and Their Metabolites in Human Serum from Obese Patients A.C. Dirtu, Toxicological Centre, Univ of Antwerp, Dept of Pharmaceutical Sciences; E. Dirinck, Antwerp Univ Hospital and Univ of Antwerp, Dept of Endocrinology, Diabetology and Clinical Pharmacology; H. Neels, Toxicological Centre, Univ of Antwerp, Dept of Pharmaceutical Sciences; L. Van Gaal, P. Jorens, Antwerp Univ Hospital and Univ of Antwerp, Dept of Endocrinology, Diabetology and Clinical Pharmacology; A. Covaci, Toxicological Centre, Univ of Antwerp, Dept of Pharmaceutical Sciences. Due to their persistent, bioaccumulative and toxic properties, persistent organic pollutants remain important to be evaluated in humans. In the present study, we evaluated the levels and profiles of several PCB congeners and their hydroxylated metabolites (HO-PCBs), polybrominated diphenyl ethers (PBDEs), pentachlorophenol (PCP) and some organochlorine pesticides (OCPs) in obese humans with an increased body mass index. We collected serum from obese individuals visiting the Obesity and Diabetes Clinic of the Univ Hospital of Antwerp, Belgium. These patients participate in a weight loss program by undergoing either bariatric surgery or through diet and physical exercises. Serum was sampled before the patients entered the program (N=95) and after approximately 6 (N=55) and 10 months (N=39), respectively. Time dependencies were tested for the most important PCB congeners (CB 118, 153, 180 and 170) and indicated that PCB levels increased significantly for each patient, independent of the treatment method employed, even when the results were adjusted for the lipid content. These results may be important, since organochlorines released in plasma during weight loss have been associated with the decrease in the serum thyroxin concentrations. Additionally, HO-PCBs were used to evaluate the influence of the treatment method on the metabolic capacity of the patients. Even if less significant, an increasing level with time was observed only for some HO-PCB metabolites (3HO-CB153, 4HO-CB107 and 4HO-CB146). Moreover, a change in time of their profile was noticed, mainly through an increasing contribution of 3′HO-CB138 to the total HO-PCBs concentration. The most important OCP was *pp′*-DDE, a metabolite of *pp′*-DDT, while hexachlorobenzene, hexachlorocyclohexanes and chlordanes were measured at lower levels. The levels of PBDEs were in most of the cases close to the method limit of quantification and were thus less important compared to other classes of neutral contaminants. Apart from HO-PCBs, the most important phenolic contaminant was PCP with median concentrations of 450 pg/mL for patients before entering the program and nearly similar median concentrations of 520 pg/mL at 6 and 10 months after the program was initiated. Our results corroborate the hypothesis that some endocrine disrupting chemicals not only might play a role in the occurence of obesity, but also in the metabolic derangements seen during fat loss.

375 Adverse Outcome Pathways During Early Fish Development: A Conceptual Framework for Identification of Chemical Screening and Prioritization Strategies D. Volz, Univ of South Carolina, Univ of South Carolina, Dept of Environmental Health Sciences; S. Belanger, The Procter & Gamble Company; M. Embry, ILSI Health and Environmental Sciences Institute ; S. Padilla, US Environmental Protection Agency; H. Sanderson, Aarhus Univ; K. Schirmer, Swiss Federal Institute of Aquatic Science and Technology; S. Scholz, UFZ – Helmholtz Center for Environmental Research; D. Villeneuve, US Environmental Protection Agency. The fish early life-stage (FELS) test guideline (OECD 210 or OCSPP 850.1400) is the most frequently used bioassay for predicting chronic fish toxicity and supporting aquatic ecological risk assessments around the world. For each chemical, the FELS test requires a minimum of 360 fish and one to three months from test initiation to termination. While valuable for predicting fish full life-cycle toxicity, FELS tests are labor- and resource-intensive and, due to an emphasis on apical endpoints, provide little to no information about chemical mode-of-action. Therefore, the development and implementation of alternative testing strategies for screening and prioritizing chemicals has the potential to reduce the cost and number of animals required for estimating fish early life-stage toxicity and, at the same time, provide insights into mechanisms of toxicity. Using three reference chemicals with well-established yet distinct adverse outcome pathways (AOPs) in early life-stages of fish, we proposed FELS-specific AOPs as conceptual frameworks for identifying useful chemical screening and prioritization strategies. The reference chemicals selected as case studies were a cardiotoxic aryl hydrocarbon receptor agonist (2,3,7,8-tetrachlorodibenzo-*p*-dioxin); neurotoxic acetylcholinesterase inhibitor (chlorpyrifos); and narcotic surfactant (linear alkylbenzene sulfonate). Using qualitative descriptions for each chemical during early fish development, we developed generalized AOPs and, based on these examples, proposed a three-tiered testing strategy for screening and prioritizing chemicals for FELS testing. Linked with biologically based, concentration-response models, a tiered testing strategy may help reduce the reliance on long-term and costly FELS tests required for assessing the hazard of thousands of chemicals currently in commerce.

376 Differential Regulation of Resource Genes in Carbon Nanotube Exposed *Daphnia magna* A. Edgington, Clemson Univ, Biological Science and CU-ENTOX, Clemson Institute of Environmental Toxicology; S.J. Klaine, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX). Engineered carbon nanotubes (CNTs) have been shown to become stable in aqueous suspensions once functionalized with natural organic matter (NOM). This allows the material to become bioavailable to many aquatic organisms, including the filter feeding zooplankton *Daphnia magna*. Previous research has shown microscopically that once ingested the CNTs can impact the gut tract of *D. magna* and this may interfere with the normal digestive processes. One area of digestion that may be interrupted is the peritrophic matrix (PM) layer within the gut. The PM is a layer of chitin and proteins produced by the lumen. Its function is not completely known, but it h been shown to aid in digestion and protect the organism from toxic chemicals and pathogens. Furthermore, researchers have also shown that there are as many as 14 genes differentialy regulated when *D. magna* is presented with different qualities of food. The objectives of this research were to determine the differential regulation of peritrophic matrix and resource genes to carbon nanotube exposed *D. magna*. Seventy-two hr ol *D. magna* were exposed to 0, 0.5, and 2.0 mg/L multi-walled (MWNT) and single-walled nanotubes (SWNT) for 24 hrs. Organisms within treatments were pooled and processed for Real Time PCR. The results show t both SWNT and MWNT exposure has an effect on PM and resource gene expression. Genes associated with PM production were upregulated with MWNT and SWNT exposure. Resource genes were differentially expressed with SWNT and MWNT exposure with an increase in genes associated with metabolism (ATPsynthase) and molting (cuticle protein). The results from this study suggested that the physical stress that MWNTs and SWNTs have on *D. magna* gut induces a biochemical response. The gene differentiation suggest that *D. magna* respond to the physical stressor by increasing the protective PM layer within the gut tract and changing expression of resource genes to handle the nutrient poor MWNTs and SWNTs.

377 Development of a Knowledge-base Web Application for Adverse Outcome Pathways: The AOP App N. Garcia-Reyero, Jackson State Univ; P. Gong, SpecPro Inc., Enivronmental Services; K.A. Gust, US Army, Engineer Research and Development Center, Environmental Laboratory, US Army, Engineer Research and Development Center, Us Army Engineer Research & Development Center, ERDC-EL-EP-P; T. Suedel, US Army Engineer Research and Development Center, CEERD-EP-R, US Army Engineer Research and Development Center, Environmental Laboratory, Waterways Experiment Station EP-R; V. Dickerson, US Army, Engineer Research & Development Center; E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Us Army Engineering Research & Development, Environmental Processes & Effect Division.

Advances in biological sciences and related technologies are changing the types and amount of data that toxicologists can collect and analyze in an efficient, cost-effective, and reliable manner. More recently, "omics" and systems biology approaches have emerged as tools for both basic biology and toxicology/ecotoxicology research. Overall, ecotoxicology in the 21st century is characterized by an increased mechanistic understanding of basic biology, and increased ability to analyze complex data, integrate and manage diverse information, and conduct in silico simulations. Furthermore, advances in science and technology are increasing the feasibility to use alternative data/endpoints (e.g., biomarkers, in vitro bioassays, genomics) as a scientifically credible basis for ecological risk assessment (ERA). Recently, a strategy organized around the identification of adverse outcome pathways (AOPs) has gained interest within the ecotoxicology community. It is envisioned that AOP-based QSARs (quantitative structure-activity relationship), in vitro bioassays, and biomarkers, coupled with quantitative extrapolation tools, will assume a more prominent role in ERA as the science of predictive ecotoxicology develops. Our aim is to develop a web application to integrate all the available information and facilitate the use of AOPs. We are coupling "omics" technologies with other physiological measurements and literature research to define and predict AOPs relevant to ERA. We have begun by focusing on the AOPs related to reproduction, liver toxicity, and neurotoxicity. The idea is to characterize and understand the different AOPs of interest, and then upload this information into a knowledge base web application that is under development, the *AOP App*. The *AOP App* will allow users to explore and understand AOPs of interest and allow for users to input data in order to predict the potential toxicity and relation to AOPs of the chemicals of interest. The type of data that the *AOP App* will support will be analogous to the data used to create the database, such as omics data, and physiological measures among other conditions. In summary, the AOP App will provide integrative ecotoxicological utilities for scientists and regulators alike.

378 Development of a Cell-free Neurochemical Screening Battery to Predict Adverse Outcomes in Mammals, Fish and Birds N. Basu, Univ of Michigan, Dept of Environmental Health Sciences, Univ of Michigan, Dept of Environmental Health; D. Nam, J. Head, Univ of Michigan; C. Murphy, Michigan State Univ. Cell free, in vitro bioassays have been developed in biomedicine to screen, for example, neurotoxic agents and novel pharmaceuticals. These cell-free methods are now being used by the USEPA's ToxCast program, and adaptation/development of such bioassays for predicting adverse outcomes is particularly attractive in ecological risk assessment owing to the lack of high-throughput in vitro screening methods that span several taxa, and the limited ability to conduct whole-animal bioassays. Here we describe a series of in vitro assays that may be used to assess whether contaminants interact with, and possibly disrupt the function of, various neurotransmitters receptors and enzymes that mediate fish reproduction. Specifically, in this presentation it was hypothesized that metals (Hg^{2+}, CH_3Hg^{+}, Pb^{2+}, total Se, Sn^{2+}, As^{3+}, Cd^{2+}, Cr^{6+}, Mn^{2+}) will emerge to inhibit binding to the muscarinic acetylcholnine receptor (mAChR) and N-methyl-D-aspartate receptor (NMDAR) in brain cortical tissues collected from several fish (goldfish, perch, lemon shark, mako shark), birds (chicken, bald eagle), and mammals (mouse, polar bear, mink, common dolphin, Atlantic white-sided dolphin). First, saturation binding curves were developed from each species to calculate mean receptor density (Bmax) and ligand affinity (Kd). Next, samples were exposed to the aforementioned metals at several concentrations to derive IC50 (inhibition concentration 50%) values. Based on IC50 values and resulting inhibition constants (Ki), generalized rank-order potencies for metals and species were developed and will be presented. These comparative results concerning interspecies and inter-metals differences potentially provide a high throughput, in vitro framework for evaluating neuroendocrine risk to ecological organisms. Further, we have developed (and continue to develop) cell-free in vitro methods for several other neuroendocrine receptors and enzymes (e.g., estrogen receptor, androgen receptor, GABA receptor) of concern to vertebrate reproduction, with the ultimate goal of modeling the in vitro results to individuals and populations.

379 What is a Model Species? Linking Sublethal Stress Responses to Population Impacts via Computational Modeling in Great Lakes Fish C.A. Murphy, Michigan State Univ, Dept of Fisheries and Wildlife, Lyman Briggs College, Michigan State Univ, Lyman Briggs College; S. Smith, Michigan State Univ; J. Head, Cooperative Institute for Limnology and Ecosystems Research ; N. Basu, Univ of Michigan; R. Goetz, M. Carvan, Great Lakes WATER Institute; S. Sitar, Michigan Dept of Natural Resources. The development of appropriate extrapolation models to link key molecular initiating events to adverse outcomes is a crucial component of the adverse outcome pathway (AOP) framework. Only recently, a few of these models, that convert sublethal responses of stressors to endpoints that can be interpreted at higher levels of biological organization, have been developed – and only in a few model species, eg fathead minnow. Very few extrapolation models exist for larger, long-lived, commercially valuable species. Here we present two "in progress" case studies on species of relevance to the Great Lakes, lake trout (*Salvelinus namaycush*) and yellow perch (*Perca flavescens*). We compare and contrast the sublethal effects of two different stressors (sea lamprey parasitism and mercury contamination) on the Hypothalmus-Pituitary-Gonadal (HPG) axis of lake trout and perch and illustrate different modeling approaches to convert the effects of these stressors that often manifest at the suborganism level, to population relevant points such as fecundity and growth. Such endpoints can then be input into population models to project population effects. In these models, we attempt to incorporate differences that manifest as a result of differences in life history within and between species. We discuss the difficulties and assumptions that are necessary to make between population and between species comparisons. With further refinement, our approach may be useful to determine the harmful effects of stressors across a wider array of populations and species.

380 Incorporation of Predictive Population Modeling into the AOP Framework: A Case Study with White Suckers Exposed to Pulp Effluent D.H. Miller, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; J.E. Tietge, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; M.E. McMaster, Environment Canada, National Water Research Institute; K. Munkittrick, Univ of New Brunswick, Canadian Rivers Institute, Univ of New Brunswick, Dept of Biology; X. Xia, Computer Sciences Corporation; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division. A need in ecological risk assessment is the ability to create linkages between chemically-induced alterations at molecular and biochemical levels of organization with adverse outcomes in whole organisms and populations. A predictive model was developed to translate changes in the fecundity of a breeding population of white sucker (Catostomus commersoni) collected in the field to alterations in population growth rate. Individual-level responses of fish exposed to pulp mill effluent at a study site in Jackfish Bay, Lake Superior, were used to demonstrate the model's capability to project alterations in population status. The Jackfish Bay study site also has monitoring data for biochemical endpoints of interest in the white sucker, including steroid measurements amenable to interpretation through different adverse outcome pathways (AOPs) for reproductive effects. Linkage of the population model to biochemical measurements relevant to adverse outcomes can facilitate extrapolation of data from the Jackfish Bay study site to other white sucker populations at sites that are less data rich. Application requires only a life table for the organism of interest, a measure of carrying capacity for the given population, and estimation of the effect of stressors on vital rates within the fish of the study population. This abstract does not necessarily reflect USEPA Policy.

381 Methylmercury Effects of Larval Fish in the Lab: Modeling to the Population Level M.J. Carvan, Univ of Wisconsin-Milwaukee, School of Freshwater Sciences, Univ of Wisconsin-Milwaukee, Childrens Environmental Health Sciences Center; C.A. Murphy, Michigan State Univ, Dept of Fisheries and Wildlife, Lyman Briggs College, Michigan State Univ, Lyman Briggs College; D. Weber, Univ of Wisconsin-Milwaukee, Childrens Environmental Health Sciences Center, Univ of Wisconsin-Milwaukee, Great Lakes Water Institute, Univ of Wisconsin-Milwaukee; F. Goetz, Univ of Wisconsin-Milwaukee, School of Freshwater Sciences; J. Head, Univ of Michigan, Cooperative Institute of Limnology and Ecosystem Research, Univ of Michigan, Cooperative Institute for Limnology and Ecosystem Research; N. Basu, Univ of Michigan, Dept of Environmental Health Sciences, Univ of Michigan, Dept of Environmental Health. Zebrafish have been utilized as a model for developmental exposures to mercury and are a useful model for both human and other vertebrate species due to short intergenerational periods. Using startle response and learning behaviors, we examined the effects of developmental waterborne and maternal-derived exposures to

mercury on both short- and long-term outcomes. These behavioral changes were related to specific anatomical, physiological, and molecular initiating events and we have investigated the ability of specific factors to mitigate these behavioral deficits. Mercury exposures affect 3 parameters: latency of reaction, maximum escape velocity, and duration of escape swim. In mercury-exposed fish, reaction time to a vibrational stimulus is slower, maximum escape velocity is slower, and duration of escape swim is longer than control fish. Reaction to a visual stimulus by adult fish developmentally exposed to mercury is also decreased. Learning in a spatial alternation task is impaired in fish developmentally exposed to mercury. Recent data suggests that selenium compounds in the diet may be important in mitigating specific neurobehavioral deficits due to MeHg exposure. Co-exposures of methylmercury (MeHg) and selenomethionine (SeMet) during early embryogenesis did result in an improvement in visual startle responses, including improvements in K+ efflux in retinal bipolar cells. In contrast, similar co-exposures of MeHg and SeMet did not result in improvements in learning or cell body numbers in the telencephalon. These subtle changes in behavior and learning were then incorporated into and individual-based model to predict the effects on survival and growth of a cohort – endpoints that can be modeled to determine population relevant effects. Future studies will perform the same suite of experiments on larval perch to determine the efficacy of extrapolating across species and to link adverse effects from molecular initiating events to population level impacts in a Great lakes species of ecological and economic importance, via an adverse outcome pathway framework.

382 Estrogenic Effects on Largemouth Bass at Multiple Biological Levels from Chronic Ethinyl Estradiol Exposure Following an Adverse Outcomes Paradigm D.M. Papoulias, US Geological Survey, Columbia Environmental Research Center; C.A. Richter, USGS – Biological Resources Division, Columbia Environmental Research Center, US Geological Survey, Columbia Environmental Research Center; M. Wildhaber, US Geological Survey, USGS; D.E. Tillitt, US Geological Survey, Columbia Environmental Research Center; N.D. Denslow, A.C. Mehinto, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology; K.J. Kroll, Univ of Florida, Physiological Sciences. Feminized male fish from marine and freshwaters have been reported with increasing frequency. Exposure to estrogenic chemicals is suspected based on evaluation of known biomarkers of estrogenicity such as male vitellogenin production and appearance of ovo-testes, among others. Although useful for evaluating individual exposure, it is generally not known how well such diagnostic measures predict adverse effects on functional outcomes such as reproduction. We studied the effects of an environmentally-relevant concentration of EE2 on virgin adult largemouth bass in outdoor mesocosms. The reproductive success of exposed and unexposed bass was compared at the end of the exposure. We evaluated effects of exposure at multiple levels of biological organization along the AOP from the molecular level through the organismal level. Fecundity and fertility data were then used in a simple model to predict population size into the future. Mean egg production was 30% lower in ponds when fish had been exposed to EE2 for 18 months, but not significantly different from controls. Plasma vitellogenin was greatly increased in both sexes and gonads of EE2-exposed fish were underdeveloped at the organ level. Unexpectedly, testicular oocytes were not observed in any testes examined despite complete sectioning and evaluation of an entire lobe from each of 90 individual males. The molecular results were in part consistent with our findings at higher levels but also provided new insights and identified potentially new biomarkers. Our results are timely because feminized largemouth bass have been reported for several drainages in North America but as yet, definitive causes have not been identified. Ethinyl estradiol at an environmental concentration similar to or higher than that used in this study is commonly found in these same drainages but effects of chronic exposure on fish reproduction are not fully understood. This study provides a good example of the use of the AOP approach as it ties together multiple cause and effect events that together lead to impaired reproduction from xeno-estrogen exposure.

383 Contamination from Formerly Used Defense Sites in Alaska Native Villages Along Norton Sound and St. Lawrence Island F.A. von Hippel, Univ of Alaska Anchorage, Dept of Biological Sciences; P.K. Miller, C. Keane, Alaska Community Action on Toxics; R. Bernhardt, Univ of Alaska Anchorage; V. Waghiyi, Alaska Community Action on Toxics; L. Buck, Univ of Alaska Anchorage. Alaska has approximately 700 formerly used defense sites (FUDS), many of which are located in close proximity to Alaska Native communities in remote parts of the state. Some communities have raised concerns that legacy contaminants from FUDS may be contaminating their water supplies and traditional foods. Because Alaska Natives rely heavily on subsistence harvest of top carnivores, they have the potential to ingest unsafe quantities of contaminants that have bioaccumulated and biomagnified in the lipid-rich Arctic food web. Here we report on results examining contaminant load and endocrine disruption in freshwater fishes from aquatic sites near FUDS in Alaska Native villages along Norton Sound. At the request of local communities, the threespine stickleback was used to test for estrogenic and anti-estrogenic contaminants using the vitellogenin biomarker, and to test for androgenic and anti-androgenic contaminants using the spiggin biomarker. Many male stickleback from the sites in the villages of Wales and Unalakleet expressed elevated levels of vitellogenin, demonstrating that they had been exposed to estrogenic xenobiotics. The US Army Corps of Engineers and the Alaska Dept of Environmental Conservation cleaned the White Alice Communication site at Northeast Cape on St. Lawrence Island in 2003. Despite this cleanup, we found that Alaska blackfish downstream of the site contained 7-35 ppb total PCBs in their tissues. PCB Aroclor 1260 was the most common parent product, indicating that the majority of the contamination originates in the remediated site and is not acquired through global transport. These results suggest that FUDS pose a risk to the health of local inhabitants, and that detailed characterization of these sites is important to prioritize cleanup efforts.

384 Overview of the Aquatic Ecotoxicology of the Explosives TNT, RDX and HMX G. Lotufo, US Army Engineer Research and Development Center, Environmental Laboratory, U S Army ERDC; G. Rosen, SPAWAR Systems Center Pacific, Environmental, SPAWAR Systems Center Pacific, Scientist; J.B. Belden, Oklahoma State Univ, Dept of Zoology; B. Wild, SPAWAR Systems Center Pacific. To support the assessment of risk associated with the presence of explosives in aquatic environments, laboratory-based toxicity data have been derived for a variety of freshwater and marine fish and invertebrate species and endpoints in exposure to spiked water. Most of those studies have involved the use of unrealistically high water or sediment concentrations in order to derive toxicity benchmarks. TNT and its transformation products caused decreased survival at concentrations ranging from < 1 to 10 mg/L. Species vary in their relative sensitive to TNT and its major aminated transformation products. RDX caused decreased survival of some fish and invertebrate species at similar concentrations than those reported as acutely toxic for TNT, while some fish species and invertebrates exhibited decreased survival in exposure to concentrations approaching its solubility limit. HMX caused no decreased survival in saturated solution. Because of high biotransformation rates, body residues of most nitroaromatic compounds in exposed animals are reported at levels substantially lower than those predicted by their hydrophobicity. Bioconcentration factors were < 1 ml/g for HMX and approximately 2 ml/g for RDX. Higher values, ranging from 1 to 13 ml/g, were obtained for TNT and its transformation products. Therefore, explosives in tissues of aquatic receptors are expected to exceed the concentration in the surrounding water by only less than one order of magnitude. Uptake of TNT in fish and aquatic invertebrates resulted in substantial bioaccumulation of nonextractable compounds which have lower rates of elimination than the parent compound. For fish, aqueous exposure is likely the dominant route of exposure for explosive compounds, with dietary uptake providing only minimal contribution. Elimination half-lives ranged from a fraction of one hour to a few hours, requiring constant exposure to contaminated water for the retention of explosives in the tissues. Explosives have been detected in surface water from contaminated field sites. However, a lack of adequate information on spatial distribution of contamination and potential to elicit toxicity at contaminated sites preclude an accurate evaluation of the local and global environmental significance of the presence of explosives in aquatic systems. A laboratory experiment simulating real-world exposures concluded that the presence of UXOs in marine environments is unlikely to result in sufficient exposure to cause biological effects to aquatic invertebrates and fish. Verification of this conclusion, however, should be pursued by determining exposure risk at field sites where underwater explosives are present.

385 Multiple Environmental Stressors in the Western Fence Lizard (*Sceloporus occidentalis*) C. McFarland, US Army Public Health Command (provisional), and Preventive Medicne, US Army Public Health Command, Health Effects Research Program; L. Talent, Oklahoma State Univ; K. Gust, US Army Corps of Engineers; M. Quinn, US Army Public

Health Command; M. Bazar, US Army PHC; M. Wilbanks, E. Perkins, US Army Corps of Engineers; R. Gogal, Univ of Georgia; M. Johnson, US Army PHC. Wildlife experience a variety of stressors, with exposure to potentially toxic chemicals being only one of them. The relative influence of chemical exposure with other stressors such as food limitation and pathogenic infection is a question of management concern, particularly for threatened and endangered species. Contamination of the soil with the explosive 2,4,6-trinitrotoluene (TNT) has been found at military munitions ranges and industrial waste sites where valued reptile species occur. TNT has been shown to cause anemia at high repetitive exposures. In addition, malarial parasites (*Plasmodium* spp.) are common in most lizard families and can also cause anemia. Diet restriction can exacerbate this condition. The present study investigated the combined and separate influence of food limitation, TNT exposure, and *Plasmodium mexicanum* infection in the Western Fence Lizard (*Sceloporus occidentalis*). Three experimental treatment groups were established based on 1) Experiment I – TNT x Food Limitation, 2) Experiment II – Food Limitation x Malaria Infection, and 3) Experiment III – TNT x Malaria Infection. Preliminary results of the pairwise stressors 1) TNT x Food Limitation, 2) Food Limitation x Malaria Infection, and 3) TNT x Malaria Infection are currently completed examining survival, body weight, and cricket consumption. Experiments with TNT exposure demonstrated changes in most of the measured endpoints: approximately 67% in Experiment I and 43% in Experiment III were significantly different. Malaria infection affected cricket consumption, spleen and testes weight, and total WBC counts in Experiments II and III. Limited cricket intake was associated with a loss in body weight, testes and inguinal fat organ weights, albumin and cholesterol blood levels, and total WBC counts in Experiments I and II. Additional results from these experiments will be presented.

386 Effects of Dinitrotoluenes on Carbon Mineralization and Microbial Biomass in Sassafras Sandy Loam Soil M.L. Minyard, Defense Threat Reduction Agency; R.G. Kuperman, US Army Edgewood Chemical Biological Center, Environmental Toxicology, US Army Edgewood Chemical Biological Center, Edgewood Chemical Biological Center, Environmental Toxicology, Edgewood Chemical Biological Center, Environmental Toxicology Branch; R.T. Checkai, The Ohio State Univ, School of Environment and Natural Resources, US Army Edgewood Chemical Biological Center, Environmental Toxicology, US Army Edgewood Chemical Biological Ctr, Dept of Environmental Toxicology; S. Rocheleau, Biotechnology Research Institute, Applied Ecotoxicology; L. Paquet, J. Hawari, Biotechnology Research Institute; G.I. Sunahara, NRC-Biotechnology Research Institute, NRC-Biotechnology Research Institute. We assessed the effects of energetic materials (EM) 2,4-dinitrotoluene (2,4-DNT), 2-amino-4,6-dinitrotoluene (2-ADNT), and 4-amino-2,6-dinitrotoluene (4-ADNT) on basal and substrate-induced respiration (BR and SIR) in Sassafras sandy loam (SSL) soil. Studies were designed to determine toxicity benchmarks for developing Biological Activity-based Soil Screening Concentrations (BA-SSC) and for assessing ecological risks at EM-contaminated sites. EM treatments consisted of freshly-collected SSL soil, amended and thoroughly mixed to prepare nominal concentrations ranging from 10 to 10000 mg EM/kg dry soil, plus carrier (acetone) Control. Preliminary results showed that BR rate was inhibited by 2,4-DNT with the EC20 and EC50 values (mg/kg) of 651 and 2023, respectively on day 7 of soil incubation; and 1033 and 3200, respectively for the 95-h cumulative BR. The initial SIR and biomass C, calculated after 3 h of SIR, were more sensitive endpoints for assessing the effects of 2,4-DNT on carbon mineralization when compared to BR. The respective EC20 and EC50 values (mg/kg) were 20 and 63 for SIR, and 23 and 71 for biomass C. 2-ADNT did not affect BR or SIR (after 10 h) up to and including 10000 mg/kg, but significantly (p=0.003) inhibited biomass C at 10000 mg/kg (Lowest Observed Effect Concentration; LOEC). 4-ADNT significantly (p=0.009) inhibited BR rate at 10000 mg/kg (LOEC) on day 7, but did not affect the cumulative BR up to and including 10000 mg/kg. These preliminary results are consistent with our earlier studies that assessed the effects of 2,4-DNT, 2-ADNT, and 4-ADNT on decomposition of Orchard grass (Dactylis glomerata) straw in similar SSL soil. Both studies suggest that biologically-mediated processes in soil can be inhibited when soil is contaminated with dinitrotoluenes. Our studies also demonstrated that the toxicity benchmarks for some nitroaromatic EM, and corresponding BA-SSC values, can be reliably established for soil biological processes and comply with the stipulations and requirements developed by the US Environmental Protection Agency for terrestrial plant-based or soil invertebrate-based Ecological Soils Screening Levels (http://cfpub.epa.gov/ecotox/). Assessment of the soil microbial activity endpoints can provide valuable information on the effects of EM on critical ecosystem-level processes, such as energy cycling, complimenting and expanding upon ecotoxicological significance of data from standardized single-species toxicity tests.

387 Effect of Kinetics on the Resistance to Desorption of Munitions Constituents (MC) from Soil R. Gonzalez, K. Michelson, Univ of Delaware, Dept of Civil and Environmental Engineering; D.M. Di Toro, Univ of Delaware, Dept of Civil Engineering; H.E. Allen, Univ of Delaware, Civil & Environmental Engineering Dept. The majority of research has focused on the adsorption of munitions constituents (MC) onto soils, but not on the more environmentally relevant desorption and resistance to desorption, which ultimately determines the environmental threat of these contaminants and their transport through the groundwater. The kinetics of desorption of munitions constituents study has applicability in formulating accurate risk assessments to different operational ranges. We conducted batch experiments near 1:1 soil to solution ratios reflecting field conditions that contained HMX, RDX, nitroglycerine (NG), TNT and 2,4-dinitro toluene as MC. The soils used varied from 0.1 to 12.5 percent organic matter and the experiment involved one adsorption step followed by four consecutive desorptions. Adsorption experiments were conducted on samples that were mixed for 2, 5, 10, and 30 days, and the changes in the adsorption isotherm for the low organic matter content soil was small for the MC with the exception of NG, while larger changes were observed for all MC in the high organic matter content soil. Degradation was the principle cause of these changes and transformation products were observed after each desorption step. For each adsorption experiment desorption steps were carried out for 1, 12, 24, and 72 hours. The most important observation was that the isotherms for each desorption time had the same slope. This implies that desorption hysteresis is not changed by the length of the desorption time, regardless of the initial adsorption time.

388 A Site Transformation Model of Adsorption-Desorption Hysteresis D.M. Di Toro, Univ of Delaware, Dept of Civil Engineering. The non-reversibility of adsorption and desorption, i.e., the fact that desorption isotherms do not conform to the adsorption isotherm is commonly observed. This hysteresis has been variously attributed to kinetic effects, i.e., the hysteresis would disappear if the desorption time were long enough, or to the existence of a metastable equilibrium where the hysteresis persists long enough and is stable enough so that it can be modeled as though it were at equilibrium. The site transformation model of sorption hysteresis is based on the idea that at adsorption equilibrium a fraction of the sites with adsorbed chemical are transformed into sites that reversibly bind the chemical more strongly than the untransformed sites. Therefore both the untransformed and transformed sites are reversible. The model equations makes explicit the transformation step and predict the form of the consecutive desorption isotherm. Depending on the model used for the adsorption isotherm, the model reproduces the Reversible-Resistant and the Linear – Langmuir models that have been fit to experimental adsorption-desorption data. For the site transformation model the form of the consecutive desorption isotherm is not chosen to fit the data but rather follows from the adsorption isotherm and the equation that describes the site transformation. This isolates the hypothesis that produces the hysteresis so that experiments can be designed to test various site transformation mechanisms.

389 Evaluation of Polycyclic Aromatic Hydrocarbons in Clay Target Fragments and Surface Soil at Shot Gun Ranges G. Hoeger, B. Magee, ARCADIS. The US Dept of Defense (DoD) oversees more than 3,000 active small arms firing ranges (SAFRs), and there are an additional 9,000 nonmilitary outdoor ranges in the United States. Many of these SAFR sites include trap and skeet ranges, which have elevated lead and polycyclic aromatic hydrocarbon (PAH) concentrations in surface soil in relatively predictable fallout areas based on trap and/or skeet shooting patterns. The clay targets used at trap and skeet ranges are typically made of lime with either coal tar or petroleum pitch as a binding agent. The coal tar and petroleum pitch are the source of PAHs in the target fragments, and they typically include mixtures of high-molecular weight PAHs, many of which are classified as probable human carcinogens by the United States Environmental Protection Agency (USEPA). In 2010, USEPA also proposed to expand the list of PAHs that must be evaluated as potentially carcinogenic to humans. Limited information is available concerning the bioavailability of PAHs in the limestone/coal tar matrix of the clay targets. The work performed by

Baer et al. (1995), who reported that PAHs in the limestone/coal tar matrix were not toxic to aquatic receptors using an EPA toxicity testing methodology, has been used to support the conclusion that PAHs in clay targets are inert and not available for absorption by human or ecological receptors. However, to date, no studies have been identified that directly address the potential bioavailability of PAHs in clay target fragments and impacted surface soil in animal models or human populations. As a result, PAHs in surface soil have become an increasingly important issue for closure of shot gun range (SGR) sites in various states across the country. Many regulators have required the use of default, generic risk-based screening and cleanup levels for the characterization and remediation of SGR sites. These screening and cleanup levels do not account for the limestone/coal tar matrix of the clay targets and assume 100% relative bioavailability. Even when site-specific risk assessment is performed, regulators typically require an assumption of 100% relative bioavailability. The application of default criteria and default risk assessment methodologies at SGR sites, therefore, overestimates the true risks posed by these clay target fragments. This paper will discuss the role that site-specific bioavailability studies can play in developing realistic risk estimates for SGR sites.

390 Update on Toxicology of 1,4-Dioxane B.J. Locey, ARCADIS, Risk Assessment and Environmental Services; B. Magee, ARCADIS 1,4-dioxane (1,4-D) was used by the US Dept of Defense (DoD) as a stabilizer for chlorinated solvents used as degreasing agents and in the manufacture of small arms ammunition. Because of its solubility and persistence in groundwater, it is found in and around US Air Force bases, and regulatory authorities are requiring the USAF to monitor for and remediate it. Two recent inhalation bioassays have confirmed 1,4-D's carcinogenic potential in rats by this route, but the relevance of the rat data to human risk assessment is unclear. Based on information provided in USEPA's Integrated Risk Information System (IRIS) Track, inhalation toxicity values have been developed that are currently undergoing interagency review and the draft assessment is scheduled to be released for external peer review during the summer of 2011. It is anticipated that the inhalation toxicity values will have major implications for the investigation and remediation of USAF facilities. This paper will present the key issues associated with the development of inhalation toxicity values for 1,4-D based on the recent and other studies, and will include a discussion of mode of action. The oral toxicological assessment, which was finalized in 2010, and the anticipated draft inhalation assessment, which is scheduled to be available by the end of the summer, will be reviewed in light of the National Academy of Science's recent evaluation of the methods and procedures used to evaluate animal toxicology studies and their appropriateness for deriving toxicity values for use in human health risk assessments in their recent review of the draft IRIS toxicological assessment for formaldehyde, as well as within the context of the on-going debate about the relevance of rodent tumor data for naphthalene to human risk assessment.

391 Effectiveness and Effects of Sea Surface Dispersants Used During the Deepwater Horizon Oil Spill and Their Future in Spill Response A.C. Bejarano, Research Planning Inc., Research Planning Inc.; A.J. Mearns, NOAA, Hazmat; J. Farr, E. Levine, NOAA; S. Miles, Louisiana State Univ; J. Michel, Research Planning, Inc. Despite decades of research on dispersants there remains controversy over the effectiveness and efficacy of their use. During the Deepwater Horizon (DWH) oil spill, ~25,505 bbls of dispersants were applied over ~305 square miles during 83 days of continuous aerial operations. A comprehensive evaluation of the dispersant monitoring programs and scientific studies conducted during the DWH oil spill is an important step towards building the foundation for planning and decision making in future spills. One of such programs, Special Monitoring of Applied Response Technologies (SMART), was used to monitor dispersant operations of surface dispersant applications. Tiers of this monitoring effort collected water samples for chemical analysis (~150 samples) and fluorometry measurements (indicators of dispersant effectiveness) at 1 and 10 m depth before and shortly after surface dispersant applications. Chemical analysis included a suite of PAHs (47 analytes in samples from the M/V International Peace and 38 analytes in samples from the M/V Warrior dispersant missions) and TPH measurements, as well as dipropylene glycol n-butyl ether (DPnB; a chemical marker for the presence of dispersants). In selected samples, the toxicity of PAH mixtures to aquatic receptors was characterized using the Equilibrium Partitioning Benchmark Toxic Unit approach (ESBTU), where ESBTU greater than 1 may indicate the potential for adverse effects to aquatic organisms. Preliminary results showed that, despite the lack of a clear correlation between dispersant effectiveness and total TPH concentrations, samples collected at 1 m depth and categorized as chemically dispersed generally had higher TPH concentrations (345± 637 µg/L) than either naturally dispersed (111± 107 µg/L) or background samples (175± 132 µg/L). ESBTUs >1 were observed in water samples collected at the surface (1 m), but not in deeper waters (10 m), and samples with the highest measured DPnB concentrations (>24 ug/L) had ESBTUs >1 (range: 3-11). In samples with ESBTUs >1, the analytes with the greatest contribution to the overall risk (74-83% to the ESBTU values) included the C1-C4 Chrysene alkylated analogs, C2-C4 Phenanthrenes/Anthracenes, and C2-C3 Fluoranthenes/Pyrenes. Although there was not a clear correlation between ESBTU values and dispersant effectiveness (assessed on-site by SMART teams), ESBTU >1 generally coincided with dispersant applications assessed as moderate to very effective.

392 Defining the Proper Role of Toxicity Monitoring in Oil Spill Response Activities G.M. Coelho, D.V. Aurand, J.R. Clark, Ecosystem Management & Associates, Inc. During the Deepwater Horizon oil release, subsea dispersant injection was utilized as part of an overall spill response strategy. BP was directed to develop and implement a water column monitoring program which included shipboard toxicity testing. The commercial aquatic toxicity screening kit (Rotoxkit M) that utilizes the rotifer, *Brachionus plicatilis*, was selected based on results of prior monitoring work to evaluate shipboard toxicity testing. Even though prior studies indicated that any of the tests considered for shipboard work were difficult to implement, this test had the greatest likelihood of success for this effort. The criteria developed for inclusion in the Directive were arbitrary, and were made without specific data on the organism's sensitivity to crude oil. As expected, when weather conditions were not good, shipboard conditions were not optimal for culture and testing the animals, leading to decreased control survival. However, as they gained experience, technicians were able to achieve acceptable results. Rotifer mortality was never sufficiently high to initiate discussions about restricting injection. In 99% of the 900 samples tested there was 75% or greater survival relative to controls. Concurrently with the field monitoring, laboratory toxicity testing indicated that the 24-hr LC50 ranged from 7.6 to 16.9 ppm. The fact that mortality in the shipboard tests was low is a positive result, but had there been significant mortality it is unclear how that information would have been used in making risk decisions. In short, there is little to recommend such tests, and many reasons to question their utility as a decision tool during emergency response operations. Estimates of hydrocarbon exposure concentrations, initially determined with a CDOM fluorometer and later using shipboard GC MS units, provide a better basis to assess environmental risk than shipboard test results for one species with responses to a variety of shipboard stresses. Field hydrocarbon concentrations can be compared to laboratory results for multiple species and other oils. Even so, neither approach, by itself, can be used to evaluate the appropriateness of dispersant use. While these data are useful, they must be tied back to Net Environmental Benefit Analysis or Ecological Risk Assessments to reach management decisions. These need to be prepared as part of the planning process, and then reexamined during the spill to determine if the approach still appears to be valid.

392.5 Biomarkers of Sustained Exposure in Resident Marsh Fish from Oiled Locations in Barataria Bay, Louisiana Following the Deepwater Horizon Oil Spill B. Dubansky, Louisiana State Univ, Dept of Biological Sciences; C. Rice, Clemson Univ, Biological Sciences; C. Bodinier, W. Stickle, A. Whitehead, F. Galvez, Louisiana State Univ, Dept of Biological Sciences. Coastal marsh habitats in Barataria Bay Louisiana were highly oiled in the months following the Deepwater Horizon Oil spill, and are still contaminated despite extensive cleaning efforts. We are currently investigating the effects of crude oil exposure on resident populations of *Fundulus grandis* (gulf killifish) collected from 15 locations, consisting of oiled and reference sites. Gulf killifish are an ideal species to investigate the effects of exposure to crude oil and its constituents because of their high home-range fidelity, and because they comprise a large percentage of the high marsh biomass and secondary productivity. We utilized immunohistochemistry and ELISA techniques to evaluate the induction of cytochrome p4501A (CYP1A) as a biomarker of exposure to PAHs acting through the aryl hydrocarbon receptor (AhR). Liver, gills, intestine, and head kidneys were sampled in situ and analyzed under laboratory conditions. Results were then paired with water chemistry analyses using passive sampling (polyethylene membrane devices, PEMDs) membranes deployed in Barataria Bay prior to, and at regular intervals following the spill to evaluate temporal changes in total polyaromatic hydrocarbon (PAH) concentration and composition. PAHs attributed to the Deepwater Horizon event peaked in September, and continued at lower levels near affected sampling sites. We found very little CYP1A expression in liver tissues after September, whereas CYP1A protein expression remained highly elevated in the gill, intestine, and renal endothelial cells. Future studies to evaluate the remediation of these areas will include extensive tissue analysis including continued monitoring for CYP1A protein expression, measures of population fitness and fecundity, and continued monitoring of water and sediment chemistry.

393 Overview of the Trustee's Aquatic Toxicity Testing Program in Support of the Deepwater Horizon Oil Spill Natural Resource Damage Assessment J.M. Morris, J. Holmes, J. Lipton, Stratus Consulting; M. Gielazyn, R. Ricker, L. DiPinto, NOAA. The Trustees for the *Deepwater Horizon* natural resource damage assessment have developed a comprehensive aquatic toxicity testing program to assess the potential impacts of *Deepwater Horizon* oil and dispersant on a variety of Gulf of Mexico fish and invertebrates. NOAA and Stratus Consulting are co-leading the program, which includes scientists from multiple federal, state and private laboratories and research institutions. The *Deepwater Horizon* incident resulted in oil releases to many different habitats under many different conditions over a long period of time. Organisms may have been exposed to wide range of oil variations, from relatively fresh oil and dispersant in pelagic habitat near the well, to highly weathered oil in shallow water or shoreline habitats. Therefore, the Trustees are exposing a wide variety of organisms to multiple oil preparations under different conditions. Example species in the toxicity testing program include pelagic fish such as cobia (*Rachycentron canadum*) and mahi mahi (*Coryphaena hippurus*); shallow water fish such as speckled sea trout (*Cynoscion nebulosus*) and red drum (*Sciaenops ocellatus*); typical model fish such as sheepshead minnow (*Cyprinodon variegates*); motile invertebrates such as white shrimp (*Penaeus setiferus*) and blue crab (*Callinectes sapidus*); and sessile invertebrates such as eastern oysters (*Crassostrea virginica*). The testing program includes exposing organisms to unweathered source oil, artificially weathered source oil, surface slick oil collected near the Macondo well, and/or more weathered slick oil collected closer to shore. Various methods will be employed to create water-accommodated fractions (WAFs) of oil, including high-energy mixtures, low-energy mixtures, and chemically-enhanced WAFs (CEWAFs) using COREXIT 9500 dispersant. The Trustees will evaluate several variables that may affect toxicity, such as potential enhancement of PAH toxicity under ultraviolet light, or changes in toxicity resulting from changes in salinity. Multiple toxicological endpoints will be examined in addition to mortality, including reduced fecundity/reproductive success, adverse changes to cardiac and metabolic functions, and reduced predator avoidance. This comprehensive aquatic toxicity program will help the Trustees to evaluate the adverse effects of the *Deepwater Horizon* oil and dispersant on exposed fish and invertebrates in the Gulf of Mexico.

394 Mixture Toxicity of Louisiana Sweet Crude Oil and Corexit 9500 to Estuarine Organisms M.E. DeLorenzo, NOAA, National Ocean Service, Dept of Marine Ecotoxicology, NOAA, National Ocean Service; K.W. Chung, P.B. Key, NOAA, National Ocean Service; L. Ferguson, Duke Univ, Dept of Civil and Environmental Engineering; M.H. Fulton, NOAA, National Ocean Service. About 2 million gallons of dispersants were applied to the oil spilled in the Deepwater Horizon event. Here we describe the results of laboratory testing aimed at quantifying the interactive effects of oil and dispersants to estuarine species. The toxicity of Louisiana Sweet Crude Oil to four representative estuarine species (fish, *Fundulus heteroclitus*; grass shrimp, *Palaemonetes pugio*; juvenile clam, *Mercenaria mercenaria*; green algae, *Dunaliella tertiolecta*) was determined with and without the addition of the oil dispersant, Corexit 9500. For each species, a static, 96 hour laboratory exposure was conducted at 25°C, 16h light:8h dark photoperiod, and 20 ppt salinity. The oil was added as a surface slick, and then Corexit was applied (1:20 v/v). Mortality was assessed daily. Growth rate was determined for the algae, and EROD activity was determined from the surviving fish after 96h. Oil toxicity varied among the species tested, with grass shrimp being the most sensitive. The mixture of Corexit 9500 with Louisiana Sweet Crude Oil, however, was significantly more toxic than the oil alone. For example, with grass shrimp, a 1:20 application of Corexit to the oil treatments increased mortality by approximately 60% compared to the same concentrations of oil alone. Chemical analysis of the oil and the Corexit 9500 was performed to quantify oil levels in the water after 96h, and to examine degradation of the dispersant over time. Mortality effects levels for the individual compounds and the mixture will be presented, along with results for the sublethal endpoints and chemical fate analysis.

396 Monitoring Polycyclic Aromatic Hydrocarbons (PAHs) in Seafood in Mississippi in Response to the Gulf Oil Spill K. Armbrust, Office of the State Chemist – Mississippi, Mississippi State Univ; K. Xia, Office of the State Chemist – Mississippi, Mississippi State Chemical Lab; G. Hagood, Office of the State Chemist – Mississippi, Mississippi State Univ; J. Jewell, D. Diaz, Mississippi Dept of Marine Resources; A. Brown, Mississippi State Univ, Biochemistry, Molecular Biology, Entomology and Plant Pathology; N. Gatian, H. Folmer, Mississippi Dept of Environmental Quality. Following the sinking of the Deepwater Horizon, the State of Mississippi began sampling and monitoring crabs, shrimp, oysters and several species of fish from numerous locations within Mississippi State Waters. From the end of May 2010 to date, over 400 samples have been analyzed by the State for Polycyclic Aromatic Hydrocarbons (PAHs) as listed in the NOAA method for analysis of PAHs in seafood. Additional samples were also collected and submitted to the NOAA laboratory in Pascagoula. MS to support the reopening of state waters in accordance with the protocol jointly developed by the gulf coast states, FDA and NOAA. PAHs have not been detected in any sample collected to date at levels above the Level of Concern (LOC) as established in the reopening protocol. However PAHs were routinely detected in most samples at low part-per-billion levels and are consistent with values commonly detected in samples measured in other studies along the gulf coast before, and unrelated to, the oil spill. The levels measured in seafood were also consistent with or below levels of PAHs detected in food items (smoked turkey, ham, chicken, catfish and barbecued pork) purchased at major retail supermarkets and restaurants.

397 Mapping of Sediment and Benthic Conditions around the Deepwater Horizon Accident Site J. Germano, D. Browning, Germano & Associates, Inc.; E. Revelas, Integral Consulting; L. Riege, Cardno Entrix. In Spring 2011, as part of a cooperative effort by BP and Federal Trustees to assess the potential effects of the Deepwater Horizon accident on the natural resources of the deep benthic sediments, a study team mapped the extent of deposits that may have resulted from drilling and well control activities in the area surrounding the MC-252 wellhead. The study used a Sediment Profiling and Plan View Imaging (SPI/PV) camera system to collect both surface and cross-sectional images of seafloor sediments in approximately 1,500 meters of water. The study complements previous and planned studies of sediment PAH concentrations and benthic infaunal community structure in the area around the wellhead. Comparison studies include (1) historical studies conducted by the Bureau of Ocean Energy Management, Regulation and Enforcement (BOEMRE) (2) recent studies by the Unified Area Command Operational Science Advisory Team (OSAT), and (3) a follow-up study by BP and the Federal Trustees in Spring 2011. The talk presents the results of the SPI/PV study and correlations between sediment PAH concentrations published by the OSAT and by the historical BOEMRE studies. The talk also discusses planned analyses correlating the SPI/PV results with infaunal community and sediment chemistry results from the Spring 2011 follow-up study.

398 Impact of Global Climate Change on Foundations of Environmental Toxicology and Chemistry: Results of the Pellston Workshop R.G. Stahl, DuPont Company, Corporate Remediation Dept, Principal Consultant, DuPont Corporate Remediation Group. A SETAC, Pellston-style workshop was held July 16-21, 2011 at the Wingspread Conference Center, Racine, Wisconsin to address the potential influence of global climate change (GCC) on the foundations of environmental toxicology and chemistry. Several years in the making, the workshop culminated the efforts of scientists from around the world to determine what, if any, changes need to be made in the underlying approaches used to assess the potential fate and effects of chemical toxicants. In addition, the participants addressed the potential that GCC will have on environmental restoration projects and how the design and implementation of those projects may need to change. A summary of the workshop proceedings will be presented along with plans for final publication of the workshop results.

399 Climate Change Impacts on Exposures, Fate, Transport and Deposition of Chemicals in the Environment T. Gouin, Unilever, Safety and Environmental Assurance Centre; J. Armitage, Univ of Toronto Scarborough; I. Cousins, Stockholm Univ; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, Environment Canada, National Water Research Institute; C. Ng, ETH. A SETAC Pellston workshop, held in July, 2011, brought together an international group of experts in environmental chemistry, toxicology, ecology, human health and risk assessment, to advance the level of scientific understanding of how global climate change may affect the environmental fate, bioavailability and toxicity of chemicals in the environment. Six workgroups addressed a range of areas that may be affected by climate change. The emphasis of workgroup 1 was aimed at assessing the influence of climate change on exposure, fate, transport, and deposition of chemicals in the environment, and how potential changes may impact environmental risk and hazard assessments. A key challenge identified relates to the complexity of interconnected environmental processes that may result in enhanced or reduced exposure of chemical contaminants. The complexity of the interactions can lead to non-intuitive results, making projections of how chemical fate and bioavailability might change in a world impacted by GCC difficult to assess. Nevertheless, efforts are made to demonstrate how models can quantify the physical-chemical properties of substances that may be more sensitive to changes in climate than others. Additionally, we attempt to demonstrate which global regions enhanced chemical exposure is more likely to occur. Utilizing an appreciation for the uncertainty and sensitivity of model parameters, as defined for both environmental fate models and climate change models, we attempt to demonstrate how model output can complement the collection of empirical data in a manner that can better inform our ability to assess potential relationships between chemical fate and bioavailability and changes in climate that can be attributed to climate change.

400 Mechanistic Toxicology in the Face of Global Climate Change M.J. Hooper, USGS, Columbia Environmental Research Center; G. Ankley, USEPA; D.A. Cristol, College of William and Mary; L.A. Maryoung, Univeristy of California, Riverside; P.D. Noyes, Duke Univ, Nicholas School of the Environment ; K.E. Pinkerton, Univeristy of California, Davis, Center for Health and the Environment. Incorporation of global climate change (GCC) effects into regulatory assessments of chemical risk and injury requires an understanding of GCC effects on mechanisms of chemical toxicity. Effects on mechanisms include those acting on toxicokinetics of chemical absorption, distribution, metabolism and excretion, as well as those affecting toxicodynamic interactions between chemicals and target molecules. GCC can further modify an organism's baseline physiological processes for coping with the external environment (water balance, thermoregulation, immune-endocrine-neurological systems), processes with distinct age, sex, and taxonomic specificities. In organisms living in GCC modified climates, increased investment in adaptation to GCC can lead to increased susceptibility to chemicals, disease and other stressors. Physiological processes critical to surviving temperature, hydration, nutrition and disease stresses will be particularly sensitive to even the slightest perturbations by chemicals when pushed to their functional limits. In simplest terms, GCC can make

organisms more sensitive to chemical stressors while, alternatively, chemical exposure can make organisms more sensitive to GCC stressors. Implications of GCC interactions with chemical mechanisms of toxicity are applicable to both ecological and human health effects assessments. To better address the complexities of these interactions, we employed adverse outcome pathways (AOPs), constructs that depict linkages between molecular initiating events and subsequent responses occurring across biological levels of organization, culminating in impacts in individuals or populations that can be used for assessing risk. Through a series of examples and case studies, we demonstrate how chemical- and climate-specific exposure scenarios can lead to adverse outcomes. Scenarios are prospective, hypothesizing outcomes based on known or anticipated chemical/GCC interactions, as well as retrospective, where mechanisms are proposed for known or demonstrated chemical-climate interactions. Understanding GCC interactions along AOPs provides opportunities for extrapolation between species or other levels of organization, development of questions, hypotheses and focal areas for further research, and improved inputs for risk and injury assessments.

401 Combined Effects of Climate Change and Toxicants on Populations and Communities J. Moe, Norwegian Institute for Water Research (NIVA), Climate and environmental modelling, Norwegian Institute for Water Resea, Section for Freshwater Biodiversity; K.A. De Schamphelaere, Ghent Univ, Environmental Toxicology and Aquatic Ecology, Ghent. Univ (UGent), Environmental Toxicology and Aquatic Ecology, Ghent Univ, Environmental Toxicology and Aquatic Ecology; W.H. Clements, Colorado State Univ, Fish, Wildlife and Conservation Biology, Colorado State Univ, Colorado State Univ, Fish, Wildlife and Conservation Biology; M. Sorensen, Environ International, ENVIRON International Corporation, Senior Science Advisor, Environ International; P.J. van den Brink, Alterra and Wageningen Univ, Alterra and Wageningen Univ, Centre of Water and Climate, Alterra and Wageningen Univ; M. Liess, Helmholtz centre for environmental research – UFZ, Dept of System Ecotoxicology, UFZ Center for Environmental Research, Dept of Chemical Ecotoxicology, Helmholtz centre for environmental research – UFZ, Dept of System Ecotoxicology. A SETAC international workshop, held in July, 2011, brought together a group of experts in environmental chemistry, toxicology, ecology, human health and risk assessment and natural resource damage assessment, to advance the level of scientific understanding of how global climate change (GCC) may affect the environmental fate, bioavailability and toxicity of chemicals in the environment. Six workgroups addressed a range of areas that may be affected by GCC. This presentation will discuss the anticipated joint impacts of GCC and toxicants on higher levels of ecological organization, i.e., populations and communities. Climatic changes such as higher temperature and CO_2 levels have documented negative impacts on many species, e.g., amphibians and coral reefs. GCC-related stress and toxicant exposure can therefore be regarded as multiple stressors, where the combined impacts on individuals can be stronger than the sum of the two factors (i.e., synergistic interaction) or weaker than the sum (i.e., antagonistic interaction). Since GCC can also influence the exposure, fate and toxicity of toxicants, the combined impacts of GCC and toxicants may be more complex than for other multiple stressors. Moreover, GCC can also directly impact on population and community processes, e.g., disrupt the timing of predator-prey interactions. A great challenge for ecotoxicology is to predict the how joint effects of GCC and toxicants at the individual level (e.g., reduced survival or reproduction) will be transferred to the population level (e.g., population growth rate) or to the community level (e.g., species richnesss). Given the large complexity and variability of GCC impacts on the environment, it is not possible to give general predictions for GCC x toxicant interactions on higher ecological levels. In this paper we focus on (i) how GCC directly and indirectly can alter toxicant exposure and impacts on organisms; (ii) species traits that may have particular importance for species' responses to GCC and thus to combined effects of GCC and toxicants, and (iii) ecological and evolutionary mechanisms which may have particular importance for GCC x toxicant interactions across ecological levels. Within this framework, case studies from three continents are used to illustrate the complexity of joint effects of GCC and toxicants on populations and communities.

402 How Will Global Climate Change Affect Human Health Risk Assessment? J.M. Balbus, NIEHS; A. Boxall, Univ of York, Environment Dept; R. Fenske, Univ of Washington, Dept Env Occ Health Sciences; T. McKone, Univ of California, Berkeley, Univ of California and Lawrence Berkeley National Laboratory, Univ of California, Univ of California and Lawrence Berkeley National Laboratory; L. Zeise, California EPA Office of Environmental Health Haza. Global climate change is predicted to alter long-term weather characteristics in different regions. These changes, including increased temperature, greater precipitation extremes, and loss of glacial and polar ice, have implications for human exposure to chemical contaminants. Climate change may also directly and indirectly affect the vulnerability of humans to chemical exposures. Changes in human exposure may arise from altered use, inputs, fate and transport of chemicals due to climatic and other drivers. Human vulnerability may be affected directly by heat and other weather-related stressors, or indirectly through altered co-exposures or disease patterns. To further explore the implications of climate change for the assessment and management of chemical risks, the authors examine four specific risk contexts: natural toxins, pesticides, air pollutants, and legacy chemicals (e.g., mercury, POPs). For the specific types of decisions to be made in each of these contexts, we examine how assessments and management decisions may be affected by climate change, and how significant the impacts of climate change may be. Climate change is likely to both increase and decrease human exposures, depending on the specific contaminant and specific region or other exposure context. There is limited evidence that climate change will increase the sensitivity of humans to chemical exposures. But small changes in exposure variability or human vulnerability can translate into significant changes in population risk profiles. To assess and manage chemical risks effectively, exposure data sources will need to be regularly updated and defaults and assumptions used in exposure assessment evaluated in a context of changing climate. Monitoring and sampling should be done with frequency sufficient to capture variability, which is likely to increase in many places. There are many research gaps in interactions between climate and weather parameters and human responses to chemical exposures. These factors will all exacerbate gaps in chemical protection between developed and developing countries.

403 Ecological Risk Assessment in the Context of Global Climate Change W.G. Landis, Institute of Environmental Toxicology, Western Washington Univ, Western Washington Univ, Institute of Environmental Toxicology, Western Washington Univ, Institute of Environmental Tox. & Chem.; J. Durda, Integral Consulting Inc; M. Brooks, Southern Illinois Univ; P.M. Chapman, Golder Associates Ltd; C. Menzie, Exponent, Inc., Exponent, Principal; R.G. Stahl, DuPont Company, Corporate Remediation Dept, Principal Consultant, DuPont Corporate Remediation Group; J. Stauber, CSIRO. This paper originates from the SETAC Pellston Workshop entitled "The Influence of Global Climate Change (GCC) on the Scientific Foundations and Applications of Environmental Toxicology and Chemistry" and specifically, from the workgroup charged with determining how ecological risk assessment (ERA) will encompass the challenges presented by GCC. Although the basic ERA structure remains useful, the process needs to broaden beyond contaminant issues per se to include interactions with changing habitats that alter biologic communities and recognize that landscape ecology (a.k.a. regional risk assessment) needs to be embraced to optimize effective environmental management decisions in the context of GCC. We propose seven principles for conducting ERAs under GCC: 1) evaluate a priori whether climate-related factors are likely to impact to a given ERA process and management decisions; 2) develop and express assessment endpoints as ecosystem services; 3) recognize that responses, (changes in ecosystem services), can be positive or negative; 4) recognize that the risk assessment process requires a multiple stressor approach with non-linear interactions; 5) develop conceptual cause-effect diagrams that consider context-dependent management decisions, at the appropriate spatial and temporal scales while ranking direct and indirect effects; 6) determine the major drivers of uncertainty by estimating and bounding stochastic uncertainty spatially, and across time; and, 7) plan for adaptive management to account for changing environmental conditions and consequent changes to ecosystem services. Given the complexities and uncertainties associated with GCC, good communication is essential for making risk-related information understandable and useful for managers and stakeholders.

404 Environmental Contaminants and Global Climate Change: Implications for Environmental Damage Assessment and Restoration/ Rehabilitation R.C. Helm, US Fish & Wildlife Service, Chief, Division Environmental Quality, , US Fish & Wildlife Service – Chief, Division Environmental Quality, ; S. Brasfield, US Army Engineer Research and Development Center, Environmental Laboratory; A. Fritz, NOAA/OR&R/

CPRD, Coastal Protection and Restoration Division, NOAA/OR&R/ARD, Assessment and Restoration Division, NOAA/OR&R/CPRD, Coastal Protection and Restoration Division; C. Hickey, Natl. Inst. of Water & Atmospheric Res., NIWA Ecosystems; P. Johnson, Fisheries and Ecological Services, US Fish and Wildlife Service; J. Rohr, Univ of South Florida, Dept of Integrative Biology. A SETAC international workshop, held in July, 2011, brought together an international group of experts in environmental chemistry, toxicology, ecology, human health and risk assessment and natural resource damage assessment, to advance the level of scientific understanding of how global climate change (GCC) may affect the environmental fate, bioavailability and toxicity of chemicals in the environment. Six workgroups addressed a range of areas that may be affected by GCC. The emphasis of the restoration workgroup was environmental damage assessment and restoration/rehabilitation in relation to GCC, specifically addressing: (i) legislation relating to contaminant management, damage assessment and restoration/rehabilitation requirements; (ii) experience with damage assessment and restoration implementation; and (iii) potential direct and indirect influences of GCC on damage assessment and restoration/rehabilitation processes. An example is provided in the US, where legislated requirements for damage assessment and restoration incorporate chemical exposure and ecosystem effects from site contaminants to assess the injury to resources and estimate damages paid for restoration of those resources. GCC will impact the processes of assessing injury and rehabilitating/restoring and conserving resources by affecting the magnitude of impact of contaminants on natural resources and altering potential restoration/rehabilitation efforts. Baseline/reference conditions for estimating resource injury and restoration/rehabilitation also may shift significantly and exhibit greater variability due to GCC, representing a significant challenge to practitioners. This presentation will discuss how such future environmental damage assessments and restorations might be influenced by GCC and provide recommendations of research needs in the field.

405 Potential Effects of Climate Change on Water Quality in Mineralized Watersheds A.S. Todd, US Geological Survey, Crustal Geophysics and Geochemistry Science Center; A. Manning, USGS, Crustal Geophysics and Geochemistry Science Center; D. McKnight, Univ of Colorado at Boulder, Institute of Arctic and Alpine Research; C. Crouch, Institute of Arctic and Alpine Research. A unique long-term water chemistry dataset has been compiled for the Upper Snake River, a stream draining a mineralized mountain watershed in Summit County, Colorado, USA. Trace metal and sulfate concentrations in stream water at baseflow have increased by a factor of two to four over the past three decades. Several small mines are located in the watershed, but they are abandoned and no mining or mine-remediation activities have occurred during this period. A similar increase in sulfate concentration has been observed in another part of the Colorado Rockies in lakes within mineralized watersheds also free of recent mining activity. These trends are concerning because mineralized watersheds are common throughout the mountains of the western US, and further water quality degradation could negatively impact important downstream drinking water resources and aquatic ecosystems. At sites in the lower Snake River watershed, resident fish populations are vulnerable to increasing metals concentrations, as is reflected in reduced densities of brook trout captured through electrofishing surveys in recent years. Climate change is a plausible cause of these observed trends, as surface and sub-surface hydrology play an important role in the generation of acid-rock drainage (ARD). While the specific links between climate and the natural production of low-pH, ARD in mineralized watersheds are poorly understood, preliminary modeling results suggest that water-table depth, recharge rate, and the magnitude of seasonal water-table fluctuations may be of primary importance. Climate change scenarios involving increasing temperature and decreasing snowpack, as predicted for much of the western US, may thus portend further water quality degradation in many mineralized watersheds.

406 Absorbance and Fluorescence Properties of Natural Organic Matter as Quality Measures Predicting Protective Effect Against Cu Toxicity to *Daphnia magna* H. Al-Reasi, C. Wood, McMaster Univ, Biology; S. Smith, Wilfrid Laurier Univ, Dept of Chemistry, Wilfrid Laurier Univ, Chemistry. The protection of natural organic matter (NOM) against metal toxicity, in particular copper (Cu), is potentially source-dependent. In the presence of NOM of different sources, but similar quantity (estimated as dissolved organic carbon, DOC, in mg C L^{-1}) and water chemistry, observed variability in Cu acute median-lethal concentrations (LC50s) remains unexplained. Here, quality measures of NOM, based on absorbance and fluorescence measurements, are proposed for possible incorporation into toxicity models, such as biotic ligand model (BLM), in order to improve predictive capabilities and account for observed NOM source-dependent variations. Using *Daphnia magna*, Cu toxicity tests were conducted in dechlorinated hard water (140 mg $CaCO_3$ L^{-1}) in the absence and presence of different freshwater NOMs isolates added at two DOC concentrations. With ranges of dissolved LC50s of 23.4 – 160.1 and 32.0 – 211.5 µg Cu L^{-1} reported at 3 and 6 mg DOC L^{-1}, respectively, up to 4-fold source-dependent differences in protection was observed. Relative humic-like fluorescent concentration was quantified for each NOM source using parallel factor analysis (PARAFAC), a multivariate approach applied to excitation-emission matrices. Optimization of lethal Cu accumulation (LA50) and utilization of PARAFAC-derived %HA as BLM input instead of the default 10%HA significantly improved the prediction of the BLM. At LA50 of 0.0120, the predicted and observed LC50s were weakly correlated (predictive LC50 = 0.41 measured LC50 + 17.04, R^2 = 0.28) with the use of default 10% assumption, however the relationship turned strong (predictive LC50 = 1.00 measured LC50 + 4.16, R^2 = 0.77) with the use of PARAFAC-derived %HA. The specific absorbance coefficient (SAC_{340nm}), an easily measured index of aromaticity of NOM, was highly correlated (R^2 = 0.96) with the PARAFAC- derived %HA of the NOMs, suggesting the contribution of aromatic constituents to both fluorescence and absorbance. To facilitate incorporation into the BLM, SAC_{340nm} for each NOM isolate was employed to predict %HA, which was optimized separately for each LC50 determination. The optimized PARAFAC-derived %HA were still strongly linked to the SAC_{340nm} (R^2 = 0.80), indicating the applicability of the BLM to have fluorescence quality measure with absorbance based correction. Funded by NSERC to CMW and DSS, and scholarship from Government of the Sultanate of Oman to HAA.

407 Biofilm Response to Metal-contaminated Sediment Depends on Sediment and Stream Context D. Costello, A. Burton, Univ of Michigan, School of Natural Resources & Environment. In metal-contaminated streams, biofilms are exposed to and accumulate metals, which can reduce biofilm growth, alter function, and expose consumers to potentially toxic dietary metal. Exposure can occur through dissolved metal in surface waters; however, metal-contaminated sediments may also affect biofilms. We exposed biofilm to metal-spiked sediments (Ni and Cu together) from two streams by growing it on porous glass disks atop sediment-filled cups. Biofilm cups were placed in closed (Big Pup) and open (Salmon-Trout) canopy streams near Marquette, MI. Two sediments, which were characterized by acid-volatile sulfide, organic carbon, and iron and manganese oxide content, were amended with metal and deployed in each of the streams. After 28 days, biofilms were analyzed for O_2 production, chlorophyll *a*, biomass, and metal concentrations. Biofilm production and chlorophyll *a* were sensitive to metal concentrations, but the response differed in the two streams; biofilm cups placed in the closed canopy stream were more sensitive to metals than biofilms in the open stream. Geochemistry differed between our two sediments, yet the biofilm growth and production was reduced more when grown on sediments with greater concentrations of binding ligands. This suggests that current metal bioavailability models may not be amenable to natural biofilm communities and that photosynthetic activity may modify the toxicity of contaminated sediments.

408 Copper-induced Oxidative Stress in the Sea Anemone *Actinia bermudensis* V. Cavicchioli-Azevedo, M.M. Lauer, N.L. Yano, A. Bianchini, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas. Copper catalyzes the formation of reactive oxygen species (ROS), but little is known about its effect on antioxidant defenses and protein repair mechanism in osmoconformers. We evaluated the copper effects on antioxidant defenses [superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), reduced glutathione (GSH), glutamate cysteine __ligase (GCL), glutathione-*S*-transferase (GST)], total antioxidant capacity against peroxyl radical (ACAP), oxidative damage (lipid peroxidation and protein carbonyl content), and protein repair mechanism (HSP70) in the sea anemone *Actinia bermudensis*. Animals (n=5) were exposed to copper (5, 10, 50 ug Cu/L) for 96 h at salinity 30 ppt. A control treatment (no copper addition) was also run. Temperature (20ºC) and photoperiod (12h L:12h D) were fixed. No mortality was observed. Copper exposure increased SOD activity, probably due to an increased anion superoxide formation. Copper also increased CAT activity, likely associated with a higher H_2O_2 concentration

resulting from the increased SOD activity. Since SOD and CAT represent the first line of defense against the anion superoxide and H_2O_2, their increased activity protected against ROS. In the other hand, GPx activity was inhibited in copper-exposed animals, decreasing the efficiency of the second line of defense against ROS. In addition, no effect on GSH level, GCL and GST activity was observed. This lack of effect was probably due to the reduced use of GSH by GPx. After copper exposure, a reduced ACAP was observed, likely due to the inhibition of GPx and the low consumption of GSH. Reduced ACAP led to an increased lipid peroxidation and protein carbonyl content in copper-exposed sea anemones. An increased HSP70 concentration was observed in sea anemones exposed to 5 and 10 ug Cu/L, suggesting a stimulation of the mechanism of protein repair. At 50 ug Cu/L, this mechanism seems to be overwhelmed, since a decrease in the HSP70 concentration was observed. Taken altogether, results showed that copper exposure reduces the antioxidant capacity leading to oxidative damage in lipids and proteins in spite of an increased response of the protein repair mechanism in the sea anemone *A. bermudensis*. These findings indicate that the mechanism of copper toxicity in marine osmoconformers is associated with oxidative stress. [Supported by the Brazilian CNPq (INCT-TA) and CAPES (Ciências do Mar) and the Canadian IDRC].

409 Cu and Pb Internalization by *Chlamydomonas reinhardtii* at Varying Carbonate Concentrations: Agreement with FIAM? P. Sanchez-Marin, C. Fortin, P.G. Campbell, Institut National de la Recherche Scientifique, Centre Eau Terre Environnement. Over the past 10+ years, substantial efforts have been devoted to the development of biotic ligand models (BLMs) to predict the bioavailability of metals. These models are focused mainly on the responses of metal bioavailability (uptake or toxicity) to variations in major ion composition (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, Cl^{-}), pH, and to the presence of natural ligands such as dissolved organic matter. However, the effect of carbonate, an inorganic ligand ubiquitously present in aquatic environments, has rarely been investigated. Carbonate concentrations can vary in natural waters due to differences in the underlying geology, pH variations, as a result of photosynthesis/respiration processes, or due to the continuously increasing anthropogenic CO_2 concentrations in the atmosphere. Both carbonate and bicarbonate can form complexes with metal ions, and although the stability constants of these complexes are quite well established for Cu, a high uncertainty remains on those defining the degree of complexation of Pb with these anions. By dissolving $NaHCO_3$ in closed vessels and accurately measuring inorganic carbon concentrations, we have studied both the speciation and bioavailability of Cu and Pb at varying carbonate concentrations (from 10 to 3000 µM C) at constant pH and ionic strength. Cu^{2+} and Pb^{2+} concentrations were measured by ion selective electrodes and related to the short term internalization of Cu and Pb by the freshwater microalga *Chlamydomonas reinhardtii*. The results showed that the internalization of both metals depends on the activity of the free metal ions, as controlled by their complexation with carbonate. There was no evidence for uptake of metal carbonate complexes. These results can be included in current BLMs for freshwater algae to take into account the presence and variation of dissolved inorganic carbon concentrations in natural waters.

410 Influence of Water Quality to Zinc Toxicity in the Florida Apple Snail (*Pomacea paludosa*) T.C. Hoang, Florida International Univ, Southeast Environmental Research Center/Dept of Environ Study, Loyola Univ Chicago, Center for Urban Environmental Research and Policy; G. Rand, Florida International Univ, Ecotoxicology and Risk Assessment. Aquatic toxicology research has been conducted to characterize the toxicity of zinc to standard aquatic organisms (e.g., Fathead minnow, *Daphnia magna*, etc.). However, research of zinc toxicity to non-standard test organisms such as Apple snails has not been conducted. Apple snails are widely distributed in the southeastern US In Florida, apple snails play a major role as the main food source of many higher trophic organisms in the Everglades ecosystem. Our recent research indicates that the Florida apple snail is sensitive to copper and water quality significantly influences Cu toxicity to Florida apple snails. The present research characterizes the influence of water quality on Zn toxicity to Florida apple snails. Static renewal acute toxicity tests were conducted in this study. Water quality used in this study varied from soft to very hard water. Concentrations of dissolved organic carbon (DOC) ranged from 0 to 10 mg/L. Results of this study indicate that hardness had a protective effect on zinc toxicity to Florida apple snails. The 48-h LC50 values of the snail increased from 160 to 1190 µg/L dissolved Zn when hardness increased from 20 to 200 mg/L, as $CaCO_3$. The 96-h LC50 values were 140 µg/L and 1017 µg/L dissolved Zn at hardness of 20 mg/L and 200 mg/L as $CaCO_3$, respectively. These results are in contrast with the results of our earlier study that hardness was not protective to Florida apple snails from Cu toxicity. Similar to Cu, DOC also mitigated the toxicity of Zn to Florida apple snails. When DOC increased from 0 to 10 mg/L, 48-h and 96-h LC50 values of the snail increased from 605 to 845µg/L and from 463 µg/L to 632 µg/L dissolved Zn, respectively. Results of this study indicate that Florida apple snails are sensitive to Zn. The effects of pH and alkalinity on Zn toxicity to Florida apple snails should be investigated and a biotic ligand model for Zn and apple snails should be developed.

411 Modelling Uptake of Trivalent Trace Metals by Phytoplankton Using a BLM Approach A. Cremazy, P. Campbell, C. Fortin, INRS-ETE. Major progress has been achieved in recent years in our ability to predict metal bioavailability to aquatic biota. This is due in large measure to the development and improvement of models such as the Biotic Ligand Model (BLM). These models allow for the prediction of trace metal uptake and toxicity to aquatic organisms in natural waters and are thus useful tools for the ecological risk assessment of metals. According to the BLM, metal accumulation, and therefore toxicity, are proportional to the free ion activity. The applicability of the BLM to divalent trace metals has been thoroughly investigated since the pioneering work of Sunda and co-workers in the 1970s. However, its relevance to trivalent trace metals such as aluminium is still largely unknown. Although the toxic effects of aluminium are relatively well documented, the uptake mechanisms are still speculative and the links between speciation and accumulation remain elusive. This situation is mainly caused by the analytical difficulties encountered when working with trivalent metals: their aqueous coordination chemistry is complex, they tend to bind tightly to cell walls, and there is a lack of affordable and suitable radio-isotopes and a dearth of sensitive analytical techniques. Scandium was used in the present study as a substitute for aluminium, to investigate the applicability of the BLM to unicellular algae. Scandium is a trivalent trace metal with chemical similarities to aluminium and it has a suitable radio-isotope (Sc-46, half life of 83.8 days) for carrying out uptake experiments. Measurements of scandium internalization fluxes (J_{int}) in a unicellular alga (*Chlamydomonas reinhardtii*) have been performed in kinetic uptake experiments. Changes in the chemistry of the exposure media ([Sc], pH, ionic strength, etc.) were then related to the J_{int} values in order to explore the uptake mechanisms of scandium and to identify which metallic species are involved in the internalization. For example, J_{int} increased from 3.0 ± 0.1 to 31.6 ± 3.1 $nmol \cdot m^{-2} \cdot nM^{-1} \cdot h^{-1}$ (n=3) with a decrease in the pH from 7.75 to 6.00. J_{int} also increased with a decrease in Ca^{2+} and Na^{+} concentrations. The ability of the BLM to explain the uptake kinetics will be discussed.

412 The Effect of Cd on Repeated Swim Performance in Relation to Metabolic Recovery in Rainbow Trout (*O. mykiss*) During Sublethal Waterborne Exposure J. Cunningham, Wilfrid Laurier Univ, Biology; J. McGeer, Wilfrid Laurier Univ. Swimming ability is frequently used to characterize the integrated metabolic costs associated with exposure to contaminants, including Cd. Repeat swimming challenges provide a more sensitive indicator of effects by identifying impairment that was not observed in a singular swim challenge alone. Sublethal Cd exposure has previously been shown not to affect swimming performance in individual swim challenges; however we have recently shown that exposure to 2 µg Cd L-1 resulted in a dramatic reduction in performance in subsequent swim trials. For example, performance in the second swim trial, following an initial swim and 30 min recovery period, resulted in reductions of sustained swimming capacity (Ucrit) as great as 31% in Cd exposed brown trout (Salmo trutta). Drawing on this, recovery periods of varying duration were used inorder to determine the role of the rest period in the recovery of swimming ability and metabolic parameters. This study employs two consecutive swimming challenges, separated by a recovery period of varying duration (0.5, 1.5 and 6 h) inorder to investigate the effects of Cd (2 µg Cd L-1, 140 mg $CaCO_3$) on repeated swimming ability in juvenile rainbow trout (*Oncorhynchus mykiss*). Blood, organ and muscle samples were taken before and after each of the swim trials and rest periods, and tissue Cd burden, plasma ion composition, metabolic fluctuations and stress response were measured. Following a 30 minute recovery period, Cd exposed fish had a decreased Ucrit of 3.0 ± 0.3 bl s-1, compaired with 4.4 ± 0.3 bl s-1 in controls, in subsequent challenges. However, with a 1.5 hour recovery period Cd exposed fish performed significantly better in subsequent swimming challenges (5.2 ± 0.2 bl s-1) than did controls (4.3 ± 0.2 bl s-1), with no differences observed

between treatments after 6 hours of recovery. Metabolic fuel sources, utilized to power muscular contraction and physical activity, such as glycogen and ATP were directly linked to the changes in swim performance at different recovery times. The increased swimming capacity of Cd exposed fish following a 1.5 h recovery was correlated with greater restoration of glycogen (5x) and ATP (1.5x) compared to controls. The results establish linkages between exposure, bioaccumulation and the physiological disruption induced by Cd to provide an improved understanding of the mechanisms underlying impairment of whole animal performance. This research is supported through the NSERC Discovery Program.

413 Toxicity of Metal Mixtures to *Daphnia magna*: Implications for a Multi-metal, Multi-site Biotic Ligand Model J. Meyer, Arcadis US, Inc., ARCADIS; J. Ranville, Colorado School of Mines, Chemistry and Geochemistry, Colorado School of Mines; M. Pontasch, Colorado School of Mines; R. Santore, A.C. Ryan, HDR|HydroQual; J. Gorsuch, Copper Development Association; W.J. Adams, Rio Tinto, Product Stewardship. For decades, a simplistic summation of toxic units based on concentrations of dissolved metals has been used to semi-quantitatively predict the toxicity of metal mixtures. However, that approach tends to over-predict toxicity. In its place, we have been developing a mechanistic model based on tissue residues of metals and on the concept that the toxicity of a mixture of metals can be either dose-additive or response-additive, depending on the mechanisms of action. To calculate tissue residues and thereby predict toxicity across wide ranges of water quality, we have been developing a multi-metal, multi-site biotic ligand model (MMMS BLM) that concurrently accounts for metal-metal competition for binding on dissolved ligands in the water and at sites of toxicity on organisms. In our initial tests, we exposed *Daphnia magna* to mixtures of Cu and Zn or mixtures of Cd and Cu in moderately hard reconstituted water containing dissolved organic carbon (DOC; added as Suwannee River fulvic acid) at 3 mg/L, and compared observed mortality to the response-additive mortality predicted from results of concurrent Cu-only and Zn-only toxicity tests or concurrent Cd-only and Cu-only toxicity tests. This research has revealed several apparent metal-metal interactions that otherwise might lead to conclusions that metals interact in non-additive ways, yet simple geochemical speciation in the BLM can explain these interactions and reconcile the apparent non-additive toxicity. For example, the toxicity of Cu-Zn mixtures always appeared to be more-than-additive or additive when based on dissolved metal concentrations, whether Cu was varied while Zn was held constant, or vice versa; whereas in the same tests, the toxicity of the Cu-Zn mixtures always appeared to be less-than-additive or additive when based on free-metal-ion concentrations. In contrast to the results for Cu-Zn mixtures, the toxicity of Cd-Cu mixtures always appeared to be less-than-additive or additive when based on dissolved metal concentrations. These preliminary results demonstrate that different metal mixtures can appear to interact differently based on dissolved-metal or free-ion concentrations, but a MMMS BLM could help reconcile those apparent inconsistencies and could be an effective tool to help water quality agencies implement more appropriate methods to regulate metal mixtures than the current default, overly conservative toxic-units approach.

414 Effects of Maternally Transferred Methylmercury Chloride on Stress Induced Corticosterone Levels in *Nerodia sipedon* Neonates P.W. Cusaac, Middle Tennessee State Univ, Dept of Biology; R.W. Wright, C. Henry, Middle Tennessee State Univ; F. Bailey, Middle Tennessee State Univ, Dept of Biology. Stress responses in ectothermic organisms play a crucial role in their ability to survive. Cause and response interactions of stressors are relatively well studied, however studies showing the effects of heavy metal toxicity on stress are lacking, particularly in squamate reptiles. This study was designed to examine the effects of maternally transferred methylmercury chloride on stress-induced plasma corticosterone (a hormone that normally increases in response to stress) levels in Northern Water Snake (*Nerodia sipedon*) neonates. The objective of this study was to determine if neonates from methylmercury-dosed females exhibit a diminished increase in corticosterone in response to confinement stress when compared to controls. Gravid females were dosed with 0, 10, or 10,000 ug/Kg methylmercury (3, 3, and 4 each treatment, respectively). 10 neonates from each female were used for Corticosterone testing (5 baseline and 5 stressed). Liver mercury concentrations differed significantly among the treatments (ANOVA, $F_{(2,8)} = 9.012$, $MSE = 0.04$, $p = 0.016$). We found no significant difference of the degree of increase in corticosterone levels between dosing treatments (RM ANOVA; $F_{(2,8)} = 1.046$, $MSE = 0.018$, H-F $p = 0.395$). We therefore conclude that methylmercury chloride has no effect on stress induced corticosterone levels in neonate *N. sipedon*.

415 Lacertid Lizards as Bioindicators of Pesticide Exposure and Toxicity in Agricultural Areas M. Amaral, CIBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos, CESAM & Departament of Biology, CIBIO Centro de Investigação em Biodiversidade e Recursos Genéticos, Universidade de Aveiro, CESAM & Departamento de Biologia, Universidade de Aveiro, CESAM & Dept of Biology; M.A. Carretero, CIBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos; R. Bicho, Universidade de Aveiro, CESAM & Depto de Biologia; J.C. Sanchez-Hernandez, Universidad de Castilla-La Mancha, Facultad de Ciencias del Medio Ambiente; F. Guarino, Università degli Studi di Napoli Federico II, Dipartimento di Biologia Strutturale & Funzionale ; A. Faustino, Universidade do Porto, Departamento de Patologia e Imunologia Molecular, ICBAS; A.M. Soares, Universidade de Aveiro, CESAM & Depto de Biologia; R.M. Mann, Univ of Aveiro, CESAM & Dept of Biology, Hydrobiology. Lizards are among the least studied groups in ecotoxicology, and despite a recent increase in the number of studies, there is still a lack of knowledge regarding their response to environmental contamination. In Europe, lacertid lizards have been identified as potential model species for reptile ecotoxicology. The main question of our project was to assess if highly abundant lacertid lizards belonging to the genus *Podarcis*, could be used as bioindicator of pesticide exposure and toxicity in agricultural areas. To achieve this end, we used a three-stage tiered approach. The first tier took the form of a field survey to document both exposure and population endpoints of lacertids occurring in areas of intensive pesticide and usage and areas of negligible pesticide usage. The second tier was a mesocosm study in which naïve lizards were exposed to pesticides in a controlled experiment. Finally, the third tier included a laboratorial approach to the effects of one of the most common insecticides used worldwide, chlorpyrifos. We assessed pesticide impact using a comprehensive set of endpoints applied at different levels of biological organization, including behavioral, physiological, biochemical and histological biomarkers. The field work confirmed the difficulty of differentiation between the effect of contaminants and other (local) factors at the population level but our results suggest a difference in the metabolic activity between animals from reference and exposed locations. Animals from exposed fields seem to be in worst body conditions and in a deficitary energy balance when compared to animals from the reference locations. The results of the mesocosm study validated the correlative data obtained in the field survey. While the laboratory approach showed that environmentally relevant dosages of chlorpyrifos can affect *P. bocagei*. According to our data, P. bocagei seems to be a suitable indicator of sub-lethal exposure to pesticides.

416 Characterization and Toxicological Applications of Loggerhead Sea Turtle (*Caretta caretta*) Primary Skin Cell Cultures S.J. Webb, G.V. Zychowski, J.M. Cole, S.L. Wiggins, Texas Tech Univ, The institute of environmental and human health; B.M. Higgins, NOAA/NMFS. Within the past several decades, sea turtles have seen a major decline in population to the point of being listed as threatened or endangered. A large body of research has investigated several possible factors in this decline, including disruption of habitat, boat strikes, entanglement in fishing gear, and diseases such as fibropapillomatosis. However, the impact of chemical contaminants is not well-studied. Sea turtles come into contact with a variety of contaminants in the marine environment, such as polycyclic aromatic hydrocarbons, organochlorines, polychlorobiphenyls, and heavy metals. It is challenging to conduct toxicological investigations in these animals due to their threatened status. The aim of this study was to develop a method of toxicological testing using primary cell cultures developed from sea turtle skin biopsies. Here, we report on 1) the characterization of Loggerhead sea turtle (*Caretta caretta*) primary fibroblast skin cell cultures, and 2) the optimization of cytotoxicity assays such as MTT and growth curve assays. Cells were dosed with benzo[*a*]pyrene, a prototypical PAH and known marine contaminant, at concentrations of 10 µM, 1 µM, 100 nM, and 10 nM. Data analyses showed that RPMI 1640 medium, 30°C incubation, 10% serum concentration, and a tissue culture treated growth surface for cell adhesion were optimal growth conditions. Preliminary growth curve analyses of cells exposed to 10 _M B[*a*]P showed markedly lower growth, and MTT assays suggest toxicity to cells following 96-hour exposure to B[*a*]P at all tested concentrations. Following optimization, these toxicological assays will be useful not only in single contaminant exposures but also in examining interactions between these contaminants and other natural stressors. This

research was conducted under US Fish and Wildlife Service Endangered Species Act Section 10a(1)a Scientific Research Permit# TE_676379_4 and TE#676379_5 and Florida Fish and Wildlife Conservation Commission, FWC MTP_015 and complied with all institutional animal care guidelines.

417 Effects of Contaminants on the Emerging Infectious Amphibian Diseases Ranavirus and Chytrid J. Kerby, Univ of South Dakota, Biology. While both contaminant exposure and emerging infectious diseases have been implicated in recent amphibian declines, little work has been done to examine any potential interaction among these two factors. Amphibian populations can be found in areas that contain both significant levels of contamination and a high prevalence of pathogen infection. To examine some of the potential for interactions between the two, I set up three separate experiments examining the interaction of different contaminants with the pathogens Ranavirus and *Batrochochytrium dendrobatidis* (Bd). In the first experiment, I found that Tiger Salamanders (*Ambystoma tigrinum*) in the presence of chlorpyrifos (2 µg/L) and atrazine (20 µg/L) exhibited increased susceptibility to Ranavirus infection and subsequent mortality. In a subsequent experiment, the addition of a predator cue stressor with the insecticide carbaryl (500 µg/L) also significantly increased susceptibility to Ranavirus infection. In the final experiment, exposure to the antimicrobial Triclosan (100 µg/L) caused significant direct mortality to Woodhouse's Toads (*Anaxyrus woodhousii*). Exposure to lower levels of Triclosan (10 µg/L) resulted in a protective effect that actually increased survival of tadpoles also exposed to Bd. These experiments show that interactive effects can be exhibited in a laboratory setting and can both positively and negatively impact amphibian survival. Given this potential, greater attention is required in field level surveys regarding the monitoring of these two stressors and understanding the importance of their potential impacts. Additionally, further laboratory and mesocosm level experimental work should provide a greater insight to potential interactions that can occur between these two diseases and contaminant exposure.

418 Agricultural Land Use Stresses Amphibians and Alters Immune Function P. Falso, S. Gallipeau, Univ of California, Berkeley; T. Hayes, Univ of California – Berkeley, Dept of Integrative Biology. Amphibian populations are dramatically declining worldwide. Approximately 30% of all amphibian species are in decline and increased disease has been implicated as a major contributor. Increases in susceptibility to pathogens may result from stressful habitat conditions and subsequent disruption of immune response. Amphibian populations in agricultural regions are subject to diverse environmental stressors resulting from human habitat manipulation. The invasive American bullfrog (*Rana catesbeiana*) was used as a surrogate model for examining possible effects of agricultural contaminants and habitat disruption on sensitive native amphibian populations in the Salinas, San Joaquin, and Sacramento River systems in California. We analyzed the endocrine and immune function of bullfrogs collected at sites along a gradient of agricultural land use within these three rivers systems. Elevated plasma stress hormone levels (corticosterone) and altered white blood cell (WBC) differentials and WBC activities were observed in bullfrogs collected from agricultural sites compared to sites upstream of agriculture. In the laboratory, increased plasma corticosterone levels correlated with both altered WBC differentials and WBC activity in bullfrogs. Together these experiments give insight into the effects of stress induced by habitat alteration on endocrine and immune function in amphibians.

419 Amphibians, Atrazine, Immunity, and Infections J. Rohr, Univ of South Florida, Dept of Integrative Biology; T. McMahon, N. Halstead, L. Martin, T. Raffel, Univ of South Florida; S. Johnsons, Univ of Florida. Amphibians are the most threatened vertebrate taxon on the globe and many of their declines have been linked to diseases, such as chytridiomycosis, which is caused by the amphibian chytrid fungus, Batrachochytrium dendrobatidis (Bd). Although chemical contaminants have been implicated in amphibian declines, few contaminants cause enough direct mortality at ecologically relevant concentrations to drive declines, suggesting that, if there is a link, it could be indirect and perhaps mediated by contaminant effects on infections given how important they are to amphibian losses. Using a meta-analytical approach, we reveal that exposure to atrazine, the second most commonly used herbicide and pesticide in the US, is consistently associated with immunomodulation and elevated infections in amphibians. In dose-response studies on Bd, atrazine reduced Bd growth rates suggesting that it might temporarily reduce the risk of Bd infections. However, one-week, early-life exposure of amphibians to the expected environmental concentration of atrazine (~102 µg/L) was associated with significant immediate and long-term (7 weeks after atrazine exposure) increases in amphibian mortality due to Bd. Additionally, this increase in Bd-induced mortality was independent of when the atrazine exposure occurred during development. Our findings indicate that atrazine must be present to kill Bd, but only has to have been present in the past to cause persistent increases in the risk of Bd-induced amphibian mortality. Hence, our results support the hypothesis that the net effect of atrazine could increase the threat posed by Bd, but clearly the effects are complex and we encourage further investigations into the role of this widespread herbicide in amphibian health. Overall, this work highlights the need for more research on the role of contaminants in mediating changes in host-symbiont interactions.

420 Effects of Contaminated Sediments, UV-Exposure, Maternal Effect and Predators on the Abnormalities Observed in Bermuda's Cane Toads (*Rhinella marina*) J. Bacon, Bermuda Zoological Society, Research, Bermuda Zoological Society; B. Todhunter, C. Fort, H. Fort, D. Fort, Fort Environmental Laboratories. The interactive effects of contaminants, uv-exposure, maternal transfer and predators on the incidence and types of abnormalities observed were measured in newly-metamorphosed cane toads (toadlets) from four ponds contaminated with petrochemicals and metals. Abnormalities were compared in toadlets that were field-caught (FC), reared in in situ predator exclusion cages (PEC), reared in laboratory microcosms exposed to media from the same four ponds (LM), and reared in laboratory microcosms exposed to three intensities of uv-light and media from two of the ponds. Comparisons were also made to predator-induced limb injuries from laboratory studies. Percent abnormal for FC, PEC and LM toadlets ranged between 14-48%, 15-59%, and 25-63% by site and year respectively. The types of limb abnormalities observed were similar in all treatments. Percent hind limb versus forelimb abnormalities, however, was statistically greater in FC toadlets, statistically less in PEC toadlets, and not statistically different in LM toadlets. In our first uv study, no abnormalities occurred in the unexposed or uv-exposed control treatments indicating that a maternal effect and uv-light alone did not induce abnormalities in this cohort. Unexposed and uv-exposed site media treatments did induce various abnormalities as expected, however. Further, concurrent exposure to uv-light and site media induced a significantly higher percentage of hind limb abnormalities (68%) than exposure to site media alone (13%). In contrast, a significant maternal effect was found in the cohort used in the second uv study; 37% of toadlets were abnormal in the unexposed control treatment. Percent abnormal in the unexposed site media treatment was significantly higher (62%), however, but the types of malformations observed were the same. Additionally, in the two uv-exposed site media treatments, both the percent abnormal (49%, 86%) and the percent of limb abnormalities involving the hind limbs (89%, 85%) were significantly higher in than the corresponding control treatments (22%, 33%), (15%, 22%). These data suggest that the types of abnormalities expressed are determined by contaminant exposure and maternal effect, but that uv-light exposure causes limb abnormalities to occur primarily in the hind limbs. Comparisons with predator-induced injuries also suggest that some cases of ectromelia and brachydactyly in field-caught specimens in Bermuda may be predator-induced.

421 Amphibians and Nitrogen Pollution: Comparative Sensitivity and Factors Influencing Toxicity B.K. Williams, E.E. Little, H.J. Puglis, E.L. Beahan, USGS, Columbia Environmental Research Center. Nitrogen pollution is one of the most ubiquitous stressors affecting aquatic systems worldwide. Nitrite, nitrate and ammonia pose a hazard to aquatic organisms, and have been shown to affect survival and development, induce deformities, and impair behavior in larval amphibians. In addition to causing direct injury to amphibians, nitrogen species are known to interact with other chemical and biological stressors. Improved understanding of nitrogen toxicity is necessary for elucidating interactions with other stressors, as well as for predicting the likelihood of harm to amphibian populations under field conditions. Unfortunately, published reports of nitrogen toxicity vary widely and there is a general lack of chronic toxicity data for all three nitrogen species. We conducted acute and chronic toxicity tests with nitrite, nitrate, and ammonia exposures to several amphibian species, including gray treefrogs (*Hyla versicolor*), wood frogs (*Lithobates sylvaticus*), and spotted salamanders (*Ambystoma maculatum*). Acute tests were initiated with early-stage larvae (Gosner Stage 25) and included calculation of 96-hour LC50s and EC50s

for behavioral impairment. Chronic flow-through studies were initiated with newly fertilized eggs and continued through metamorphosis (52 days for gray treefrogs and 77 days for wood frogs), with calculation of chronic LC50s and evaluation of sublethal endpoints (time to and mass at metamorphosis). These results will allow us to 1) determine the relative sensitivities of several amphibian species to nitrogen pollution, 2) compare mortality from the chronic tests with acute-to-chronic projections, and 3) derive species mean acute and chronic criterion values for these common nitrogen pollutants. In addition, the results from these studies will be discussed in the broader context of biotic and abiotic sources of variability contributing to widespread inconsistency in reported nitrogen toxicity values.

422 Application of Multicriteria Decision Analysis to Support the US Army Corp's Individual and General Permitting Decisions C. Foran, US Army Corps of Engineers, Engineer Research and Development Center; Z. Collier, US Army Corps of Engineers, Engineer Research & Development Center; I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center. USACE personnel responsible for making permitting decisions are faced with the task of evaluating multiple factors associated with proposed project alternatives. Complex tradeoffs between project alternatives containing potential environmental impacts should be assessed, but current laws and guidance document provide only general directions on such evaluations. Given the inherent complexities in environmental decision making, a structured framework is needed to guide the decision maker in a way that is transparent and repeatable. We propose applying the principles and tools of multicriteria decision analysis (MCDA) to the environmental regulatory permitting process. For individual permits, we have established a structured, multi-staged screening process that incorporates MCDA to guide regulators through the permitting process, including tools for identification of the least environmentally damaging practicable alternative (LEDPA) and for the Corps Public Interest Review. For general permits issued to states, we illustrate the application of formal decision analysis tools to enhance the current cumulative impact assessment process. Once again using an MCDA framework, we combine technical data collected in different units and qualitative expert judgment. A series of impact objectives are evaluated using criteria based on available data (i.e., GIS layers from state agencies). The relative importance of these criteria are set by assigning criteria weights and the impact scores for current and projected impacts are evaluated and compared to threshold values for the functional resource.

423 Geospatial Optimization of Complex Sediment Management Decisions M.E. Bates, US Army Corps of Engineers, Environmental Lab, Engineer Research and Development Center; A. Tkachuk, Decision Partners; I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center; M.J. Wiechmann, US Army Corps of Engineers, San Francisco District. The management and disposal of dredged materials is a complex process, with project goals of minimizing environmental risk, maximizing beneficial use, minimizing project costs and maximizing material throughput that often conflict. Through the use of optimization, GIS, and Decision Analysis, the redeveloped D2M2-J software platform is a management tool that brings transparency, flexibility, and mathematical rigor to an otherwise uncertain and subjective planning process. This approach will be especially useful in situations involving highly contaminated sediments or complex ecological interactions, and also allows users to transparently integrate stakeholder values in the decision process. The software effectively analyzes millions of combinations of dredging and placement sites to find optimal allocations of specific volumes of dredged material between sites. It optimizes management value under multiple constraints, including sediment type, dredging equipment, transportation paths, storage needs, material use, environmental concerns and other factors. The updated software will first be applied to dredged-materials management planning in the San Francisco Bay and Long Island Sound, and will be freely available for other uses. The project is currently underway with a scheduled release date in early 2012.

424 Use of Conceptual Site Models in Natural Resource Damage Assessments to Promote Natural Resource Service Restoration B. Goldsmith, Barbara J. Goldsmith & Company, Environmental Management and Consul; T. TBD, N/A. This presentation will describe how the decision analysis tool, Conceptual Site Models (CSM), and similar models can be used to further the objectives of the natural resource damage assessment (NRDA) process, namely to restore services provided to the public by a natural resource to its baseline through restoration, replacement or acquisition of the equivalent of the injured natural resource. Currently, there are two sets of federal regulations that provide an overall sequential framework for performing NRDAs; however, the regulations are optional and do not provide an opportunity to set priorities at a specific site, make key decisions at specific junctures of an assessment, address conflicts as they arise, and ultimately resolve claims sooner. Natural resource damage (NRD) claims may be brought to restore injured, destroyed or lost natural resources (land, fish, wildlife, biota, air, water, groundwater, drinking water supplies and resources) related to oil spills or hazardous waste releases. NRD is in addition to site remediation or "clean up" requirements in those instances where natural recovery and remediation do not restore injured natural resources to baseline. Requirements for NRD claims are defined under both federal and state laws. The presentation will present how a CSM may be utilized during various stages of an NRDA in order to set priorities, resolve conflict, address key issues and restore resource and ecosystem services. The presentation will identify possible uses of CSM in the NRDA and restoration context via case example. The presentation will focus on how a CSM can be used in the NRDA and identify restoration project alternatives, including discussion on how outcomes might differ with and without the structured use of a CSM.

425 Enhanced Adaptive Management: Using Decision Analytical Methods to Transparently Integrate Science, Expert Knowledge, Decisions, and Monitoring M. Convertino, Univ of Florida, Agricultural and Biological Engineering; M.E. Bates, US Army Corps of Engineers, Environmental Lab, Engineer Research and Development Center; J.T. Vogel II, C. Foran, US Army Corps of Engineers, Engineer Research and Development Center; J.M. Keisler, U Mass Boston, Management; A. LoSchiavo, US Army Corps of Engineers, Jacksonville District; I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center. Adaptive management has been increasingly acknowledged and implemented as a means to navigate project/program success in the face of uncertain future conditions, uncertain performance of alternative management plans, and increasing resource scarcity. Many prior applications of adaptive management, however, have been criticized for falling short of their full potential. We propose to supplement existing adaptive management efforts with a comprehensive decision-analytical approach that both guides initial selection of management alternatives and allows for adjustment based on the transparent integration of monitoring information and other factors in the value of information framework. We demonstrate a hypothetical adaptive management model for a land management case study inspired by restoration needs in the Florida Everglades. The results of the model show that certain assumptions, such as the cost associated with switching between management plans, have a major impact on optimal strategy selection. The process itself demonstrates that a decision model can link science, monitoring information, and management choices to help to shape monitoring plans and move adaptive management beyond "trial and error" and provide a robust framework to guide the selection management alternatives both initially and in the future.

427 NOAA's Climate Assessment and Proactive Response Initiative Puget Sound Pilot R. Neely, NOAA; M. Steinhoff, NOAA, Office of Response and Restoration; B. Shorr, A. Dvarskas, M. Baker, NOAA; A. Merten, NOAA, Coastal Response Research Center; A. Jones, D. Hudgens, N. Etre, K. Glodzik, Industrial Economics; Z. Nixon, A. Bejarano, Research Planning, Inc. The mission of NOAA's Damage Assessment, Remediation and Restoration Program (DARRP) is to protect and restore coastal and marine resources threatened or injured by oil spills and releases of hazardous substances. Hazardous waste facilities and oil infrastructure in coastal areas may be more vulnerable to releases due to climate related impacts. In response, DARRP developed the Climate Assessment and Proactive Response Initiative (CAPRI) to provide a framework and tool to evaluate potential contaminant impacts in the coastal zone related to climate change. CAPRI's flexible GIS-based framework incorporates an assessment of regionalized climate change forecasts, contaminant threats, and ecosystem and species values and sensitivities into a screening level vulnerability index. The CAPRI framework encompasses four major components: assessment of climate change impacts and related contaminant threats; development of a spatial vulnerability index; use of the web-based, open source Environmental Response Management Application (ERMA) for visualization and analysis of data layers and results; and identification of efficient prevention, response,

and restoration options. Selected sites within the Puget Sound are the initial testing ground for the CAPRI framework. This pilot incorporates Puget Sound area-specific datasets. The CAPRI framework is intended to provide a national model that can be adapted to the unique data available in a particular region or coastal area. CAPRI will enable NOAA and other local, state, regional, and federal decision makers to better prepare for and adapt to climate change by improving understanding of contaminant impacts to coastal resources.

428 Synthetic Biology and Environmental Risks: Evaluation Using Integrated Risk Assessment, Life Cycle Assessment and Multi-Criteria Decision Analysis A. Bockelie, MIT; E. Chu, Carnegie Mellon Univ; I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center. Synthetic biology is a rapidly expanding field that has the potential to provide wide-ranging and unprecedented benefits in fields such as bioremediation to new pharmaceutical development methods. However, synthetic biology's relatively new and emergent nature creates an environment where the risks and possible effects of synthesized organisms and components are widely unknown and its current risk governance may be insufficient to properly evaluate the field's inherent risks. Additionally, the environmental behavior of synthetic biological organisms and components is unknown. If released, they may exchange genetic material across species and contaminate wild organisms. There is also the distinct possibility that the same technology in synthetic biology used to produce a vaccine could easily be used to engineer a new and deadly virus. Materials required to foster synthetic biology are becoming cheaper and more readily available to the point that virtually anyone may soon be able to create agents of biological warfare. Additionally, as synthetic biology deals with the possible creation of life, there will be ethical and social factors to consider. Governments and policy makers will be required to make informed decisions regarding tradeoffs between potential risks and benefits. Even though a traditional regulatory risk assessment framework may be applicable to synthetic biology, the lack of knowledge and significant data uncertainty will make it difficult to implement. Integrated with risk analysis and life cycle assessment, a multi-criteria decision analysis (MCDA) approach could be useful to screen an analysis of risks associated with different technologies relating to synthetic biology. The proposed framework uses LCA and RA to evaluate and assess the different risks associated with synthetic biology, including biosafety and biosecurity, at different lifecycle stages. MCDA is used to compare the risks and benefits of different technologies, products, or processes. Through the results of this model, decision makers can make informed decisions with respect to synthetic biology policy via a full understanding of the risks currently facing the field. As this framework has already been tested in an equally emergent yet uncertain field in nanotechnology, it could be useful for the emerging field of synthetic biology.

429 Towards Sustainable Management of Contaminated Sediment – An Integrated Approach Based on Stochastic Multi-criteria Outranking Methods M. Sparrevik, Norwegian Geotechnical Institute; M. Bates, I. Linkov, US Army Engineer Research and Development Center. Sediment contamination in a river basin or urban coastal area is often related to a complex combination of contributing sources. Contamination may have a local source, from effluent releases from present or former industrial sites, or non-local source like diffuse urban run-off or long-range pollutant transport. The sediments often act as a sink, accumulating contamination from all sources, thus making it likely to find elevated levels of contamination across large geographical areas. Large sediment volumes therefore need to be considered in remedial operations. Sustainable management of contaminated sediments will have to balance cost, environmental considerations and potentially conflicting social interests. The decision methods supporting management will therefore require use of multiple methodologies to be conclusive. The integration of these diverse decision criteria may be achieved by combining multiple analytical approaches like risk analysis (RA), life cycle analysis (LCA), multi criteria analysis (MCA) and socio-economic evaluations in an integrative framework. We propose use of stochastic multi-criteria decision analysis (MCDA) using PROMETHEE II outranking method. In the paper we have used MCDA to select the preferable magnitude of a clean material sediment capping operation for the dibenzo-*p*-dioxins and -furans (PCDD/Fs) contaminated Grenland fjord in Norway. In the analysis, positive utility for health-risk reduction and socio-economic benefit from removing the seafood bans has been evaluated against negative utility from project cost and life-cycle environmental impact. A value-plural based weighing of criteria is compared to criteria weights mimicking a traditional cost effectiveness (CE) and cost benefit (CB) analysis. Use of this methodology may serve as a flexible framework for decision support in future cases and can be a step towards more sustainable decisions for the management of contaminated sediments and in other related areas.

430 Impacts of Pharmaceuticals and Personal Care Products in the Environment: What Are the Big Questions? A. Boxall, Univ of York, Environment Dept; J. Staveley, Exponent; D.J. Caldwell, Johnson & Johnson; K. Choi, Seoul National Univ, School of Public Health, Seoul National Univ, Dept of Environ. Health; T. Verslycke, Gradient; S. Hickmann, German Federal Environment Agency (UBA), Pharmaceuticals Dept; K. Ostapyk, L. Innes, Health Canada; B.W. Brooks, Baylor Univ, Environmental Science and Biomedical Studies, Baylor Univ, Dept of Environmental Science; M. Rudd, Univ of York, Environment Dept. Over the past 10-15 years, a significant amount of work has been investeddone by the scientific, regulatory and business communities into the effects and risks of pharmaceuticals and personal care products (PPCPs) in the environment. It is now timely to review the current knowledge and to identify the key issues regarding the impacts of PPCPs in the environment so that future resources can be focused on the most important areas. This presentation describes a 20 Question Exercise that was initiated by the SETAC Pharmaceutical Advisory Group to identify the big issues that we need to address in order to better understand and manage the effects of PPCPs in the environment. In the first phase of the exercise, questions were solicited from the academic, government and business communities around the globe. A total of 403 questions were submitted which were then reviewed to remove questions outside the scope of the exercise and redundant questions, giving a final list of 101 questions. In second phase of the exercise, the 101 questions were discussed at a 2 d workshop involving academics, governmental/regulatory organisations and the business sector from N. America, Europe, Asia and Latin America and a top 20 list was developed. The top 20 questions fell into a number of broad categories, namely: a) more intelligent assessment of PPCPs; b) areas where our understanding of exposure and effects of PPCPs is less well developed; c) issues around antibiotic resistance and its control; d) risk management issues; and d) general issues, that are equally relevant to other classes of environmental contaminants. It is hoped that the conclusions from this prioritisation exercise will be used as a basis to focus future work on the risks of PPCPs in the natural environment.

431 Response of Fathead Minnow (*Pimephales promelas*) Populations to an Estrogen Used in Human Birth Control A. Schwindt, Colorado State Univ, Fish, Wildlife, and Conservation Biology; D. Winkelman, USGS and Colorado State Univ, Colorado Cooperative Fish and Wildlife Research Unit. Fishes in streams receiving effluent from waste water treatment plants are subjected to chemical stressors that can affect normal reproductive function. Synthetic estrogens represent one component of this effluent which can disrupt reproduction. Cellular and physiological effects are well known but little is known about potential population level consequences of reproductive disruption. We evaluated the effects of 17alpha-ethinylestradiol (EE2), the synthetic estrogen in human birth control, on fathead minnow (*Pimephales promelas*) populations. We constructed 25, 1100L aquatic mesocosms at the Colorado State Univ Foothills Fisheries Laboratory and 10 male and 10 female fish were introduced to each mesocosm. The randomized and replicated treatments consisted of EE2 concentrations ranging from 0, 2.5, 5, 10, and 20ng/L for 105 days with 5 mesocosms per treatment. Fish were allowed to behave naturally during the experiment. Adult survivorship, egg production, numbers and size of offspring, and biomarkers of estrogen exposure were collected during the experiment and used to parameterize stage-structured population models. Modeling results and physiological changes indicated that fish populations can be negatively impacted by environmentally relevant EE2 concentrations.

432 Assessment of Estrogenic and CYP1A1-inducing Compounds in the Assabet River Basin K. Auger, Umass Amherst, Veterinary and Animal Sciences; K. Arcaro, Umass Amherst; S. Flint, A. Field-Juma, OARS; M. Zimmerman, J. Colman, USGS. The Assabet River located in eastern Massachusetts receives treated wastewater discharges from four major municipal wastewater treatment plants: Westborough, Marlborough, Hudson and Maynard. In periods of low flow, up to 95% of the Assabet River is wastewater effluent and return flow from septic systems. Chemical analyses have

shown that municipal wastewaters can contain estrogenic and CYP1A1-inducing compounds. Estrogenic compounds such as the natural estrogen 17b-estradiol, the synthetic estrogen 17a-ethynylestradiol, and the industrial compound nonylphenol can cause feminization in male fish through the induction of vitellogenin (VTG). CYP1A1-inducing compounds such as the polycyclic aromatic hydrocarbons and polybrominated diphenyl ethers can produce both overt toxicity and alter reproductive function through the metabolism of natural estrogens. The purpose of the present research is to assess the estrogenic and CYP1A1-inducing compounds in the Assabet River. We use both a bioassay that measures the induction of VTG and Cyp1A1 in male Japanese Medaka (*Oryzias latipes*) as well as analytical chemistry to measure the levels of selected compounds. In the summer of 2010 water samples were collected from five locations along the Assabet River and its tributaries. Male Medaka were exposed to each of the five water samples. VTG and Cyp1A1 induction were measured using quantitative RT-PCR. Concurrently collected samples were analyzed for more than 80 compounds associated with human activity including several estrogenic EDCs and CYP1A1-inducing compounds. The bioassay and chemical analysis of limited samples from season one reveal no statistically significant levels of estrogenic or CYP1A1-inducing compounds associated with stream reaches dominated by treated municipal wastewater or tributaries dominated by septic system return flow.

433 Impact of Changes in pH on the Uptake of Pharmaceuticals and Personal Care Products into Invertebrates M. Karlsson, Univ of York, Environment, Univ of York, Environment Dept, Central Science Laboratory, Central Science Laboratory; S. Marshall, Unilever; A. Boxall, Univ of York, Environment Dept. Following release to aquatic systems, Pharmaceuticals and Personal Care Products may associate with the sediment compartment where they may be taken up by benthic organisms. In order to establish the risks of PPCPs to benthic organisms, it is important to understand the uptake of the compounds from sediment into organisms and the effects of environmental conditions on uptake. Recent work in our laboratory has shown that the main uptake route for PPCPs into a sediment dwelling oligochaete is via the water and that uptake can be estimated based on predicted sediment pore water concentrations and bioconcentration factors from water-only studies. In this study, we extended this work to consider the effects of environmental properties (i.e., pH) on uptake of PPCPs from sediment. Uptake and depuration studies were performed for diclofenac, fluoxetine, triclosan and caffeine. The first three compounds are partly ionised at environmentally relevant pH values whereas caffeine is a neutral molecule and acted as a reference chemical in the studies. The studies were performed at pH values of 5.5, 7 and 8.5 and involved an uptake phase of 48 hours followed by a depuration phase of 48 hours. Radiolabelled chemicals were used to lower the limit of detection. The uptake and depuration rates were modelled using a two compartment model. Uptake and depuration rates were then used to calculate bioconcentration factors for the study compounds at the different pH values. Results show that bioconcentration factors can range from a log BCF of 1.0 (pH 8.5) to 5.7 (pH 5.5) for the acidic pharmaceutical diclofenac and Log BCF values for the basic pharmaceutical fluoxetine ranged 4.4 (pH 5.5) to 5.7 (pH 8.5). Changes in pH had no effect on the uptake of triclosan or caffeine. Results for diclofenac, fluoxetine and caffeine can be explained by the underlying chemistry of the study compounds. However, the observations for triclosan (an acidic compound) were not as expected. The data highlight the importance of considering the effects of pH on the uptake (and toxicity) of PPCPs in aquatic organisms. Our work is ongoing to develop modelling approaches for better predicting uptake of PPCPs from sediments under different environmental conditions.

434 Effects of Antibiotics on the Structure and Function of Planktonic and Attached Microbial Communities from an Effluent Dominated Prairie Stream M.J. Waiser, J.R. Lawrence, V. Tumber, Water Science and Technology Directorate, Environment Canada, Water Science and Technology Directorate; G. Swerhone, Water Sciences and Technology Directorate, Environment Canada; J. Roy, Water Science and Technology Directorate, Environment Canada. Recent worldwide surveys have established the ubiquitous presence of pharmaceuticals in surface waters receiving treated sewage effluent. Systems where such effluent dominates flow may be at the high est risk for ecosystem level changes. Regina, Saskatchewan, Canada (population 190,400) treats its sewage at a modern tertiary sewage treatment facility on Wascana Creek. In winter, treated sewage effluent makes up almost 100% of stream flow. Hazard quotients calculated using existing ambient antibiotic concentrations indicated that erythromycin (ER) and trimethoprim (TR) could present a risk to aquatic organisms. Laboratory microcosm and mesocosm experiments were subsequently, conducted to establish effects of ER, TR and clindamycin (CL) on creek planktonic and attached (biofilm) microbial communities. For planktonic communities, microcosm experiments indicated that bacterial numbers (using DAPI and epifluorescent microscope counts) and production (^{3}H thymidine incorporation) were significantly less than controls, especially in the ER treatments. Measures of algal biomass (Chl *a*), however, were not greatly affected. Confocal laser microscopy of biofilms grown in rotating annular reactors and exposed to varying single and mixtures antibiotic concentrations, singly and as mixtures indicated that biofilm thickness, bacterial biomass and exopolymer composition were significantly different in treated as compared to control biofilms, especially in the ER treatments. DGGE analyses on all biofilms were conducted and then data compared by principal component analysis (PCA). Results indicated that treatments TR and ER were significantly different in terms of bacterial diversity when compared to the control. Of these two, ER showed the greatest effect with its microbial community diversity grouping away from both the control and all other treatments. Results from these studies clearly indicate that antibiotics have effects on microbial community structure and function at environmentally relevant concentrations.

435 The Fate and Effects of Triclocarban in the Aquatic Environment C.D. Metcalfe, Trent Univ, Environmental & Resource Studies, Trent Univ, Dept of Environmental & Resource Studies; B. McIlwain, Trent Univ; T. Metcalfe, Trent Univ, ERS. Triclocarban (TCC) is an antimicrobial compound that is widely used in hard antibacterial soaps in amounts that are typically in the range of 2% by weight. The primary source of these compounds in the aquatic environment is the release of treated wastewater from municipal wastewater treatment plants (WWTPs). While there has been a considerable amount of research and regulatory focus on the ecological risks of the antimicrobial compound, triclosan, there has been relatively little scrutiny of the potential risks associated with the release of TCC. In our analysis of wastewater from several WWTPs in Ontario, Canada, up to 6.5 µg/L of TCC were detected in untreated wastewater, but concentrations typically declined to < 1 µg/L in treated wastewater. By deploying semi-permeable membrane devices (SPMDs) as passive samplers in surface waters in Ontario, Canada, we estimated the time weighted average concentrations of TCC in water to be as high as 0.5 µg/L. In early life stage toxicity tests with the Japanese medaka (*Oryzias latipes*) from egg fertilization to exogenous feeding of the fry (i.e., 19 d), mortalities occurred at a nominal LOEC of 500 µg/L and the nominal NOEC was 100 µg/L. In partial life cycle tests with Japanese medaka exposed to nominal TCC concentrations of 10, 30 and 100 µg/L from hatch to sexual maturity, with solution renewal every 72 h, there was a marked reduction in the production of viable eggs per female in all treatments when exposed males were mated with exposed females. Average measured TCC concentrations in the test vessels over the 72 h renewal period were about 40% of nominal. There was also evidence of masculinisation of female medaka, as indicated by the appearance of some male secondary sex characteristics. These data support an in vitro study that indicated that TCC disrupts the androgen endocrine system through an as yet unknown mechanism. Overall, these data indicate that chronic exposure of aquatic organisms to low ppb concentrations of TCC in surface waters that are impacted by discharges of municipal wastewater may cause sublethal effects, including altered development and reproductive capacity.

436 Patterns of Removal of PPCPs from Wastewater Treatment and Their Fate in Lake Michigan: Choosing Model Chemicals for Monitoring B.D. Blair, Univ of Wisconsin-Milwaukee, School of Freshwater Sciences; J. Crago, Univ of Wisconsin-Milwaukee, Dept of Biology; C. Hedman, Univ of Wisconsin-Madison, State Laboratory of Hygiene; C. Magruder, Milwaukee Metropolitan Sewer District; S. Royer, Veolia Water Milwaukee; R. Treguer, Veolia Water North America; R. Klaper, Univ of Wisconsin-Milwaukee, School of Freshwater Sciences. Pharmaceutical and Personal Care Products (PPCPs) have been recorded in wastewater effluent worldwide and the environmental impact of many of these PPCPs is unknown. Wastewater processes have not been optimized to remove influent PPCPs and increasing the predictability of which PPCP compounds need monitoring is necessary. The purpose of our experiment was to monitor the total concentrations at each stage of treatment, determine which compounds behave similarly and could be used to predict the behavior of other compounds in the wastewater treatment process, and determine the retention

and transport in Lake Michigan. PPCP and hormone concentration levels were determined for 48 compounds. Wastewater samples were collected on six different dates over a two-year period (Spring 2009 – Fall 2010) at South Shore Water Reclamation Facility (Wastewater Treatment Plant) in Milwaukee, WI. Wastewater samples were collected as raw influent, primary effluent, secondary effluent and final effluent, and the analysis was conducted using the Environment Protection Agency methods 1694 and 1698. Additionally, the fate and transport of these compounds was assessed by collecting samples at eight locations in Lake Michigan with varying proximities to the effluent discharge site. Final effluent concentrations were highest for metformin, naproxen, caffeine, sulfamethoxazole, and gemfibrozil. These compounds also had notable concentrations in Lake Michigan, up to two miles from the discharge site. Many compounds had large removal efficiencies in the wastewater treatment process. For example, the total removal of acetaminophen, caffeine, naproxen, triclocarban, and triclosan was >90%, with the majority removed by the secondary treatment process. Many compounds, such as metformin, had limited removal rates where the average raw influent and average final effluent were nearly identical. In this presentation, we will discuss the behavior of chemicals based on their properties and removal at each stage of the wastewater treatment process and discuss the fate of specific compounds in Lake Michigan.

437 Mixtures of Pharmaceuticals in Surface Waters: Assessing Risks to Humans K. Solomon, Univ of Guelph, School of Environmental Sciences, Univ of Guelph, Centre for Toxicology, School of Environmental Sciences. Pharmaceuticals normally have significant databases designed to evaluate possible adverse effects in humans and animals from intended and expected exposures. Even so, many individual products do not have officially determined values for acceptable daily intake (ADI) or Reference Dose (RfD). This study evaluated the potential utility of applying various approaches in a Tier 0 to Tier 1 assessment to prioritize the need for further evaluation of a mixture of residues of pharmaceuticals. The method used a Hazard Index (HI) based on the assumption of potency additivity to characterize the risk of mixtures of pharmaceuticals. This study used the Cramer classes, which have been used to define three potency bins for non-cancer endpoints in the threshold of concentration (TTC) approach. Additional evaluations of mixtures of pharmaceutical were conducted using a variety of approaches to assess the usefulness of other techniques for conducting a conservative screening. The results showed that the TTC approach based on Cramer classes was not conservative enough to use as an initial tier in the assessment of mixtures of pharmaceuticals. Use of ADIs based on the therapeutic dose divided by an uncertainty factor of 1000 to 10,000gave HIs > 1 for maximum concentrations of pharmaceuticals reported in surface waters. When applied to reported concentrations of pharmaceuticals in drinking water, the HI was < 1, suggesting low risk. Treatment of drinking water probably resulted in reductions in exposures that further reduced risks from exposures to mixtures. Probabilistic assessment of mixtures of antibiotics measured in surface waters over time and space provided a worst case site- and day-specific HI of 0.07, suggesting negligible risk from exposures, even in the absence of any removal during treatment. The implications of these assessments will be discussed. The author acknowledges the contributions of the ILSI HESI committee on risk assessment of mixtures for their input to this case assessment which was prepared for a WHO-OECD workshop.

438 An Evaluation of the Relationship Between DDT in Indoor Settled Dust and DDT in Outdoor Air D. Langseth, Gradient; N. Grasso, J. Chandalia, Gradient, 29 Wachusett Drive. Due to extensive use and slow degradation rate, dichlorodiphenyltrichloroethane (DDT) and/or its metabolites dichlorodiphenyldichloroethylene (DDD) and dichlorodiphenyldichloroethane (DDE) (collectively DDTr) are nearly ubiquitous in environmental media throughout the world. Among the media in which DDTr has been detected are outdoor air and indoor settled dust. Substantial data for each of these media have been developed. The relationship between DDTr in soils and overlying air has been studied, but we are not aware that the relationship between outdoor air and indoor settled dust concentrations has been evaluated for DDTr. Such relationships have been developed for other substances, notably lead, using both empirical and mechanistic models. There is a substantial body of data on both indoor settled dust concentrations and outdoor air concentrations, but no studies of which we are aware that measured both at the same time in the same vicinity. Further, the lack of construction and activity data for individual homes in which indoor settle dust DDTr concentrations have been measured and lack of longitudinal data for ambient air and houses in a given location severely restricts the extent to which mechanistic indoor/outdoor exchange models can be applied. Evaluation of the available data in the general framework of such mechanistic models is nevertheless instructive and suggests that a substantial portion of the DDTr found in indoor dust may be associated with DDTr in the ambient outdoor air. Other likely sources to indoor settled dust include indoor reservoirs of DDTr related to historic indoor use and drift from historic outdoor applications. Track-in from outdoor soils may in some circumstances provide historic or continuing contributions.

439 Large Volatilization Losses of PAHs Soon After Application of Coal-Tar-Based Pavement Sealant P. Van Metre, US Geological Survey; B. Mahler, US Geological Survey, Water Resources Discipline; M.S. Majewski, US Geological Survey; W.T. Foreman, US Geological Survey, National Water Quality Laboratory; C. Braun, J. Wilson, T. Burbank, US Geological Survey. Widespread application of coal-tar-based pavement sealants in the United States has been linked to polycyclic aromatic hydrocarbon (PAH) contamination of urban streams, lakes, soils, and indoor dust. To test whether the sealants also are a source of PAHs to air, we measured PAH concentrations in air at two heights (0.03 and 1.28 m) over a sealed pavement surface during 1 year, beginning 2 hours after sealant application in September 2009 and then at increasing time intervals (9 samples total). Air concentrations and wind speed were used to estimate volatilization fluxes. For comparison, we also measured PAHs losses from the adhered sealant, assuming losses were dominantly to the atmosphere, by measuring PAH concentrations in dried sealant and in sealant scraped from the pavement surface coincident with each air sampling. PAH concentrations initially were very high: the sum of eight PAH frequently detected in air ($T\text{-}PAH_8$) was 297,000 ng/m^3 in the surface air layer (0.03-m height) 2 hours after application and $T\text{-}PAH_8$ was 26,000 mg/kg in the sealant product. After 5 days, $T\text{-}PAH_8$ in the surface air layer had decreased to 84,200 ng/m^3 and had decreased to 11,000 mg/kg in a sample of sealant scraped from the pavement. Concentrations in both media and the estimated flux to air decreased logarithmically during the first month after application. Concentrations in the surface air layer continued to decrease reaching a wintertime low of 301 ng/m^3, before increasing the following summer to 13,200 ng/m^3. Using a logarithmic function with an approximate correction for diurnal changes, the total flux of $T\text{-}PAH_8$ was estimated for the initial 14 days after application at about 2.4 g/m^2. The estimated volatilization loss over this time period based on the scraping samples was about 2 times greater than the total flux estimated from the air measurements, reasonable agreement given the uncertainties in the two approaches. These results indicate that large volatilization losses occur during and soon after application of coal-tar-based pavement sealants. Combining an estimate of national annual coal-tar-based sealant use and that of PAH losses to air in the first 14 days after application from this study indicates that PAH emissions from sealants might be of the same order of magnitude as vehicle emissions of PAHs in the United States.

440 Occurrence and Distribution Patterns of Synthetic Musk Compounds in Ambient Air from Korea S. Oh, U. Kim, Pusan National Univ; T. Jung, Busan Metropolitan City Institute of Health and Environment; J. Oh, Pusan National Univ, Environmental Engineering. Synthetic musk compounds (SMCs) have been used to make a fragrance in various types of personel care products (e.g., deodrant, shampoo, cosmetic and others) as a fragrance susbstitue for natural musk. There are two types of SMCs [i.e., nitro musk (e.g., musk ketone and musk xylene) and polycyclic musk (e.g., HHCB and AHTN taking up 90% of produced SMCs)]. As the increase of widespread usage, some SMCs have been regulated and monitored as emerging persistent organic pollutants in European Union due to their persistency, bio-accumulation and the possibilty of toxicity effect on human and environment. In various media, SMCs have been detected on the order of a few ng/m^3 down topg/m^3 levels in environment and especially, some of reserchers have been reported at the levels of 1 to 5 ng/m^3 in ambient air (HHCB and AHTN in gas phase). Morever,even remote regionlikein the lake of the Alps, the trace levels of SMCs contamination has been detected. However, there are no proper data about SMCs occurrence in ambient air in Korea. Therefore, the objective of this paper is to investigate the occurrence and the fate of SMCs in Korean ambient air.High volume samplers (SIBATA, HV-1000) were used to collect gas and particle phase of SMCs with PUF (polyurethane foam) and GFF (glass fiber filter), respectively, from five different sampling sites in Busan, Korea. GC/EI-MS was used to analyze SMCs in air samples with selected ion monitoring mode. The target SMCs

are six polycyclic musk compounds(HHCB, AHTN, AHDI, AHMI, ATII and DPMI) and nitro musk compounds (musk xylene). 3 PMCs(HHCB, AHTN, DPMI) and musk xylene were detected in all samples. HHCB concentrations ranged from 3.43 to 801.58 pg/m^3 and AHTN concentration was from 3.38 to 195.38 pg/m^3. MX and DPMI were observedfrom 8.61 to277.13 pg/m^3; and 10.51 to 27.51 pg/m^3, respectively. Other compounds (ATII, ADBI and AHDI) weredetected below 10% of the total SMCs load. The detailed discussion about SMCs' distribution pattern between gas and particulate phase and seasonal variation of SMCs concentration will be presented in the conference.

441 Deposition and Accumulation of Airborne Organic Contaminants in Yosemite National Park, California D. Alvarez, US Geological Survey, USGS Columbia Environmental Research Center; M.A. Mast, USGS Colorado Water Science Center; S. Zaugg, US Geological Survey, Methods Research and Development Group, National Water Quality Laboratory; W. Cranor, USGS Columbia Environmental Research Center; H. Forrester, National Park Service, Yosemite National Park. Deposition and accumulation of airborne organic contaminants in Yosemite National Park were examined by sampling wet deposition (snow and rain), lichen, and lake sediment at different elevations in the park during 2008-2009. In 2009, the semipermeable membrane device (SPMD) passive samplers were deployed in ten high-elevation lakes to estimate surface-water concentrations. Frequently detected compounds included the current-use pesticides endosulfan, dacthal, and chlorpyrifos and the legacy pesticides DDD/DDE, chlordane, HCB, dieldrin, and PCBs. Snowpack concentrations were fairly uniform and showed little variation with elevation. Temporal variation in rain concentrations of endosulfan appeared to coincide with application rates in the San Joaquin Valley. More than 70% of annual pesticide inputs from wet deposition occurred during winter largely because most precipitation at high elevations falls as snow. Lichen concentrations showed positive gradients with elevation for some compounds indicating cold condensation may be an important control on pesticide accumulation particularly endosulfan and chlordane. The opposite pattern in lichens was found for chlorpyrifos likely reflecting high application rates of this pesticide in nearby agricultural areas. Sediment concentrations were inversely correlated with elevation partly due to organic carbon content of sediments but also perhaps greater mobility of organic contaminants at lower elevations. Surface-water concentrations inferred from passive samplers were at sub part per trillion concentrations indicating minimal exposure to aquatic organisms from the water column. Sediment concentrations generally were low except for DDD in Tenaya Lake, which exceeded sediment guidelines for protection of benthic organisms.

442 Trends of Current Use Pesticides (CUPs) in Canadian Arctic Air and Water: 1999-2010 A. Gawor, Univ of Toronto, Dept of Chemistry; F. Wania, Univ of Toronto Scarborough, Dept of Physical & Enviro. Science, Univ of Toronto at Scarborough, Dept of Physical & Enviro. Science; L.M. Jantunen, T.F. Bidleman, Environment Canada; F. Wong, Univ of Toronto, Chemistry; G. Stern, Freshwater Institute, Dept of Fisheries and Oceans; H. Kylin, Swedish Univ of Agricultural Sciences, Aquatic Sciences and Assessment; P.A. Helm, Ontario Ministry of the Environment, Environmental Monitoring and Reporting Branch. Since the ban on organochlorine pesticides (OCPs), the use of other forms of insecticides, fungicides and herbicides, otherwise known as current use pesticides (CUPs), have increased. CUPs are generally less persistent than the older style OCPs, however, some can still undergo atmospheric transport. Transport of pesticides from agricultural fields to non-target areas is of great interest because their occurrence in remote regions is recognized as evidence for long-range transport under international protocols, which were implemented to control persistent, bioaccumulative, and toxic substances. Some CUPs ultimately make their way to the Canadian Arctic, where they were detected in air, water, ice, and biotic species. Due to colder conditions, they persist in the environment for longer periods of time. CUPs that were detected in Arctic air and water include: dacthal, chlorpyrifos, endosulfan-I, trifluralin, chlorothalonil and pentachlorothioanisole. All of these CUPs are still in use in Canada, although dacthal has very limited usage. Temporal and spatial trends for these contaminants are essential to understand the effect that CUPs will have on the environment; especially since the diminishing Arctic sea-ice due to warming temperatures may change the mobility of the chemicals in the environment. Air and water samples were collected as part of Tundra Northwest-99, the International Polar Year 2007-2008 and ArcticNet-2010 to determine the occurrence and levels of CUPs over time. Results have shown that for some CUPs, specificially endosulfan and chlorothalonil, concentrations have increased in the Arctic water between 1999-2010, whereas CUPs like dacthal, concentrations have remained relatively constant.

443 Persistent Organic Pollutants in the Atlantic and Southern Oceans and Oceanic Atmosphere J. Luek, R.M. Dickhut, Virginia Institute of Marine Science; R. Falconer, Chatham Univ, Chatham College, Dept of Chemistry; M. Cochran, Virginia Institute of Marine Science; H. Kylin, Swedish Univ of Agricultural Sciences, Aquatic Sciences and Assessment. Persistent organic pollutants (POPs) are toxic chemicals that bioaccumulate and biomagnify in organisms, and many POPs undergo atmospheric transport to remote areas. The Atlantic Ocean and the Western Antarctic Ice sheet may be sinks for currently used agricultural and industrial organohalogen compounds, while these regions may be sources for POPs that have been severely restricted and banned. Air and seawater samples were collected aboard the Swedish Icebreaker Oden as it traveled from Goteberg, Sweden to McMurdo Station, Antarctica during Oct. – Dec. 2007. These samples were analyzed for POPs to examine the current global distribution of POPs in the marine waters and atmosphere. Both air and surface seawater samples consistently contained α-hexachlorocyclohexane (α-HCH), g-HCH, and hexachlorobenzene (HCB), while air samples additionally contained several polychlorinated biphenyls (PCBs) and a-Endosulfan. Sample concentrations for most compounds in air were significantly higher in the northern hemisphere ($p < 0.01$), with the exception of HCB, which had high concentrations in the northern and southern latitudes and low concentrations near the equator. Air and seawater concentrations of a- and g-HCH were compared to determine the net flux of these pollutants between the air and seawater, and with the exception of α-HCH in the northern most waters of the Atlantic, Atlantic and Southern Ocean waters were found to be a sink for both a- and g-HCH.

444 Pesticides in Rain in the Mississippi River Valley: A Comparison Between 1995 and 2007 M.S. Majewski, S.J. Kalkhoff, R.H. Coupe, P.D. Capel, US Geological Survey; W.T. Foreman, US Geological Survey, National Water Quality Laboratory. Weekly composite rainfall samples were collected during the 1995 and 2007 growing seasons at two agricultural locations in both Iowa and Mississippi, and analyzed for 47 pesticides and transformation products (TPs) in 1995, and 76 in 2007. Thirty two analytes were detected at least once in one or both years; 11 analytes were detected both years. Herbicides were the predominant type of pesticide detected in both years and states. In Iowa, 15 herbicides, 7 insecticides, and 2 TPs were detected in 1995 with total flux of 445 μg/m^2/season. Nine pesticides detected in 50% or more of the samples accounted for 94% of the deposited mass. In 2007, 8 herbicides, 3 insecticides, 2 fungicides, and 4 TPs were detected with a total flux of 186 μg/m^2/season. Six pesticides detected in 50% or more of the samples accounted for 86% of the flux. Acetochlor, alachlor, atrazine, CIAT (an atrazine TP), DCPA, and chlorpyrifos were among the top 10 most frequently detected compounds in both years. In Mississippi, 16 herbicides, 9 insecticides, and 1 TP were detected in 1995 with a total flux of 1981 μg/m^2/season, but methyl parathion accounted for 90% of this flux. Nine pesticides that were detected in 50% or more of the samples accounted for 98% (83% not including methyl parathion) of the deposited mass. In 2007, 11 herbicides, 6 insecticides, 2 fungicides, and 6 TPs were detected with a total flux of 436 μg/m^2/season. Five pesticides detected in 50% or more of the samples accounted for 54% of the flux. Atrazine, metolachlor, and propanil were among the top 5 compounds detected in rain in both years in Mississippi. The amount, timing, and frequency of rainfall play a critical role in when and which pesticides are detected, their concentrations, and their seasonal flux. During the spring when most herbicides are applied, rain events in Iowa were more frequent in 1995 than in 2007. This was reflected by higher detection frequencies, mean concentrations, and total flux in 1995. In Mississippi, rain events occurred more uniformly throughout the growing season in both years, yet the total pesticide flux increased from 1995 to 2007 while the number of compounds detected at greater than 50% decreased by about a half. Much of the increased 2007 deposition amount is attributed to the considerable increase in use of atrazine and glyphosate and the number of compounds detected below 50% frequency that contributed significantly to the total flux, 7 in 2007 versus 2 in 1995.

445 Comparison of the Atmospheric Occurrence and Deposition of Glyphosate and Conventional Herbicides in Two Agricultural Areas of the United States P. Capel, US Geological Survey; F. Chang, Clarkson Univ; M. Simcik, Univ of Minnesota; M. Majewski, W. Foreman, S. Kalkhoff, R. Coupe, US Geological Survey. The use of herbicides to combat weeds is an important practice in modern agriculture. During the 1990s, crops which were genetically-modified (GM) to tolerate the effects of a specific herbicide, most commonly glyphosate, were introduced and widely accepted. In 2007, glyphosate-tolerant GM-soybeans, cotton and corn comprised 95, 80 and 59 percent of these crops, respectively. The widespread adoption of herbicide-tolerant GM crops has caused a major shift away from the use of conventional pre-emergent herbicides (triazines, acetanilides, etc.) towards glyphosate. During the 2007 growing season, the air and rain at agricultural sites in Iowa and Mississippi were monitored for 23 herbicides, including glyphosate. Glyphosate, a relatively non-volatile compound, enters the atmosphere primarily through application spray drift and wind erosion. In Iowa, the median glyphosate concentration in rain (0.20 mg/L) was 10 to 100 times greater than the median concentrations of metolachlor, acetochlor and atrazine, although their detection frequencies were similar (65, 76, 71 and 59% percent for glyphosate, metolachlor, acetochlor and atrazine, respectively). The results were similar at the site in Mississippi where median glyphosate concentration in rain was 0.25 mg/L, about 10 to 100 times greater than the median concentrations of atrazine, metolachlor, and propanil. In air, glyphosate was detected less frequently (61 and 86% in Iowa and Mississippi) than the most common conventional herbicides such as atrazine, trifluralin and metolachlor, but at similar median concentrations. Wet deposition of glyphosate during the growing season was calculated to be 50 and 130 $\mu g/m^2$ compared to 90 and 104 $\mu g/m^2$ for the sum of the other 22 targeted conventional herbicides in Iowa and Mississippi, respectively. Thus, although it is non-volatile, the atmospheric occurrence, concentration, and depositional fluxes of glyphosate are similar to or greater than the more volatile conventional herbicides due to the sheer magnitude of its use.

446 Evolving Role of Passive Samplers in Whole Sediment Toxicity Identification Evaluations R.M. Burgess, USEPA, Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, USEPA, USEPA; M.M. Perron, Brown Univ; K.T. Ho, M.G. Cantwell, USEPA, Atlantic Ecology Division. In Phase I of whole sediment TIEs, causes of toxicity to freshwater and marine organisms are characterized into broad toxicant classes including ammonia, metals and organic chemicals. In Phase II of the TIE, the specific toxicants causing observed toxicity are identified. For ammonia and metals, this process is often not complex because of the limited number of metals likely to cause toxic effects and because ammonia toxicity is well understood. In contrast, identifying the specific organic chemicals causing toxicity is very challenging because of the thousands of chemicals that may be present and contributing to adverse effects. In effects directed assay (EDA) as developed in Europe, a major focus is on the identification of toxic organic chemicals using sophisticated extraction, fractionation and analytical methods often with cellular endpoints in artificial media. In the TIE approach developed in North America, the emphasis has been on exposing whole organisms in systems emulating environmental conditions including contaminant bioavailability. A consequence of the TIE strategy has been limited development of sophisticated identification methods for organic chemicals. Given that most Phase I whole sediment TIEs indicate organic chemicals are the cause of toxicity, more sophisticated Phase II identification methods are needed. A major challenge is the development of exposure techniques for whole organisms that reduce the mixture of organic chemicals potentially causing toxicity into simpler components that can be analyzed for identification. In this presentation, the evolving role of passive samplers in whole sediment TIEs will be discussed as a means for generating "simplified" sediment-based exposures that allow for identification. Use of whole sediment extraction schemes that better reflect contaminant bioaccessibility and bioavailability will be described. Additionally, the application of semi-permeable membrane devices and reverse polyethylene devices as dosing systems will be reviewed. Toxicological and chemical information will be provided evaluating the different approaches. This presentation will provide information useful for the development of identification processes for organic chemicals causing toxicity to whole organisms in freshwater and marine environments.

447 Determining the Causes of Sediment Toxicity in California B. Phillips, Univ of California – Davis, Environmental Toxicology; B. Anderson, Univ of California – Davis, Dept of Environmental Toxicology; J. Voorhees, Univeristy of California – Davis, MPSL – Environmental Toxicology; K. Siegler, Univ of California Davis; R. Tjeerdema, Univ of California – Davis, Environmental Toxicology. Sediment toxicity is pervasive in California watersheds. A recent summary of statewide data showed 47% of ambient samples were toxic to amphipods. This has regulatory implications because many California water bodies are listed as degraded due to ambient toxicity. It is necessary to determine the cause of toxicity so that contaminant sources can be identified and controlled. Research at UC Davis combines toxicity identification evaluations (TIEs) with other procedures designed to separate the effects of contaminant and non-contaminant factors, and to link laboratory effects with ecosystem impacts. Recent research has emphasized current-use pesticides such as organophosphates and synthetic pyrethroids. As part of recent monitoring, pyrethroids were detected in half of sediments collected at the base of watersheds, in toxic sediments collected in urban creeks, and in near-coastal marine sediments. Some observed toxicity was attributed to pyrethroids using several lines of evidence. Median lethal concentrations (LC50s) are used to determine if measured contaminant concentrations are greater than toxicity thresholds. Carbon-corrected LC50s allow for more accurate prediction of the bioavailable fraction of contaminants. Dose-response information developed for standard laboratory and resident species provide an important diagnostic tool. Because of their high toxicity and low solubility, accurate measurement of pyrethroids is problematic, and in many cases TIEs are relied upon to provide evidence for pyrethroid toxicity. Specific TIE methods for pyrethroids include addition of enzymes to break down pyrethroids, addition of piperonyl butoxide to inhibit pyrethroid metabolism, and manipulation of testing temperatures. When combined with solid-phase extraction techniques, and chemical analysis, these methods provide evidence for pyrethroid toxicity. Macroinvertebrate bioassessments are the primary tool to assess ecosystem impacts in California watersheds. Measures of contaminant and non-contaminant factors, habitat, and toxicity testing provide data linking stressors with impacts. Primary stressors identified through correlation analyses are further investigated using laboratory experiments, including dose-response experiments with key resident fauna. Data from this research has indicated the relative contributions of current-use pesticides to aquatic habitat degradation in California.

448 Identification of Compounds in Heavy Oil that are Toxic to Fish Embryos Using Effect-driven Chemical Fractionation and Chronic Toxicity Tests J. Adams; J. Bornstein, Queen's Univ, Chemistry, Queen's Univ, Chemistry Dept; P.V. Hodson, Queen's Univ, School of Environmental Studies. Heavy fuel oil (HFO) is the refined product of crude oil distillation that is used in ships and large heating plants. When this thick, viscous oil is spilt in aquatic environments it does not behave like lighter oils that float; HFO sinks within the water column and accumulates in sediments, affecting aquatic organisms that are not typically exposed to floating oils. Effect-driven chemical fractionation (EDCF) of crude oil has identified the 3-5 ringed alkylated polycyclic aromatic hydrocarbons (PAHs) as the major toxic fraction. HFO is comprised of a higher concentration of 3-4 ringed alkyl PAH and an abundance of 5-6 ringed PAH, and is predicted to be more toxic to fish. There has been little chemical characterization and identification of the compounds within HFO responsible for toxicity. This research is the first ever EDCF of HFO based on embryo toxicity tests conducted to identify the specific classes of alkyl PAH associated with toxicity, determine whether these components are sufficiently bioavailable to cause toxicity and establish the toxicity of HFO relative to medium and light oils.

449 Toxicological and Chemical Profiling of Contaminated Surface Waters by Holistic Passive Sampling Approach C. Liscio, Univ of Sussex, Biology and Environmental Science; E. Hill, Univ of Sussex. Environmental monitoring represents an on-going challenge and constant improvements in analytical methods have further increased awareness of the presence of contaminants at trace levels which can exert harmful effects on the environment.Amongst these contaminants, Endocrine Disrupting Compounds (EDCs) are being included in European and international conventions for the protection of aquatic environment, especially of surface waters. Identifying the causative agents of endocrine disruption is of paramount importance given that EDCs potentially have very wide reaching deleterious impacts to wildlife and possibly humans too.Thus far, endocrine disruption has been mostly focussed on estrogenic activity, but recently the presence of antiandrogenic compounds in contaminated aquatic environments has

raised scientific concern.Structures of chemicals containing androgen receptor antagonist properties can be extremely diverse and it is important to use methods to identify antiandrogens which do not make any assumptions as to the nature of the chemicals involved.A bioassay-directed fractionation is the best approach to isolate antiandrogenic chemicals in complex environmental extracts and to allow further identification of the unknown active structures. However, water sampling can result particularly problematic for EDCs, since they are present at ultra-trace levels and encompass a variety of chemical classes differing significantly in physical-chemical properties.A holistic passive sampling approach can be an efficient alternative to overcome these limitations: the use of a combination of different passive samplers may allow sampling of a wide range of compounds with a significant preconcentration from surface waters, increasing the likelihood of successful identification of the chemical structures. In this study, 4 different passive samplers were used to detect antiandrogenic activity present in different contaminated surface waters.Samples were fractionated and profiles derived from the 4 passive samplers were compared and characterized.The nature of key antiandrogenic contaminants was investigated by mass spectrometry techniques. In addition, a general chemical profile of contaminants present in the waters was obtained using UPLC-TOF MS analysis of the unfractionated passive sampler extracts.Chemometrics tools were then used to model information-rich chemical data and to identify key classes of chemical contaminants associated with the different samplers.

450 Predicting Bioavailability of Polycyclic Aromatic Hydrocarbons to Soft-shelled Clams Using In Situ Deployment of Polyethylene Passive Samplers L.A. Fernandez, US Environmental Protection Agency, Office of Research and Development; P.M. Gschwend, Massachusetts Institute of Technology, Dept of Civil and Environmental Engineering. Freely-dissolved porewater PAH concentrations and chemical activities have been suggested as measures of the bioavailability of PAHs in contaminated sediment beds. However, the difficulties of measuring porewater concentrations and reaching equilibrium during laboratory exposure studies have made it challenging to correlate chemical activity with bioavailability. Passive sampling methods make it possible to measure porewater concentrations and chemical activities without disturbing sediment beds or returning bulk sediment samples to the laboratory. Sampling native organisms also ensures tissues are at a natural equilibration with sampled sediments. In this work, polyethylene (PE) passive samplers, containing performance reference compounds (PRCs) (d10-phenanthrene, d10-pyrene, and d12-chrysene), were deployed in sediment beds near Boston, MA (USA) for a one-week period. Clams (*Mya arenaria*) and sediments were then collected from the same sediments (directly adjacent to samplers). Concentrations and chemical activities of three PAHs that matched the PRCs (phenanthrene, pyrene, and chrysene) were measured in the porewaters (using PE-PRC method), in clam tissues, and in the bulk sediment. Chemical activities in clams were compared to (a) those measured in porewaters using PE samplers and (b) those calculated using sediment measurements, and equilibrium partitioning (EqP) models that includes sorption to organic carbon and black carbon fractions. While no statistically significant correlations between chemical activities in clams and sediment porewaters calculated using EqP models were found, correlations were seen when using PE to derive porewater chemical activities for both pyrene and chrysene (r^2 of 0.29 and 0.93, respectively). Ratios of porewater and organism chemical activities indicate that the clams were nearly equilibrated (within a factor of 2) with sediment porewaters for phenanthrene and chrysene, while pyrene porewater chemical activities were higher than those in organisms by about a factor of 5. EqP models overestimated porewater concentrations for the three chemicals by one to three orders of magnitude at all but one site. These data indicate the use of chemical activities based on passive sampler measurements are valuable predictors of PAH bioavailability.

451 Development of a Gene Expression Approach for Sediment Toxicity Identification S.M. Bay, Southern California Coastal Water Research Project, Toxicology Dept; C. Vulpe, Univ of California – Berkeley, Nutritional Science and Toxicology. Identification of the cause of sediment toxicity is needed in order to design effective management actions to improve sediment quality. Sediment TIEs based on traditional methods are often limited in their usefulness when multiple potential stressors are present, the magnitude of toxicity is low, or when the chemical characteristics of the toxicant are not very distinctive. A potential new method for stressor identification in sediment toxicity tests is under development that is based on measuring changes in gene expression. A custom microarray containing over 10,000 probes for gene expression was developed from the expressed genome in the marine amphipod *Eohaustarius estuarius*, a species widely used for sediment toxicity assessment. Differential gene expression in *E. estuarius* was measured following exposure to a variety of toxicants, including chlorinated pesticides, metals, current use pesticides, and PAHs. Distinctive patterns of gene expression were identified for most contaminants, suggesting that development of a diagnostic tool for stressor identification is feasible. Several sets of diagnostic genes and associated classification models were developed using multivariate statistical methods. Results from the evaluation of the classification models using independent validation samples from lab and field studies are described. The influence of population variability, exposure matrix, and dose on gene expression patterns and classification ability were also investigated. Use of gene expression is a promising tool for sediment TIE.

452 Integration of Gene Expression Biomarkers and Whole Sediment Toxicity Identification Evaluations A. Biales, USEPA, National Exposure Research Laboratory, USEPA, ORD/NERL, USEPA; M. Kostich, USEPA, NERL, National Exposure Research Laboratory, USEPA; R.M. Burgess, USEPA, Atlantic Ecology Division, National Health and Environmental Effects Research Laboratory, USEPA, USEPA; M. Pelletier, National Health and Environmental Effects Research Laboratory, USEPA, Dept: ORD NHEERL AED; L. Portis, National Health and Environmental Effects Research Laboratory, USEPA; M. Perron, Brown Univ, School of Engineering; K. Ho, National Health and Environmental Effects Research Laboratory, USEPA. Toxicity Identification and Evaluations (TIEs) use physical/chemical manipulation of a sample to isolate or change the potency of different groups of chemicals potentially toxic in a sample. Organisms are then exposed to these fractions pre- and post- manipulation to determine if the toxicity has changed. TIEs often focus on mortality to detect toxicity; however, this endpoint gives no definitive information as to the identity of the active toxicant(s). It has been suggested that gene expression profiles may be useful in identifying toxic substances from unknown samples. This is accomplished through the development of expression profiles, consisting of a number of genes, which respond in a specific manner to a given toxicant. Generally these expression profiles are established through the use of global transcriptional platforms, such as microarrays. For the current project, microarrays were constructed for the amphipod Ampelisca abdita, a model organism employed in sediment TIEs, which previously lacked any characterization on the molecular level. Exposures to eight model toxicants and mixtures were conducted at 10% of the LC50. Gene expression signatures were generated for individual exposures to specific toxicants or groups of toxicants. Using Elizabeth River, VA sediments (ER), TIEs were conducted at two sediment dilutions, one toxic (40:60; ER:control sediment; 86.7% mortality) and one non-toxic (10:90; ER:control sediment; 0% mortality). A gene expression classifier was generated that would discriminate between ER and control sediment samples. Gene expression profiles of model toxicants, ER exposed organisms and control were clustered, with the idea that the model toxicant responsible for the observed mortality in the 40% ER sample would cluster more closely to the unmanipulated ER sediment relative to the other model toxicants. TIE results of the 40% ER samples, indicated a large decrease in mortality rates with coconut charcoal addition and a moderate decrease with cation exchange resin addition. These results were compared with results obtained using gene expression as an endpoint. Comparisons were also made between results obtained using TIE and gene expression in the 10% ER sediment, where no significant results using the TIE process were obtained. This work demonstrates the utility of incorporating gene expression endpoints to confirm and accentuate whole sediment TIEs.

453 EDA of Unknown Toxicants in the Environment – Strategies to Identify Compounds Based on Chromatography, Mass Spectrometry and Calculated Properties W. Brack, Helmholtz Centre for Environmental Research UFZ, Effect-Directed Analysis, UFZ Centre for Environm. Research, Dept of Chemical Ecotoxicology; C. Hug, Helmholtz Centre for Environmental Research-UFZ, Effect-Directed Analysis; M. Krauss, Helmholtz Centre for Environmental Research UFZ, Effect-Directed Analysis, Helmholtz Centre for Environmental Research, Effect-Directed Analysis; M. Markus, German Aerospace Center DLR, Remote Sensing Technology Institute; N. Steffen, Leibnitz Institute of Plant Biochemistry, Dept for Stress and Development Biology; T. Schulze, Helmholtz Centre for Environmental Research UFZ, Effect-Directed Analysis; S. Emma, Helmholtz Centre for Environmental Research UFZ, Effekt-Directed Analysis, EAWAG – Swiss

Federal Institute of Aquatic Science and Technology; U. Nadin, P.C. Vonderohe, Helmholtz Centre for Environmental Research UFZ. While typical environmental mixtures contain thousands to ten thousands of compounds, the risk to ecosystems and human health is typically estimated on the basis of a few known target compounds, which are often unable to explain measurable effects. Effect-directed analysis (EDA) is a valuable approach to identify causative toxicants but is complicated by the presence of many unknowns detected during screening of toxic fractions but present at concentrations and purity insufficient for structure elucidation e.g., by NMR spectroscopy. To meet this challenge, we present a systematic strategy for compound identification based on chromatography, mass spectrometry and calculated properties. Firstly, database searching based on GC-MS and LC-MS is performed, considering (exact) mass, fragmentation and retention information. Alternatively, structure generation combined with substructural classifiers can be used to generate candidate structures. Secondly, a systematic reduction of the number of candidates is achieved by comparing predicted and measured retention behaviour in GC and LC, using a steric energy calculation, predicting mass spectral fragmentation patterns and finally application of QSARs and structural alerts for effect prediction. This strategy is demonstrated using examples applying this approach in EDA studies. To enhance the sharing and interpretation of especially LC-MS(n) data, we also introduce a non-commercial common database to achieve optimal synergism of chemical screening and EDA worldwide.

454 Inhibition of Thyroid Hormone Sulfotransferase Activity by Brominated Flame Retardants and Halogenated Phenolics C. Butt, H.M. Stapleton, Duke Univ, Nicholas School of the Environment. The maintenance of thyroid hormone (TH) homeostasis is complex, but critical for normal physical and mental development. The biologically active TH is 3,5,5'-triiodothyronine (T3), which is formed through deiodination of the T4 phenolic ring via deiodinase enzymes (DI). Deiodination can also occur on the tyrosyl ring resulting in the formation of 3,3',5'-triiodothyronine (rT3). Both T3 and rT3 are further deiodinated to yield 3,3'-diiodothyronine (3,3'-T2). The rT3 and 3,3'-T2 are thought to be biologically inactive. In addition to deiodination, THs undergo phase II metabolism via conjugation of the hydroxyl group with glucuronic acid or sulfate. Interestingly, the sulfation of some THs increases their deiodination efficiency as compared to non-sulfated analogue. In this study, we investigated the potential of halogenated phenolic compounds to inhibit TH sulfation using in vitro assays. We used 3,3'-T2 as the substrate since it has been shown that this compound is the most efficient TH compound for sulfation and our model system was human liver cytosol. THs and the 3,3'-T2 sulfated conjugate were analyzed by LC-MS/MS, adapted from previous methods developed in our lab. We tested several brominated flame retardants (tetrabromobisphenol A, 2,4,6-tribromophenoland), PBDE metabolites (hydroxylated BDEs) and triclosan as potential TH sulfation competitors. Further, we explored structure-activity relationships by investigating TH sulfation inhibition by fluorinated, chlorinated and iodinated analogues. All compounds tested showed the ability to inhibit 3,3'-T2 sulfation in a dose-response manner. In general, the OH-BDEs were the most potent inhibitors (IC50 values: 50-340 nM) followed by TBBPA and triclosan. Differences were observed between the various OH-BDE congeners and structure-activity relationships were developed. For example, the 3-OH BDE 47 was a more potent inhibitor than the 5-OH BDE 47. The present study demonstrated that several brominated flame retardants and the hydroxylated metabolites of PBDEs (as well as the anti-microbial, triclosan) can inhibit TH sulfation. This potentially may impact TH metabolism and thus may influence circulating TH levels in the body. This study contributes to the growing body of literature demonstrating that halogenated phenolics may disrupt TH homeostasis.

455 Determination and Characterization of Hydroxylated PCB Metabolites (OH-PCBs) in 1959-1967 Archived Serum from California Women: The Follow-up Study D. Tarrant, California Environmental Protection Agency, Dept of Toxic Substances Control; A. Rhee, California Environmental Protection Agency, Dept of Toxic Substances Control, Public Health Institute; S. Harwani, J. Park, M. Petreas, California Environmental Protection Agency, Dept of Toxic Substances Control; B. Cohn, P. Cirillo, Center for Research on Women's and Children's Health; P. Factor-Litvak, Columbia Univ, Dept of Epidemiology. The hydroxylated metabolites of PCBs (OH-PCBs) are formed and retained by the body, and may have adverse effects on the thyroid system. These metabolites compete and replace thyroxine (T4) thyroid hormone in binding to the transport protein transthyretin (TTR). Replacement of thyroxine with hydroxylated PCBs can result in endocrine related problems associated with hypothyroidism, deficits in neurodevelopment and immune functions, and impaired reproductive system in offspring. The initial pilot study that characterized and quantified the levels of specific PCBs and OH-PCBs metabolites from 30 archived third trimester or postpartum serum specimens from California mothers during 1959-1967 was successful in assessing the feasibility of measuring the OH-PCB metabolites in 1 mL of archived sera. The OH-PCB concentrations were measured at levels that are likely to be toxicologically significant, and are comparable to other studies that showed toxicological effects of these metabolites. The objective of our current research is to quantify and characterize the OH-PCB metabolites and their parent PCBs in the larger cohort (N=510) of archived maternal sera from 1959-1967. The PCB exposure levels are expected to be higher than current levels, since these maternal samples were acquired in a time period prior to regulatory action that banned the production of PCBs. Our results indicate that the sera samples contain 4-OH-CB187 and 4-OH-CB 107 as the primary and secondary metabolites respectively. This is the first large scale study to assess OH-PCB levels in a US population. The ultimate goal for this study population is to explore associations between OH-PCBs metabolites, PCBs, and thyroid effects. Disclaimer: The views expressed herein are those of the authors and do not necessarily reflect those of the Dept of Toxic Substances Control, California Environmental Protection Agency.

456 Polybrominated Diphenyl Ethers (PBDEs) and Their Hydroxylated Metabolites in Paired Maternal and Cord Serums Collected in Cincinnati A. Chen, Univ of Cincinnati; J. Park, California Environmental Protection Agency, Dept of Toxic Substances Control, California Environmental Protection Agency, Research Scientist; A. Rhee, M. Petreas, California Environmental Protection Agency, 700 Heinz Ave.; E.A. DeFranco, K.N. Dietrich, S. Ho, Univ of Cincinnati. Polybrominated diphenyl ethers (PBDEs) were widely used as flame retardants in the past three decades. These compounds are lipophilic and easily cross the placenta from mother to fetus. It is not clear whether hydroxylated PBDEs (OH-PBDEs), metabolites of PBDEs with more structural similarity to thyroid hormones but more hydrophilic, differ in maternal and cord blood samples. We analyzed both PBDEs (BDE-28, -47, -99, -100, -153, -154, -209) and OH-PBDEs (6-OH-BDE-47, 5-OH-BDE-47, 4'-OH-BDE-49, 5'-OH-BDE-99) in a pilot of first 10 pairs of maternal and cord serum samples collected in Cincinnati, OH in 2011. We used standard liquid-liquid serum extraction and phase separation techniques. Analysis of PBDE was performed by gas chromatography/high resolution mass spectrometry (GC-HRMS, Thermo-Finnegan) coupled with isotope dilution. OH-PBDEs were determined as methyl derivatives (MeO-PBDEs) by using Varian 1200 GC/MS with negative chemical ionization mode. The median concentration of ∑(7)PBDEs was 35 ng/g lipid (24-104) in maternal serum and 43 ng/g lipid (range 25-117 ng/g lipid) in cord serum samples. The median concentration of ∑(4)OH-BDEs was 33 pg/mL (17-231) in maternal serum and 43 pg/mL (23-446 pg/mL) in cord serum samples. The differences between maternal and cord blood concentrations were statistically significant by Wilcoxon signed rank test. The PBDEs and OH-PBDEs measured in cord serum were higher than in paired maternal serum samples. This suggests fetuses may receive higher PBDE and OH-PBDE exposure compared with their mothers.

457 Distribution of PCBs and Their Hydroxylated Metabolites in Human Serum from Asian Countries A. Eguchi, Ehime Univ, Center for Marine Environmental Studies, Ehime Univ, Center for Marine Environmental Studies (CMES), Ehime Univ, Center for Marine Environmental Studies Ehime Univ; K. Nomiyama, Ehime Univ, Center for Marine Environmental Studies (CMES); G. DEVANATHAN, Ehime Univ, Center for Marine Environmental Studies (CMES), Ehime Unviersity, Center for Marine Environmental Studies; A. Subramanian, Ehime Univ, Center for Marine Environmental Studies (CMES); P.H. Viet, Hanoi National Univ; P. Parthasarathy, E-parisara (P) Ltd; K.A. Bulbule, Nijalingappa College; S. Takahashi, Ehime Univ, Center for Marine Environmental Studies (CMES); S. Tanabe, Ehime Univ, Center for Marine Environmental Studies. Polychlorinated biphenyl congeners (PCBs) are known to affect endocrine systems and neurodevelopment in human and wildlife. Even though PCBs were banned in many countries in the late 1970s, they still dominate the body burden of organohalogen compounds in biota including human. In this study, we investigated the levels and profiles of PCBs and hydroxylated metabolites of PCBs (OH-PCBs) in human serum samples collected from

three Asian countries, Japan *(n = 51)*, India *(n = 42)*, and Vietnam *(n = 30)*. Median concentrations of PCBs in serum from Japanese cancer patients (2900 pg g^{-1} wet wt) were higher than Indian e-waste recycling workers and residents near coastal area (70 and 110 pg g^{-1} wet wt, respectively) and also than Vietnamese e-waste recycling workers and rural residents (300 and 400 pg g^{-1} wet wt, respectively). Median concentrations of OH-PCBs were also higher in Japanese serum (630 pg g^{-1}) samples than other locations, indicating the effects of past higher consumption of PCBs and food habits in Japan. In general, CB105, CB118, CB138, CB153 and CB180 contributed high proportion to the total PCBs. In all locations, 4-OH-CB107, 4-OH-CB146 and 4-OH-CB187 dominated the OH-PCB profiles in serum samples. However, high contributions of CB28, CB74 and 4OH-CB79 in e-waste recycling workers and the difference in PCBs and OH-PCBs pattern between e-waste recycling workers and general population might be due to the presence of specific exposure sources in e-waste recycling locations. Parent congener for 4OH-CB79 is not clear, but higher concentrations of lower chlorinated PCBs may be a source of lower chlorinated OH-PCBs in e-waste recycling workers in India.

458 Spatial and Phase Distribution of PCBs, PBDEs and Their Metabolites in Air and Soil, Korea U. Kim, S. Oh, H. Kim, Pusan National Univ; S. Choi, Ulsan National Institute for Science and Technology ; H. Moon, Hanynag Univ; J. Oh, Pusan National Univ. This paper reports concentration level, spatial and phase distribution of polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs) and their metabolites in air and soil. Although there has been quite a lot of research done for persistent organic pollutants level, distribution, physicochemical properties in environmental matrices, still only a few of information was secured about PCBs or PBDEs exsited in air phase and much less data was available for their metabolites in various type of environmental matrices. Especially in case of Korea, data of PCBs and PBDEs were not sufficient compared to other POPs like PCDD/Fs. Therefore, in this study, 20 surface soil and 14 air samples were collected from December, 2010 to July, 2011 with high volume sampler (HV-1000R, Sibata, Japan) and SPMD passive air samplers. To examine spatial distribution, sampling points were selected to cover industrial, residential and rural sites in Busan, south-eastern city of Korea. Basic information including temperature, wind velocity, humidity of sampling points was also recorded. Total PCBs and PBDEs were extracted with soxhlet, cleaned up with multi-silica or followed by alumina column and measured by HRGC/HRMS for PBDEs and LRGC/LRMS for PCBs. For hydroxylated and methoxylated metabolite analysis, PCBs and PBDEs were derivatized by methylation and acetylation, respectively, and analysed by HRGC/HRMS. For air samples, gas phase and particle phase were analysed separately. Recoveries of PCBs were 60-114% and 36-148% for PBDEs, satisfying EPA standards. The concentration level of PCBs in soil was ranged from

459 Competitive Binding of Brominated Flame Retardants, Metabolites and Halogenated Phenolics with Thyroxine to Human Thyroxine-Binding Globulin C. Butt, H.M. Stapleton, Duke Univ, Nicholas School of the Environment. Thyroid hormones (THs) are essential for normal physical and mental development in humans. THs are produced in the thyroid gland, primarily as the pro-hormone thyroxine (T4) in addition to minor amounts of the biologically active 3,3',5'-triiodothyronine (T3). Only a small fraction (< 1%) of circulating THs are "free" or unbound, and the vast majority of circulating THs are bound to plasma proteins. The plasma proteins include serum albumin, transthyretin (TTR) and thyroxine-binding globulin (TBG). TBG has the highest affinity for T4 and binds approximately 75% of serum T4. It has been shown that some halogenated phenolics can competitively bind with TBG and TTR transport proteins, thus displacing T4. Whereas the competitive binding to TTR is fairly well studied, there is comparatively less known about TBG. This study used in vitro techniques to investigate competitive binding to TBG by several halogenated phenolic compounds. Briefly, $^{13}C_{12}$-T4 was combined with human TBG in Tris-HCl buffer and various concentrations of competitors were spiked. Competitors included tetrabromobisphenol A (TBBPA), 2,4,6-tribromophenol (2,4,6-TBP) and triclosan. T4 was used as the reference compound. Control samples consisted of clean DMSO. After overnight incubation, TGB-bound $^{13}C_{12}$-T4 was separated from "free" $^{13}C_{12}$-T4 using mini-size exclusion chromatography columns as previously described. The TGB-bound $^{13}C_{12}$-T4 was analyzed by LC-MS/MS using methods previously developed by our laboratory. All three competitors tested (TBBPA, 2,4,6-TBP and triclosan) showed the ability to competitively bind to TBG in a dose-response manner. Calculated IC_{50} values were 0.22 μM, 20 μM and 149 μM for T4, TBBPA and triclosan, respectively. Competitive binding for 2,4,6-TBP was only observed at the highest dose and regression parameters could not be calculated. The corresponding relative potency values for TBBPA and triclosan were 0.01 and 0.001, respectively. The present study demonstrated that two brominated flame retardants as well as the anti-microbial, triclosan, can compete with T4 for binding to TBG. This study provides further evidence that some halogenated phenolics can competitively bind with TBG and thus may impact the circulation of THs, particularly T4, throughout the human body. Future work will investigate additional flame retardants and their metabolites (i.e., OH-BDEs).

460 Compound-specific Isotope Analysis of Halogenated 1'-methyl-1,2'-bipyrroles Narrows the Search for Their Biosynthetic Origin K. Pangallo, Colgate Univ, Chemistry; C.M. Reddy, Woods Hole Oceanographic Institution; J. Bolotin, T. Hofstetter, Eawag, Environmental Chemistry. Highly halogenated 1'-methyl-1,2'-bipyrroles are natural products that biomagnify into the upper trophic levels of the marine food web. Though they have been found throughout the world's oceans, the organism or organisms responsible for their biosynthesis remains unknown. One way to elucidate the origin of these compounds is through the isotopic signature imprinted during biosynthesis and maintained during biomagnification (we will argue it is not due to degradation). Here we use compound-specific nitrogen isotope analysis to measure this signature, and demonstrate that they are dramatically enriched in $\delta^{15}N$. This ^{15}N-enrichment is greater than that seen for other biosynthetic organic compounds measured to date, and is a distinct isotopic signature. By interpreting this result in the context of strongly fractionating biochemical pathways and enriched precursors, we suggest that future research on the origin of these compounds may want to focus on marine actinomycetes and/or *Pseudoalteromonas*.

461 Halogenated By-products of Gemfibrozil Formed in Wastewater Treatment-like Conditions: In Situ Characterization, Detection, and Biological Effects D. Bulloch, Univ of California Riverside; R. Lavado, Univ of California Riverside, Dept of Environmental Sciences; C.K. Larive, Univ of California Riverside, Dept of Chemistry; D. Schlenk, Univ of California Riverside, Dept of Environmental Sciences. The study of disinfection by-products of pharmaceuticals in wastewater is an emerging field. Most by-products of known contaminants are unregulated, and may have altered physiochemical properties and toxicity profiles compared with the parent. The lipid regulator gemfibrozil has been found consistently in the high ng/L to low μg/L range in wastewater in Southern California. Gemfibrozil can be oxidized when treated with sodium hypochlorite in deionized water to form a *p*-chlorinated species as the major product. When treated with sodium hypochlorite in wastewater, a *p*-brominated species also forms as a major product. Product evolution and distribution during chlorination reactions were monitored using a Waters Acquity ultra performance liquid chromatography with time-of-flight mass spectrometric detection. Both halogenated analogs of gemfibrozil were purified by HPLC, where subsequent structural assignments were carried out by one- and two-dimensional nuclear magnetic resonance on a Bruker Avance 600. The detection of gemfibrozil and its halogenated analogs was made using chlorinated primary effluent from a Southern California wastewater treatment plant. Measureable contaminant concentrations were determined in the effluent samples for gemfibrozil, chlorinated gemfibrozil , and brominated gemfibrozil. Characterization of the biological activity of gemfibrozil and its halogenated analogs was performed through in vitro experiments in rainbow trout primary hepatocytes at concentrations up to 100 μg/L, where no activity was observed. Biological activity characterization in vivo in a 14-day waterborne exposure using Japanese medaka yielded reduced 11-keto testosterone levels in whole fish, where the halogenated analogs elicited an enhanced anti-androgenic response compared to the parent gemfibrozil. The levels of 17-β estradiol were also measured in the whole fish, where the ratio of 11-keto testosterone to 17-β estradiol revealed a trend of enhanced endocrine disruption for gemfibrozil's halogenated analogs when compared to the parent gemfibrozil.

462 Genomic Tools for Understanding Chemical Tolerance in a Wild Population of the Estuarine Fish, *Fundulus heteroclitus* D. Proestou, US Environmental Protection Agency, Atlantic Ecology Division; J. Martinson, E. Waits, US Environmental Protection Agency, Ecological Exposure Research Division; D. Champlin, US Environmental Protection Agency,

Atlantic Ecology Division; D. Nacci, US Environmental Protection Agency. Wild populations of the killifish *Fundulus heteroclitus* residing in heavily contaminated North American Atlantic coast estuaries have recently and independently evolved dramatic, heritable, and adaptive polychlorinated biphenyl (PCB) tolerance. However, currently available genomic tools limit our ability to characterize the genetic and biochemical mechanisms associated with PCB tolerance in this species. In order to enhance ongoing research designed to reveal the genetic basis for PCB tolerance, we focused on genes associated with the aryl hydrocarbon receptor (AHR) putative target pathway and developed a suite of Single Nucleotide Polymorphism (SNP) markers. Expressed Sequence Tag (EST) sequences derived from > 100 genes of interest were mined from the *F. heteroclitus* EST database and assembled into 155 contigs using the sequence assembly program CAP3. The QualitySNP pipeline, an algorithm designed to detect polymorphisms in EST data, was used to identify 'true' SNPs within contigs. Over 400 SNPs were detected and from those, 120 markers generated. Eight fish, which differed in PCB sensitivity and represent the parental generation of 4 mapping families, were genotyped at each SNP locus using a melting temperature (Tm)-shift method. Genotype data were used to determine the utility of each marker in genetic map construction and Quantitative Trait Locus (QTL) analysis. A subset of these markers is currently being evaluated for its application in population genetic studies. This research is a reflection of the need for developing genomic tools in wild, ecologically-relevant species to better understand stress response and evolved adaptive differences among wild populations.

463 Cytochrome P4501A Promoter Polymorphisms and Activity in Natural Populations L.M. Williams, Woods Hole Oceanographic Institution, Biology; M.F. Oleksiak, Rosenstiel School of Marine & Atmospheric Sciences. Cytochrome P4501A (CYP1A) induction is a widely used biomarker of aromatic hydrocarbon exposure. Unexpectedly, CYP1A is refractory to prototypic inducers in multiple populations of the estuarine minnow, *Fundulus heteroclitus*, adapted to chronic anthropogenic pollutants. In these polluted populations, two single nucleotide polymorphisms (SNPs) in the promoter and first intron of CYP1A are under selection, indicating that natural selection is acting on the CYP1A promoter or loci linked to these SNPs. To better understand the role of these selectively important SNPs in CYP1A transcriptional regulation, 1,630 bp of the CYP1A promoter and first intron and exon were sequenced in eight individuals from each of three populations: a polluted (New Bedford Harbor, MA USA) population resistant to aromatic hydrocarbons and two sensitive, reference populations north and south of the polluted site. The CYP1A promoter was extremely variable (an average of 9.3% of the promoter nucleotides varied among all populations) and exhibited no fixed differences between populations. In vitro, a prototypic polycyclic aromatic hydrocarbon (PAH) induced transcription from the CYP1A promoter in a dose-dependent manner for both polluted New Bedford Harbor and reference population individuals. When promoters from four individuals per population were tested, transcription levels driven by CYP1A promoters from New Bedford Harbor individuals were significantly greater than those for reference individuals. This is in contrast to CYP1A expression in vivo, which is refractory to induction in New Bedford Harbor individuals. These data suggest that the nucleotide variation in the CYPIA promoter affects the PAH induced transcription, but to fully explain the pattern of expression in natural populations, other cis-acting or trans-acting factors that act through the selectively important SNP must also be involved.

464 The Role of Differential Metabolism and DNA-adduct Formation in the Resistance of Atlantic Killifish (*Fundulus heteroclitus*) to Cancer B.W. Clark, Duke Univ, Nicholas School of the Environment ; N.R. Herr, Univ of North Carolina at Chapel Hill, Dept of Environmental Sciences and Engineerging; E.M. Cooper, Duke Univ, Nicholas School of the Environment ; L.B. Collins, Univ of North Carolina at Chapel Hill, Dept of Environmental Sciences and Engineerging; B.C. Moeller, Univ of North Carolina at Chapel Hill, Dept of Environmental Sciences and Engineerging, Curriculum of Toxicology; H.M. Stapleton, Duke Univ, Nicholas School of the Environment ; J.A. Swenberg, Univ of North Carolina at Chapel Hill, Dept of Environmental Sciences and Engineerging, Curriculum of Toxicology; R. Di Giulio, Duke Univ, Nicholas School of the Environment. The Elizabeth River (ER) estuary is an urbanized and industrialized watershed at the south end of the Chesapeake Bay. The Atlantic Wood Industries Superfund Site (Portsmouth, VA, USA) on the ER is highly contaminated with creosote-derived polycyclic aromatic hydrocarbons (PAHs). Atlantic killifish (*Fundulus heteroclitus*) inhabiting the site are resistant to the acute toxicity and cardiac teratogenesis caused by some PAHs and PCB-126 (3,3',4,4',5-pentachlorobiphenyl). The resistance is linked to down regulation of the aryl hydrocarbon receptor (AHR) pathway, including recalcitrance to induction of cytochrome P450s. However, adult ER killifish show a greater prevalence of hepatic and pancreatic tumors compared with those from reference sites (Vogelbein and Unger, 2006). Despite the prevalence of cancer in wild-caught ER killifish, we recently demonstrated that they are markedly resistant to benzo[*a*]pyrene (BaP)-induced DNA damage and chronic hepatic toxicity, including cancer. We hypothesize that ER killifish are protected by down-regulation of the AHR pathway, along with upregulation of phase II and III metabolism and antioxidant defense systems. The objective of the current research was to determine the role of differential BaP metabolism and DNA adduct formation in this resistance. We developed an LC-MS/MS-SRM method to simultaneously and quantitatively monitor the benzo[*a*]pyrene diol epoxide (BPDE) stable DNA adduct and the oxidative-stress-related adduct, 8-hydroxy-2'-deoxyguanosine (8-oxo-dG), generated from base oxidation. We also measured the occurrence of abasic sites, which can be indicative of oxidative DNA damage. In addition, we refined methods for the assessment of the major BaP metabolites in liver and bile. In the current study, adult ER and King's Creek (KC, reference population) killifish were injected intraperitoneally with 10 mg/kg BaP, and liver and bile were harvested at various timepoints following exposure. We compared the levels of BPDE-dG adducts, 8-oxo-dG adducts, and abasic sites in the two populations. These results were correlated with differences in the levels of BaP and its metabolites measured in liver and bile. In addition, we compared mRNA expression of glutathione S-transferase-*mu* and the ABC transporters ABCB1 and ABCB11. This work was funded by the NIEHS-supported Superfund Research Program (P42ES10356 and P42ES010356-09S3, ARRA Supplement) and the Duke Integrated Toxicology and Environmental Health Program (T32ES07031).

465 Development and Application of Genomic Resources for *Fundulus heteroclitus* Reveal Environment Dependent Arsenic by Gene Interactions J.R. Shaw, Indiana Univ, The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics, Dartmouth College, Dept of Biology; T. Hampton, Dartmouth Medical School; J.K. Colbourne, Indiana Univ, The Center for Genomics and Bioinformatics; C.Y. Chen, Darmouth College; B.A. Stanton, Dartmouth Medical School. The killifish, *Fundulus heteroclitus*, is a phenotypically plastic, ecologically diverse, and environmentally tractable euryhaline teleost that has been widely used as both a surrogate for studies of human health and a sentinel monitor for environmental quality. It is well positioned to become a model system for environmental genomics –which seeks to understand how gene function is influenced by environmental conditions, while accounting for variation that exists within and among natural populations. To facilitate such applications, our group has been working to develop genomic resources for killifish. In the present study, we detail our efforts to define its transcriptome and develop an ultra-dense microarray. We highlight the application of these tools through functional studies on the effects of arsenic during seawater acclimation. Next generation sequencing was used to characterize the killifish transcriptome illuminated under 72 different conditions, including arsenic and salinity. The ~1,500,000 sequence reads were assembled, computationally annotated, and used to develop a microarray on the NimbleGen 12-plex platform (12 sub-arrays/slide, each containing 137,000 probes). For the functional studies, killifish were acclimated to freshwater and the transcriptomic response was measured as a function of salinity, time and arsenic exposure (100 ppb) following immediate transfer to seawater. These investigations employed a replicated, factorial design and differentially regulated genes were determined by fit to a linear model. Arsenic constrains physiological plasticity by inhibiting seawater acclimation and this was captured in the transcriptomic response, where gene-response profiles obtained following 1-h and 24-h in seawater in the presence of arsenic more closely resembled those of freshwater fish. Not surprisingly these included genes known to be involved in immune function, cellular organization and remodeling, cell signaling, ion transport, and arsenic, as well as, many novel genes. Perhaps the most striking finding was the emergence of a large interactive transcriptome –gene responses not predicted by simple addition of their activity in arsenic or seawater alone. These responses represent environment dependent gene by arsenic interactions, and highlight the critical

need for environmentally responsive model systems in defining critical toxicity pathways that influence natural populations, which live in variable environments.

466 The Role of Aryl Hydrocarbon Receptor (AHR) Variants in the Mechanism of Evolved Resistance to PCBs in Populations of *Fundulus heteroclitus* M.E. Hahn, Woods Hole Oceanographic Institution, Biology Dept; S.I. Karchner, A.M. Reitzel, Woods Hole Oceanographic Institution, Biology; M.J. Jenny, Univ of Alabama; D.G. Franks, Woods Hole Oceanographic Institution; D. Nacci, USEPA, ORD, NHEERL, Atlantic Ecology Division, USEPA, NHEERL, Atlantic Ecology Division; M.F. Oleksiak, Rosenstiel School of Marine & Atmospheric Sciences; D.B. Mark Welch, Marine Biological Laboratory; I. Wirgin, New York Univ School of Medicine, Dept of Environmental Medicine. Long-term exposure to polychlorinated biphenyls (PCBs) and other aromatic hydrocarbons has selected for populations of Atlantic killifish (*Fundulus heteroclitus*) with evolved resistance to non-*ortho*-substituted PCBs and other dioxin-like compounds that act via the aryl hydrocarbon receptor (AHR). Analysis of gene expression profiles by microarray and RNA-Seq suggest a genome-wide loss of responsiveness to AHR agonists in fish inhabiting the New Bedford Harbor, MA (NBH) Superfund site as compared to fish from Scorton Creek, MA (SC). We are studying the relative roles of aryl hydrocarbon receptor (AHR) duplicates (paralogs) and polymorphic variants of AHR1, AHR2, and AHR repressor (AHRR) in controlling the differences in sensitivity to PCBs in these populations. *Fundulus* AHR loci are highly polymorphic and display gene- and site-specific patterns of haplotype diversity and evidence of selection, especially at the AHR2 locus. However, the haplotype differences have not yet been linked to differences in AHR function that can be measured in vitro. In PCB-resistant tomcod (*Microgadus tomcod*) from the Hudson River, PCB resistance is caused by a 2-amino-acid deletion in one of two AHR2 variants, resulting in reduced binding affinity for TCDD. In contrast, killifish exhibit 26 AHR2 variants with no measurable differences in binding affinity. Deep sequencing of the *Fundulus* transcriptome revealed two additional AHR paralogs (AHR1b, AHR2b) that also might have roles in the evolved resistance. [Supported by P42ES007381, R01ES006272, and the Smith Chair.]

467 Mechanistic Basis of Resistance to PCBs and Dioxin in Atlantic Tomcod from the Hudson River I. Wirgin, New York Univ School of Medicine, Dept of Environmental Medicine; N.K. Roy, New York Univ School of Medicine, Environmental Medicine; M. Loftus, New York Univ School of Medicine; R.C. Chambers, NOAA, Northeast Fisheries Science Center; D.G. Franks, Woods Hole Oceanographic Institution, Biology; M.E. Hahn, Woods Hole Oceanographic Institution. The main stem Hudson River (HR) has the largest federal Superfund site in the US because of contamination with PCBs and the western HR estuary also contains a Superfund site because of contamination with near record levels of TCDD. We have shown that Atlantic tomcod from the main stem HR and Newark Bay bioaccumulate high hepatic levels of coplanar PCBs and TCDD, respectively, compared to tomcod from elsewhere. Atlantic tomcod from the Hudson River are highly resistant to PCBs and TCDD-induced early life-stage toxicities and induction of cytochrome P4501A, responses that are mediated by the aryl hydrocarbon receptor (AHR) pathway. We investigated the molecular basis of this resistance in tomcod. AHR2 sequence was highly conserved among tomcod populations coastwide. However, tomcod from the main stem HR and the Hackensack River (tributary of Newark Bay) exhibited two non-synonymous genetic polymorphisms (one six base deletion and one SNP) in AHR2 (the predominant form of AHR in fishes) that were nearly absent in tomcod from six other Atlantic Coast estuaries including the two in closest proximity to the HR. In contrast, haplotype frequencies at the selectively neutral mtDNA control region were significantly correlated with geographic distance indicating that the genetic dissimilarity of the Hudson River population at functionally important AHR2 was not observed at a selectively neutral locus. The variant AHR2 proteins were in vitro expressed and compared for their functional significance in two assays. In ligand binding assays, the HR-specific AHR2-1 protein was impaired compared to the more common AHR2-2 protein in binding TCDD. The HR AHR2-1 protein was also less able to drive gene expression in transient transfection assays in AHR deficient mammalian cells treated with TCDD or PCB126 than the more common AHR2-2 protein. Additional transfections with recombinant AHR2s demonstrated that the six-base deletion in AHR2 is the mechanistic basis of resistance. We are now attempting to chronicle the timing of the onset of resistance in the HR population using tomcod archived in museum collections. Our results show that the HR tomcod population has undergone rapid evolutionary change probably due to contaminant exposure. This is the first demonstration of the mechanistic basis of resistance to contaminants in a vertebrate population and shows that rapid evolutionary change can result from one variant in a single gene.

468 Evidence of Metal Effects in Wild Yellow Perch Using Biometric, Biochemical, Physiological and Molecular Approaches P. Couture, INRS, Centre Eau Terre Environnement; P.G. Campbell, INRS-Eau, Terre et Environnement, INRS-ETE, , INRS, Centre Eau Terre Environnement; L. Bernatchez, Universite Laval, Département de Biologie; F. Pierron, CNRS. Metal accumulation and toxicity to fish has been extensively studied in the laboratory. In the field, however, fish living in metal-contaminated sites have typically lived under conditions of low-level, chronic metal exposure for several generations and may have adapted to some extent to metal stress. Furthermore, variations in natural factors like temperature, food availability, competition and predation may diminish or exacerbate metal toxicity, making it difficult to discriminate metal effects on fish health from natural variations. The yellow perch (*Perca flavescens*) is ubiquitous in North American freshwaters and is particularly abundant in areas of Canada where intense metal mining and smelting activities take place. With over 50 publications examining metal accumulation and effects in this species, conducted mostly in the mining regions of Sudbury (Ontario) and Rouyn-Noranda (Québec) where the contaminants of highest concern are Cd, Cu and Ni, the yellow perch is starting to emerge as an ideal model species for the investigation of metal effects in wild fish. These studies have demonstrated that metal-contaminated wild yellow perch face energetic constraints yielding to lower aerobic capacities (as indicated by enzyme activities, swim performance and respiration rates), growth rate and energy accumulation. The expression level of genes encoding for proteins involved in metal detoxification (metallothioneins), protein protection (heat shock protein-70), growth (insulin-like growth factor-1), aerobic energy metabolism (cytochrome c oxidase, cco-1) and protection against oxidative stress (Cu/Zn superoxide dismutase) and the activity of the CCO enzyme were affected by metal contamination. Using the 454 sequencing technology, we reported that exposure to Cd and Cu was associated with a decrease in the transcription levels of numerous genes involved in protein biosynthesis, in the immune system and in lipid and energy metabolism. The recent development of a 1000-gene microarray opens up further research opportunities. A population genetics study revealed that long-term metal contamination can also yield to bottlenecks and decreased genetic diversity. Indirect (food-web induced) metal effects and natural, seasonal variations in health indicators have also been demonstrated. We will review available evidence that a combination of biometric, biochemical and molecular tools can help discriminate metal effects from natural factors in wild yellow perch.

469 Bisphenol A Modulates Expression of Sex Differentiation Genes in the Self-fertilizing Fish, *Kryptolebias marmoratus* J. Lee, Hanyang Univ, Dept of Chemistry, Hanyang Univ Graduate School, Dept of Chemistry; Y. Lee, Sangmyung Univ, Dept of Green Life Science. Endocrine disrupting chemicals (EDCs) have been a major concern in the normal reproduction and development of aquatic organisms. In the teleost, steroid hormones are synthesized via the steroidogenesis pathway, and play a key physiological role in the regulation of gonadal sex differentiation. The protogynous hermaphroditic fish, *Kryptolebias marmoratus* is the only vertebrate capable of reproducing through internal self-fertilization. To uncover the effect of bisphenol A (BPA) on sex differentiation genes on transcription, we investigated the expression patterns of several sex differentiation-related genes such as dax1, dmrt1, mis, sf1, figl˛, StAR and wt1 after BPA exposure with controls (E2 and TMX). In response to 17-estradiol (E2) exposure, a testis-specific gene, dmrt1 mRNA was down-regulated in the gonad of the secondary male but the expression of the female-specific gene, dax1 mRNA was significantly elevated in the brain and gonad. A high level of StAR mRNA was detected in the brain and gonad of both hermaphrodite and secondary males, suggesting that the elevated expression of dax1 and StAR genes would be involved in E2 exposure. As expected, upon BPA exposure, the dmrt1 and MIS mRNA level decreased in both hermaphrodite and secondary males, while the female-specific gene, figl˛ mRNA level increased in the gonad of both genders. BPA showed an opposite mode of action on the expression of dax1 (induction, $P > 0.05$) and sf1 mRNA (inhibition, $P > 0.05$) in the brain and gonad against both genders. The sensitivity of dax1

to BPA on expression was relatively high in the secondary male. The wt1 mRNA was up-regulated in most tissues except in the liver of BPA-exposed secondary males. Regarding the time course study, the figl, mRNA level increased at 6 h after BPA exposure. In addition, BPA elevated the expression of StAR, dax1, and wt1 mRNA but repressed sf1 mRNA. In this paper, we demonstrated that BPA may modulate the expression of sex differentiation and steroidogenesis pathway genes, and this finding would provide a better understanding on the modulation of transcription upon BPA exposure in steroidogenesis and sex differentiation in the hermaphroditic fish, K. marmoratus.

470 Determining the Relative Phytotoxicity of Rapidly Dewatered Oil Sands Tailings J. Cutter, J. Germida, Univ of Saskatchewan; S.A. Armstrong, Shell Health; J. Reid, Shell Canada; B. Fahlman, K. Peru, J. Headley, Environment Canada. Atmospheric fines drying (AFD) is a new tailings treatment strategy being piloted at Shell Canada's Muskeg River Mine near Fort McMurray, Alberta. The AFD process involves adding a polyacrylamide polymer to the tailings which are then thinly spread over a sloped disposal area to rapidly dewater.Hydroponic experiments using cattail (*Typha latifolia*) and common reed (*Phragmites australis*) were conducted to evaluate the relative phytotoxicity of AFD release and runoff waters in comparison to the reclaim water of traditional tailings deposits. Plant health was assessed by examining water uptake and fresh weight gain. Significant differences were found between the transpiration of control plants and plants grown in tailings water however, no statistically significant differences were found between the waters associated with different tailings treatments (traditional reclaim and AFD) on the effect of water uptake (α=0.05). Significant differences were also found between the fresh weight gain of control cattail and cattail subjected to the different tailings treatments (α=0.05) but not between treatments of MFT and AFD waters. As naphthenic acids have been identified to contribute to the toxicity of oil sands tailings, they were isolated and investigated for differences in these two types of waters. Naphthenic acids were monitored at the start and end of each experiment to test for any biodegradation or plant uptake. Results indicate that AFD release waters have a similar relative toxicity as the reclaim waters from MFT tailings and therefore will not likely increase the environmental hazard of oil sands tailings.

471 Comparison of Ozonation and Reclamation Pond Biodegradation as Treatments to Eliminate Oil Sands Process Water Toxicity in *Chironomus dilutus* J. Anderson, S.B. Wiseman, Univ of Saskatchewan, Toxicology Centre; N. Wang, Univ of Alberta, Dept of Civil and Environmental Engineering; L.A. Perez, Univ of Alberta, Div. Analytical & Environmental Toxicology; M.G. ElDin, Univ of Alberta, Dept of Civil and Environmental Engineering; J.W. Martin, Univ of Alberta, Dept of Laboratory Medicine and Pathology; K. Liber, Univ of Saskatchewan, Toxicology Centre; J.P. Giesy, Univ of Saskatchewan, Biomedical Veterinary Sciences & Toxicology Centre, Michigan State Univ, Dept of Animal Science. Global energy demands are driving a shift from conventional oil sources to alternatives such as oil sands. Canada hosts the second largest oil reserves, most of which is located within the Alberta oil sands. Bitumen extraction using hot water and caustic soda results in oil sands process water (OSPW). Over a billion m^3 of OSPW are held in settling ponds and this volume will increase due to a zero-discharge policy. OSPW is saline, alkaline, and contains high naphthenic acid (NA) concentrations. NAs are a group of carboxylic acids implicated as the primary cause for acute and chronic toxicity of OSPW. Several different approaches have been used in experimental reclamation ponds in an effort to eliminate OSPW toxicity by reducing NA concentrations via biodegradation. Ozonation has also been proposed for treatment of OSPW. To compare the effectiveness of natural aging and ozonation as methods of reducing the toxicity of OSPW, studies were conducted using *C. dilutus,* a model benthic invertebrate. Water was sampled from 3 reclamation ponds: Big Pit (mature fine tailings (MFT) capped by freshwater in 1993), FE5 (MFT capped with OSPW in 1989), and TPW (OSPW aged since 1993). In addition, relatively 'fresh' OSPW was collected from the West In-Pit (WIP) and was ozonated with 30 mg/L or 80mg/L O_3. Both a 10-day and long-term exposure assay were conducted using 8-9 day old larvae. Following the 10-day exposure, there were no differences between growth and survival in any of the reclamation pond waters compared to freshwater controls. WIP-exposed larvae were 64-77% smaller than the controls ($p< 0.05$), while ozonation of WIP attenuated growth inhibition. After chronic exposure, there was significantly less pupation in the FE5 group compared to the controls ($p< 0.05$). Exposure to untreated OSPW delayed male pupation ($p< 0.01$) and reduced adult emergence ($p< 0.05$), both of which were improved by ozonation. Emergence was significantly impaired in TPW ($p< 0.01$), with delays in both male and female emergence ($p< 0.05$). Females were also delayed in the Big Pit treatment ($p< 0.05$). These results suggest that in spite of reduced NA concentrations in reclamation ponds, there is still residual chronic toxicity of OSPW that impacts *C. dilutus* development and reproduction. Ozonation attenuates growth and reproductive effects and may be beneficial in combination with biodegradation as aging alone is not sufficient to eliminate OSPW toxicity.

472 In Vivo and In Vitro Bioassays for the Evaluation of OSPW Immunotoxicity: Potential Tools for Evaluating OSPW Remediation Processes E. Garcia-Garcia, Univ of Alberta, Biological Sciences; J. Ge, A. Oladiran, Univ of Alberta, Dept of Biological Sciences; M.G. Din, Univ of Alberta, Dept of Cival and Environmental Engineering; L.C. Perez-Estrada, J.W. Martin, Univ of Alberta, Dept of Laboratory Medicine and Pathology; M. Belosevic, Univ of Alberta. Large volumes of toxic aqueous tailings are produced in northern Alberta by the oil sands industry. Naphthenic acids (NAs) are thought to be the major toxic component in Oil Sands Process Water (OSPW), according to bacteria-based toxicological assays. In addition to NAs, OSPW organic fraction contains a complex mixture of compounds that may also be toxic particularly to multicellular organisms. We developed in vitro and in vivo bioassays to evaluate the toxicity of OSPW organic fraction in mice. A popular commercial NAs preparation from Merichem Chemicals was found not to be an adequate model for the study of OSPW NAs toxicity, as it had very different effects on mouse immune mechanisms, compared to the extracted organic fraction of OSPW (OSPW-OF), containing equivalents NAs amounts. Ozonation has recently been used as an efficient method for degrading OSPW NAs and decreasing its toxicity towards bacteria. We tested whether ozonation reduced OSPW immunotoxicity, through the degradation of NAs, and other unidentified OSPW contaminants potentially involved in the observed alterations in immune responses of mice. In vitro exposure to OSPW-OF decreased the ability of bone marrow-derived macrophages (BMDM) to produce nitric oxide, reactive oxygen intermediates, and decreased the ability of macrophages to engulf particles. Decreased nitric oxide and reactive oxygen intermediate production was related to down-regulation of gene expression of the inducible nitric oxide synthase and NADPH oxidase subunits, respectively. OSPW-OF also altered gene expression of pro-inflammatory cytokines in BMDM. Oral administration of OSPW-OF to mice altered gene expression of pro-inflammatory cytokines and chemokines in the mesenteric lymph nodes and the liver. OSPW ozonation, before extraction of the organic fraction, completely abrogated the effects of OSPW-OF in vitro, and returned the expression of most cytokine genes to control levels in vivo. Our results indicate that ozonation may be a valuable treatment process for the remediation of the large volumes of water in oil sands tailing ponds. The in vitro and in vivo assays developed in this study will be valuable tools for the evaluation of different OSPW remediation regimens.

473 A New Integrative Monitoring Program for the Canadian Oil Sands F.J. Wrona, P.D. di Cenzo, D. Wicklum, Environment Canada; P. McEachern, Alberta Environment; K. Schaefer, Environment Canada. The Canadian Oil Sands, which comprise 97% of Canada's 176 billion barrels of proven oil reserves, are located beneath 140,200 km2 of boreal forests, prairies and wetlands, and are the second largest known deposit of crude oil in the world. Presently, the resources being recovered are located in north-eastern Alberta in three main regions: Athabasca, Cold Lake, and Peace River. The Athabasca River and tributaries flow through the oil sands deposits, eroding the oil-containing sands and interacting with groundwater systems also in contact with the oil formations. Primary environmental concerns regarding water quality, quantity and ecosystem health related to oil sands development are within the lower portions of the Athabasca River catchment, primarily downstream of Fort McMurray, Alberta, although they are potentially farther reaching. Within the Lower Athabasca basin, and in particular in the oil sands region, both "pulse" and "press" environmental stressors, and related impacts, are occurring. These affect both the temporal and spatial variability in observed responses and influence the spatial and temporal replication necessary to detect impacts with sufficient statistical power. In response to criticisms of current monitoring activities in the Canadian Oil Sands region, the Canadian Minister of the Environment committed Environment Canada to lead, in collaboration with Alberta

Environment and relevant stakeholders, the development and implementation of a new, integrative monitoring program for the oil sands region. A new monitoring program has been developed, utilizing an ecosystem-based, integrative, mass-balance approach, which builds upon and integrates existing monitoring efforts into an adaptive, and holistic system. The program design is adaptive – alterations in spatial coverage and temporal sampling frequency is linked to science-based (and policy-relevant) decision-triggers. A key objective is to maintain required statistical rigour to understand, predict and report on the status and trends of water quality and quantity, accumulated state, changes in ecosystem structure, function and health and ultimately determine cumulative impacts. The program design will be continually assessed and refined based on stakeholder feedback and new science findings. This presentation provides a scientific and technical overview of the new program and highlights key challenges and steps in its implementation.

474 Development of a Comprehensive Aquatic Biomonitoring Program for Canada's Oil Sands Areas J.L. Parrott, Environment Canada, Environment Canada, National Water Research Institute, Environment Canada; M.E. McMaster, Environment Canada, National Water Research Institute; F. Wrona, P. di Cenzo, N. Glozier, J.M. Culp, Environment Canada. Canada's Minister of the Environment committed Environment Canada to lead, in collaboration with Government of Alberta and relevant stakeholders, the development of a preliminary surface water quality, biodiversity and effects monitoring plan for the lower Athabasca River. The biodiversity and effects monitoring component includes recommendations for the sampling of multiple trophic levels in the main stem of the Athabasca River, its major tributaries, and smaller streams in the area between Fort McMurray and Wood Buffalo National Park Boundary. The Fish monitoring program consists of assessment of sentient adult fish to determine if there are differences in the growth, reproduction, survival or condition of fish. Young of year fish will also be assessed on tributaries, to check for recruitment and growth effects. As well, fish communities will be surveyed at selected sites in order to assess potential changes over time and to understand community structure. The plan will also monitor concentrations of contaminants in fish tissue as an indicator of fish exposure and human usability. The proposed design for assessing ecological effects on benthic biota will include community assessments of both the algae and macroinvertebrates associated with the benthic environment. Assessments will consider changes in ecological function (e.g., food webs, river metabolism) and ecological traits related to factors such as life history and morphology. Finally, contaminant levels in biota and sediments will be measured, at least in part, to relate to upper trophic levels. Sampling will be multi-habitat in nature and tiered depending on priority areas or response patterns. The program will determine whether or not oil sands mining activities are having an effect on fish and benthic biota.

475 Assessing Spatial Patterns of Polycyclic Aromatic Compounds (PACs) in the Oil Sands Region Using Passive Air Samplers T. Harner, Environment Canada, Atmospheric Science & Technology Directorate; S. Genualdi, Environment Canada, Science And Technology Branch; J. Karpowicz, C. Mihele, C. Banic, P. Blanchard, J. Charland, Environment Canada. Development of the oil sands industry in Alberta has led to concerns regarding health risk to humans, and other terrestrial and aquatic wildlife associated with exposure to PACs, particularly along the Athabasca river and its watershed. A study was initiated in November 2010 to monitor air concentrations of PACs in the oil sands region. Passive air samplers comprising polyurethane foam (PUF) disks housed in stainless steel chambers were deployed at 17 sites, some of them close to emission sources while others at varying distances from the active zones. Compounds targeted included 16 PAHs and dibenzothiophene including their C1 to C4 alkylated homologues. The gas-phase sampling rates, sorptive capacities and resulting sample air volumes for PACs in the PUF disks were calculated based on results from previous calibration studies for nonpolar hydrophobic chemicals. For most target compounds, air sample volumes for a 1-month deployment were in the range 120 m3. For the most volatile PACs (e.g., naphthalene and alkylated naphthalenes) 'effective' air sample volumes were substantially lower due to saturation of the PUF disks (i.e., limited capacity for these compounds). The use of isotopically labeled PACs, spiked onto the PUF disks prior to deployment, is being explored as a method to improve the estimation of the sample air volumes. Air concentrations of sum of 16 PAHs in the first period samples (November 2010) ranged from 5-50 ng/m3 and were dominated by naphthalene and phenanthrene. Alkylated PAHs showed greater variability among sites and ranged from 10-1000 ng/m3. Field blanks were below detection for most target compounds. At several sites, PUF disk samplers were co-deployed alongside active air samplers which will allow for further characterization of the performance of the PUF disk sampler for gaseous and particle-associated PACs. The results from this study may also serve as a baseline against which future PAC air concentrations can be compared.

476 Atmospheric Deposition of Inorganics and Polyaromatic Compounds in the Athabasca Oil Sands Region of Alberta, Canada J.L. Kirk, Environment Canada, Research Scientist, Environment Canada; D. Muir, X. Wang, C. Teixeira, S. Backus, C. Mihele, G. Poole, C. Tunks, Environment Canada. Atmospheric deposition may be an important source of contaminants to the Athabasca River and tributaries in the Alberta Oil Sands (OS) region. In fact, Kelly et al., (PNAS vol 106, 2009) reported 2008 snowpack loadings of 391 kg of polycyclic aromatic compounds (PACs) equivalent to 600 T of bitumen to the Athabasca River and its tributaries within 50 km of the OS upgrading facilities. In spring 2011, we conducted similar snow surveys to Kelly et al. to quantify atmospheric loadings of unfiltered and filtered PACs, multi-elements, and mercury (Hg) to the Athabasca River and its tributaries. Snow samples were collected from 30 sites located 0-200 km from the upgrading facilities at maximum snowpack depth (late February-early March). At each site, snow pits were dug down to the bottom of level snow packs and integrated snowpack profiles were obtained using ultra-trace sampling techniques appropriate for each type of contaminant. In addition, heated wet-only precipitation samplers were installed at 3 locations within 20 km of the OS upgrading facilities and sampled monthly from December 2010 to present. Snow and precipitation were analysed for 45 elements by ICP-MS, 64 PACs by XAD resin extraction followed by GC-MS, and for total and methyl Hg by CVAFS. PAC profiles in precipitation were dominated by C1-C4 alkyl PACs, which represented 80-85% of the total PAC. Inorganics in precipitation were dominated by Al, Fe, Mn and Zn and contained ng/L concentrations of heavy metals Cd, Cu, Pb and Hg. Net spring-time loadings of contaminants to the Athabasca River and its tributaries, calculated using concentrations of contaminants in snow and average snow water equivalent, will be presented as well as an analysis of trends in contaminant deposition with respect to distance from the upgrading facilities.

477 Assessment of Snow Melt Waters from Oil Sands Development Areas W.P. Norwood, J. Parrott, Environment Canada, Aquatic Ecosystems Protection Research Division; P. Gillis, J. Kirk, M. Brown, C. Regan, R. McInnis, Environment Canada *Hyalella azteca* (epi-benthic amphipod), *Lampsilis fasciola* (freshwater mussel) and *Pimephales promelas* (fathead minnow) were used to assess the toxicity of snow melt samples collected in the vicinity of the Canadian oil sands process facilities along the Athabasca River. An upstream reference site on the Athabasca River, far from the oil sands, was included in the assessment. Snow samples were collected in early March 2011 prior to spring melt and then shipped back to the laboratory frozen. Acute (24 hr) toxicity was determined with mussel glochidia (larvae) and chronic (28 day) toxicity was determined with juvenile amphipods and early life cycle tests with fathead minnows. The snow melt samples were very low in essential ions, hence they were amended with $CaCl_2$, $NaHCO_3$, NaBr, KCl, and $MgSO_4$ to bring major ion levels up to those observed in the Athabasca River. Amendments reversed any lethal effects on the amphipod due to low ion concentration and improved minnow survival at most sites. However, two sites were toxic to the minnows and no sites were toxic to the amphipods or mussels. An examination of contamination due to airborne pathways will be discussed. Analyses of metals, poly-aromatic hydrocarbons, naphthenic acids, major ions and standard water quality parameters will be used in the evaluation of contamination.

478 Evaluating Human Health and Ecological Risk Assessments and Remediation Decisions: Is the Cure Worse than the Disease? J. Toll, Windward Environmental LLC. This presentation will address the question of whether risk assessment and risk management practice should give precedence to the precautionary principle, or the Hippocratic principle "first do no harm." The purpose of the presentation is to set the theme for the rest of the session. The session is intended to provide real examples of where (and how) a risk manager balanced a conservative risk estimate against the "cons" of more stringent remedial actions in order to achieve a better outcome. We will challenge the session's presenters to consider the implications of conducting risk assessments under the premise that it's better to err on the

side of conservatism in the face of uncertainty. We will question whether this principle is appropriate for protecting human health and the environment. Does it deliver maximum benefit to local human and ecological communities? If not, then what are the opportunity costs? What if an assessment leads to an invasive remedy that damages or destroys habitat or other ecosystem assets (open space, recreation opportunities, etc.)? Is there harm associated with extensive remedies that do not yield promised reductions in health risk? Does overestimation of risk lead to faulty decision-making in selection of remedial alternatives? Are we as risk assessors and risk managers doing enough to account for the risk of remedy in our actions and decisions? Should managers focus on more than risk reduction as their performance objective?

479 An Evaluation of Remedial Alternatives within the Context of Human Health and Ecological Risks Within an Urban Watershed S.L. Sager, T. Schlekat, D. Malone, R. Lepsic, ARCADIS. Historical releases at a former chemical storage facility resulted in impacts to soil, groundwater, soil gas, and potentially surface water. The site is located in an urban area with mixed residential, commercial, and industrial properties. As surface water impacts were identified, GoreTM Module surveys were used to identify sources and migration pathways within the local drainage basin. The survey indicated that one of the transport pathways originates at the former storage facility while the other potentially originates from any of the multiple industrial chemical sources west of the facility. These two plumes merge and ultimately discharge to the urban surface water body. The receiving stream is rated as "Impaired" in all segments for aquatic life because the state surface water quality criterion for turbidity was violated. A variety of constituents typical of an urban environment as well as chlorinated solvents have been detected in the stream. Both a human health risk assessment (HHRA) and a screening level ecological risk assessment (SLERA) were conducted to evaluate the stream. The results of the HHRA indicated no significant risk to receptors wading in the stream while the results of the SLERA indicated a potential threat to ecological receptors. As remedial alternatives are considered, the likelihood of successful reduction in constituent concentrations is an influence on the overall strategy. If source control at the former chemical storage facility does not result in improvement in concentrations in the stream and human health is protected, then the cost of an active remediation system may not be justified given the existing impaired status of the stream for reasons unrelated to this release. This presentation will discuss the results of the risk assessments within the context of the broader implications of the need for remediation within an impaired ecosystem.

480 Risks of Intact Residential Lead Based Paint Versus Risks of Remediation B. Magee, A. Weaver, ARCADIS. Risk assessments often lead to decisions to take action to remediate baseline risks. Proposed remedial actions are rarely evaluated against the baseline risks to ensure that the remedy does not cause more harm than good despite the presence of Federal and State laws and regulations that generally require such risk comparisons. This presentation discusses a case study of a proposed remedial action of a massive scale and a comparative risk evaluation demonstrating that the proposed remedial action would have many negative unintended consequences. The proposal was made by a State Attorney General that all residential building components that contained lead-based paint throughout the entire State, whether intact or deteriorated, be removed or enclosed. It was proposed that all doors, windows, trim, and selected other building components be removed and replaced and that all other components, like walls, floors, and ceilings, be enclosed in place. The massive project was estimated to cost $2.4B over four years. The Attorney General failed to consider that the mobilization of an estimated 10,000 workers to inspect homes, remove and replace building components, construct coverings over other building components, haul construction debris to landfills or incinerators, and perform all of the other elements of the proposed plan would present many health and safety risks to the workers and residents of the State. Adverse impacts discussed in this paper include: increased fatality rates due to automobile and truck traffic; increased injury rates due to automobile and truck traffic; increased cancer and respiratory injury rates due to increased vehicle emissions; increased effects on global climate change due to increased vehicle emissions; increased traffic due to delivery of construction materials and disposal of waste; increased injury rates from construction activities; increased rates of childhood and adult asthma; increased injuries to residents associated with moving personal belongings; increased stress to residents due to disruption in daily routines; increased losses of, or damage to, personal property; increased need for temporary housing; and increased requirements for public safety services.

481 Integrated Environmental Benefit Analysis of Sediment Remediation Thresholds A. Morrison, Exponent, Inc., EcoSciences; S. Kane Driscoll, M.E. McArdle, Exponent, Inc.; C. Menzie, Exponent, Inc., Exponent, Principal. Decisions regarding sediment remediation must consider not only the magnitude of the risk, but also the expected effectiveness of the remedy and the potential harm of the remedy in relation to short-term and long-term effects. All of these considerations can be integrated into an environmental benefit analysis that places site-specific remedial actions within the broader context of risk reduction and remedial impact. An integrated environmental benefit analysis (IEBA) was conducted for a New England river that was impacted by metal contamination. The river was sub-divided into five reaches that are bordered by various types of habitat, including industrial and residential areas, and a large recreational park with extensive areas of aquatic vegetation. Two alternative preliminary remedial goals (PRGs) were developed based on an ecological and human health risk assessment. Both PRGs (220 mg/kg and 400 mg/kg) for sediment are fully protective of human health, wildlife, and bioaccumulation of the metal into blue crab tissue (a human health risk issue); however, the site-specific community analysis results for benthic invertebrates were ambiguous. The objective of the IEBA was to compare the benefits of dredging to remove sediments with concentrations greater than 220 mg/kg versus concentrations greater than 400 mg/kg. The percent of function, or "services", lost was calculated for each type of receptor for both remediation scenarios, and for natural recovery. These calculations estimated the percent of potentially lost services that a receptor is currently experiencing, will likely experience if current conditions prevail, or will likely experience if remediation is conducted. Estimates of percent services lost were quantitative if data were available and qualitative if data were unavailable. The area-weighted service loss for each reach of the river was combined with the estimated time to recovery for each remediation scenario. A comparative matrix of results indicated that, for most receptors and reaches of the river, outcomes under the two PRGs were comparable; however, impacts related to implementation of the 220 mg/kg PRG were much greater than the 400 mg/kg PRG in the largest reach of the river because the surface area to be dredged was substantially larger, and impacts to areas of aquatic vegetation habitat were greater. IEBA was useful in the negotiation of a remedial action plan for the river.

483 Meeting Risk Management Goals and Minimizing Remedial Impacts for a PCB Contaminated Floodplain – The Habitat Enhancement Option A.L. Fogg, M.H. Henning, A.R. Glessner, N.R. Pinheiro, ENVIRON International Corporation; J.M. Johnson, Bridgestone Americas, Inc. Risk assessments demonstrated that local residents and wildlife populations in an undeveloped forested floodplain of Stony Creek, located in Noblesville, Indiana (USA) are unlikely to be at risk from exposure to PCBs in floodplain soil. However, given the presence of PCB-contaminated soils with elevated concentrations in two areas of the floodplain, remedial alternatives were evaluated through a Corrective Measures Proposal (CMP). Alternatives evaluated included no action, monitored natural recovery, habitat enhancement and vegetative stabilization, capping, and focused excavation. Risk of remedy and accordance with Green Remediation practices were among the factors considered in the CMP. Based on this analysis, the US Environmental Protection Agency Region 5 selected habitat enhancement with vegetative stabilization as the corrective measure for the undeveloped floodplain. This remedy offers a net benefit to environmental conditions; is favored by the public; results in only minimal disruptions to the community during implementation; preserves the character of the land bordering residential housing; and minimizes short-term risks. Habitat enhancement involves erecting approximately 50 bat boxes to provide immediate improvement in roosting habitat for bats (including the Indiana bat) and planting 100 seedlings of tree species favored by the bat to provide long-term habitat improvement. Vegetative stabilization of floodplain soil, which involves planting five native herbaceous groundcover species, is expected to reduce soil erosion and human and ecological contact with PCB-contaminated soils in two areas with elevated concentrations. Important considerations and challenges in design, implementation, and monitoring are discussed.

484 Guidance to Assist in the Interpretation of CCME Water Quality Guidelines for the Protection of Aquatic Life Exceedances S. Rodney, Intrinsik Environmental Sciences, Inc.; S. Teed, Intrinsik Environmental

Science Inc., Intrinsik Environment Sciences Inc.; S. Roe, Environment Canada, National Guidelines and Standards Office; T. Fletcher, Ontario Ministry of Environment, Standards Development Branch; C. Crane, Prince Edward Island Dept of the Environment. The misapplication and misinterpretation of water quality guidelines is a significant issue in risk assessment. Guidelines are generally considered to be conservative estimates of the potential for adverse effects, but when they are incorrectly applied there can be implications to aquatic ecosystem protection, costs of remedial action, and risk management. The interpretation and significance of a water quality guideline exceedance is logically dependent on two principal factors: (1) how the guideline was derived, and (2) how the exceedance was determined (including the statistical approach, the quality of the data, the quantity of the data and how representative the data are of the water under investigation). A comprehensive review of documentation from North American and several international jurisdictions revealed that there is currently no specific guidance available on the application of water quality guidelines and the interpretation of exceedances. Most jurisdictions that derive or apply guidelines have comprehensive documentation outlining how their benchmarks are derived (e.g., CCME, USEPA, etc.). Although some of those jurisdictions provide guidance on sampling and statistics for establishing exceedances, few demand precise data requirements and/or exact statistical approaches. As such, the interpretation of benchmark exceedances is complicated by the myriad of datasets collected and computational methods that may be used to establish "exceedances". Further, ecotoxicity data are generally limited, and there are numerous other sources of uncertainty (e.g., laboratory-to-real world extrapolations). Thus, there are many sources of uncertainty around any given benchmark value for the protection of aquatic life. These uncertainties typically are unquantified and therefore interpretations of benchmark exceedances with respect to the likelihood of adverse ecological effects cannot be afforded greater confidence than the benchmark on which they were established. This guidance is intended to assist in the interpretation of exceedances of Canadian Water Quality Guidelines for the Protection of Aquatic Life. The guidance will assist environmental quality managers in determining when a benchmark exceedance is likely to, or could potentially lead to, ecologically-significant adverse effects to aquatic organisms.

485 The Importance of Natural Recovery Rate Estimates for Application of Risk Assessment Outcomes to Remedial Decisions J. Field, Office of Response & Restoration, NOAA, Assessment and Restoration Division, Office of Response & Restoration, NOAA, Coastal Protection and Restoration Division; J. Kern, Kern Statistical Services, Inc.; L. Rosman, Office of Response & Restoration, NOAA. Many individual assumptions in a risk assessment may be considered “conservative” without qualifying the overall risk assessment or its’ application to decision-making as conservative. Temporal models are necessary to evaluate changes in exposure concentrations that would result from different remedial alternatives, including monitored natural attenuation. Without good estimates of temporal change in exposure concentrations, even using conservative risk assessment thresholds may lead to non-conservative remediation decisions. In this paper, we discuss how the overestimation of the rate of natural attenuation for sediment sites can affect discrimination among remedial alternatives and the projected time to achieve remedial action objectives. As an example, complex natural recovery models developed for the Hudson River PCBs Superfund site substantially over-estimated the rate of recovery. Surface PCB concentrations observed during remedial design sampling were higher than the upper bound of model uncertainty estimates and the concentrations following remediation are estimated to be about 5X higher than anticipated in two of three river sections, likely delaying recovery. Other sites have used approaches such as re-sampling of previously sampled locations or evaluation of dated cores to estimate rates of natural attenuation. We present recommendations for assessing temporal changes in exposure concentrations as part of the site characterization sampling plan.

486 Advances in Ecological Modeling for Assessing Ecological Risks and Ecosystem Services J.D. Stark, Washington State Univ, Puyallup Research and Extension Center, Dept of Entomology, Washington State Univ, Dept of Entomology. Ecosystems provide many services to human populations, including fresh water, fertile soils, pollination, climate regulation, pest control, and the decomposition of waste. Although all ecosystem services cannot be maximized all of the time everywhere – often there are tradeoffs (e.g., food production versus conservation of biodiversity), it is imperative that we work to protect these natural assets as best as possible. Protection of the environment from human disturbance is usually accomplished through the process of ecological risk assessment. However, this process relies heavily on protection of the individual organism even though protection of populations is more important. Ecological modeling, along with standardized data packages for chemicals, can help us better protect ecosystem services by providing less uncertain risk assessments. In this talk I will provide an overview of ecosystem services and how population modeling may help improve the protection of these important assets.

487 Modeling Ecological Effects in the USEPA G.W. Suter, US Environmental Protection Agency, National Center for Environmental Assessment, USEPA, National Center for Environmental A; W.R. Munns, US. EPA, Atlantic Ecology Division. While simulation models are used routinely by the US Environmental Protection Agency to estimate exposure for regulatory purposes, exposure-response modeling is largely empirical. Examples include concentration-response and dose-response relationships and species sensitivity distributions. These models are used because they are familiar and easily understood, are sufficient for most routine decisions, are equivalent in human and ecological risk assessments, are supported by policy and legal precedent, and add relatively little new uncertainty to assessments and decisions. However, the Agency has developed population and ecosystem simulation models and has applied them in some cases. These models have the advantages of incorporating mechanistic relationships, being predictive of outcomes under various management scenarios, and estimating endpoints that are more readily treated as benefits in economic analyses. Unlike exposure models, most effects simulation models developed by the USEPA remain research tools, with limited application in regulatory contexts. Examples include biologically-based dose response models, a variety of population dynamics models, vegetation growth models, linked Bayesian networks & community dynamics models, and energy-based models. Effects models are adopted by the Agency when they are scientifically defensible and have been demonstrated to result in better decisions. An example is the biotic ligand model which has been used to set water quality criteria.

488 Aquatic Ecosystem Models for Risk Assessment: EPA Tools and Applications B. Rashleigh, US Environmental Protection Agency, Research Ecologist; D.H. Miller, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division; R.G. Kreis Jr, US Environmental Protection Agency. Aquatic ecosystems are subject to multiple, interacting pressures, including climate alteration, habitat alteration, toxics, and invasive species. Ecosystem modeling is a powerful tool for the assessment of risks associated with these pressures. The US Environmental Protection Agency (EPA) has developed two main models in this area. The AQUATOX model simulates the fate of pollutants, such as nutrients and organic chemicals, and their effects on the ecosystem, including fish, invertebrates, and aquatic plants. The Lake Michigan Ecosystem (LM-Eco) model has focused on assessment for the Great Lakes. LM-Eco is spatially explicit and track densities of 12 ecological compartments, including the representation of invasive mussel species. For both models, assessment of risks associated with pressures is conducted through development of baseline scenarios, calibration with field data, and comparison of alternative scenarios of impact and for restoration. Future directions for this modeling include linking aquatic ecosystem models within model frameworks to simulate future inputs and landscape changes and translate model outputs to ecosystem services and measures of sustainability.

489 DEB-IBM, A Generic Individual-based Population Model Based on Dynamic Energy Budget Theory, Correctly Predicts Population-level Effects of Toxicants B. Martin, Helmholz Centre for Environmental Research, Dept of Ecological Modelling; E. Zimmer, Vrije Universitet Amsterdam, Dept of Theoretical Biology; T.G. Preuss, RWTH Aachen Univ, Institute for Environmental Research; T. Jager, Vrije Universitet Amsterdam; R. Nisbet, Univ of California, Santa Barbara, Ecology, Evolution & Marine Biology; V. Grimm, Helmholz Centre for Environmental Research, Dept of Ecological Modelling. Tools are badly needed that help extrapolate the results of individual-level toxicity tests to the population level, including sub-lethal effects and different exposure scenarios. Population models can be such a tool. However, developing, parameterizing and testing such models is a major task and cannot be done from scratch for all species of interest. Therefore, population models should be based more on first principles so

that the same model structure could be used for a wide range of species. Dynamic Energy Budget (DEB) theory provides such first principles. It has been used extensively for the analysis of the lethal and sub-lethal effects of toxicants on individuals. The process-based approach used in the DEB analysis of toxicity experiments differs from standard ectoxicological analysis (LC50, ECx, ect.) in that it includes exposure time as an explicit factor, links the effect to the internal concentration of the chemical, and explains the effects on different traits in one coherent framework. We developed a generic implementation DEB theory in an individual-based (IBM) context, DEB-IBM (http://cream-itn.eu/projects/wp-1/daphnia-2/deb-ibm). We parameterized DEB-IBM for *Daphnia magna*, using individual-level data on growth and reproduction, and compared population-level predictions with results from experiments. The model correctly predicted population dynamics (abundance and size structure) under control conditions. The same model correctly predicted the effect of the toxicant 3,4 dichloroaniline at the population level from data available in standard OECD tests. The advantage of developing such a model is, that when well tested, we can use it to understand how varying exposure scenarios or environmental conditions, would influence the population-level response to a toxicant. Lastly, because DEB can be used to model, in principle, all animal species, we believe DEB-IBM has great potential for population-level risk assessment because the same general model structure can be used for different test organisms.

490 Ecological Models in Risk Assessment – A Regulatory Perspective M. Reed, Chemicals Regulation Directorate. Ecological models allow environmental risk assessments account for effects on populations rather than single species in laboratories. A variety of models have been developed, particularly for aquatic organisms, birds and mammals, but their use in regulatory risk assessments has so far been limited. One of the benefits of ecological models is they can be used to link the output from toxicity tests and predictions of exposure directly to protection goals. Ecological models are routinely used in other areas of ecosystem decision making, e.g., fisheries management. The use of the ecosystem services approach has highlighted that for most groups the entity that needs to be protected is the (meta) population, although for vertebrates the individual may be important. In this context, ecological models are particularly useful for aquatic and terrestrial invertebrates to assess the impact on populations where either acute or chronic effects are predicted from laboratory data. For vertebrates they are useful where the chronic effects are predicted and a more ecologically realistic assessment is required. When considering an ecological model for risk assessment a regulator will have a number of questions in their mind: Is the model appropriate? Has it been validated? Are the input parameters justified? What are the critical parameters? What does the output mean? How does it relate to the protection goals? These areas need to be addressed. Any modeling approach also needs to be fitted within the context of the overall risk assessment. Where models are submitted for regulatory use it is important for the regulator to have confidence that the model is sensitive enough to detect adverse effects that may occur in real ecosystems in the same way that a toxic standard is used to test the sensitivity of laboratory and field systems. Another issue that needs to be addressed is whether a suite of standard models (similar to the routine use in exposure modeling) is needed or whether individual models should be produced to answer specific questions. Ecological modeling (via standard models) has been highlighted as necessary to address the specific protection goals currently being developed. In other areas the questions to be resolved are pesticide specific, so there will be a need for bespoke models. Although experience of evaluating ecological models for pesticide registration has so far been limited important lessons have been learnt about how models should be presented and applied.

491 Including Ecosystem Services in Risk Assessments: Using Ecological Modelling to Link Ecotoxicological Data with Protection Goals P. Thorbek, Syngenta Ltd, Environmental Safety, Syngenta, Environmetal Safety; P. Edwards, R. Murfitt, D. Huggett, Y. Bramley, E. Farrelly, Syngenta Ltd, Environmental Safety; R. Brain, P. Hendley, Syngenta, Environmental Safety. The European Food Safety Authority (EFSA) recently published an opinion regarding environmental protection goals which was based on the ecosystems services concept. The opinion stated that, for most ecosystem services, the protection goal is at the population level of organisation (although for vertebrates the protection goals may remain at the individual level for cultural reasons). This is in contrast to current standard ecotoxicity data requirements for pesticide registration that are focused at the level of individuals. However, ecological modelling can make use of standard data to assess the potential risks that exposure to pesticides may present to populations or higher levels of organisation and is compatible with current regulation. Here we propose a tiered system for how ecological modelling can bridge the gap between data at the level of individuals and the protection goals. We then present examples of how different types of ecological modelling can be used to refine ecological risk assessments for different pesticides. The first example demonstrates how a simple, worst case, toxicokinetic model based on field bird feeding rates can help refine avian risk assessment. The second example shows how an individual-based population model was used to perform a population level risk assessment for invertebrates. Finally we demonstrate how ecosystem models can be used to assess the risk of indirect effects on aquatic ecosystems. These examples demonstrate how ecological models can help refining risk assessments and extend the use of standard data to increase the relevance of risk assessments for protection goals.

492 Internal Dose Metrics and Toxicokinetic Modeling as the Link between Intentional Dosing and Environmental Exposure W. Schmitt, Bayer CropScience AG, Bayer CropScience AG, Environmental Modelling. A challenge frequently arising in ecological risk assessments for xenobiotics is the extrapolation from exposure patterns, typically applied in toxicity tests, to realistic exposures as they occur in nature. Basing the risk assessment on internal concentrations, i.e., the body burden, instead of external exposure leads to a solution for this issue. For the translation between external and internal exposure toxicokinetic (TK) models are needed that take into account the relevant fate processes as absorption, metabolism and excretion as well as species specific behavior like feeding patterns and avoidance. The methodology of TK modeling is in principle applicable to all kinds of biota and thus also in terrestrial as well as aquatic risk assessments. The complexity of the models, however, may vary strongly depending on the species they are developed for and the specific situations to be dealt with. In aquatic risk assessments for pesticides it is an often occurring situation that the exposure in water bodies close to treated fields is very transient, while the toxicity is determined under more or less static exposure conditions. For the example of aquatic macrophytes it will be discussed how the consideration of TK applying a suitable model allows to estimate effects of growth inhibiting substances under realistic conditions based on standard test results. A further example will be given on the consideration of feeding patterns of small mammals and birds for the estimation of body burdens in risk assessments. For acute toxicity tests dosing is often done by gavage leading to high peaks in internal concentration while under ecological conditions food uptake is usually distributed over a longer period leading to lower, but potentially longer lasting body burdens. For this purpose a physiologically based toxicokinetic (PBTK) model was developed that allows the consideration of a toxic metabolite in addition to the parent compound.

493 Modelling Honey Bees: Colony Dynamics, Foraging and Parasites M.A. Becher, Rothamsted Research, Plant and Invertebrate Ecology; V. Grimm, Helmholtz Center for Environmental Research – UFZ; P.J. Kennedy, J.K. Pell, Rothamsted Research, Plant and Invertebrate Ecology; D. Chandler, Univ of Warwick; P. Thorbek, Syngenta Ltd., Jeallott's Hill; J.L. Osborne, Rothamsted Research. Substantial losses of honey bee colonies have been reported in recent years. It is believed, that no single factor is responsible for the colonies decline but the interaction of several stressors weaken the colonies until they collapse. Important factors are parasites and diseases, availability of forage and beekeeping practices. To understand the interaction of these factors we have developed a computer model, simulating the dynamics of a single honey bee colony. In order to keep computational time low but to allow for flexibility in the decision-making we combined a cohort based population model with an agent based foraging module. We included the Varroa mite as a bee parasite which acts as vector for two different bee viruses, the deformed wing virus and the acute paralysis virus. Crop maps defining the availability of food sources can be used in a separate, spatially explicit landscape model to allow the application of realistic foraging scenarios with specifically defined nectar flows over time. Exposure of pesticides might be included in a further step. For validation of the model we will take advantage of the considerable datasets already existing (e.g., COLOSS, German Bee Monitoring Project). In this talk we will describe and explain the model's design and how it relates to existing honey bee models. We will then present verifications of the submodels and first results of the full model where in hypothetical scenarios the relative importance of the stressors is

analyzed. Finally, we will outline further steps to be taken with our model and how it could be used for better understanding the decline of honey bees.

494 Critical Radionuclide/Critical Pathway Analysis for the US Dept of Energy's Savannah River Site G.T. Jannik, Savannah River national Laboratory, Environmental Analysis; W. Kuhne, Savannah River national Laboratory, Environmental Analysis, Medical College of Georgia, Institute of Molecular Medicine and Genetics. Many different radionuclides were released to the environment from the Savannah River Site (SRS) during its operational history (1954 – present). However, only a small number of the released radionuclides were relatively significant contributors (via a small number of critical pathways) to potential doses and risks to offsite people. This paper presents the results of the radiological critical-contaminant/critical-pathway analysis currently being performed for SRS. The major steps in performing public radiation dose and risk assessments are (1) characterization and quantification of source terms, (2) calculation of atmospheric and surface water transport (dispersion/dilution), (3) identification and quantification of environmental pathway transport to humans (exposure pathways), and (4) calculation of radiation dose and subsequent risk. The analysis covers radiological releases to the atmosphere and to surface water, which are the principal media that carry contaminants off site. The analysis also incorporates the recent findings of the SRS Performance Assessment and Composite Analysis Programs. In keeping with the theme of this Environmental Radiation Special Session, a concluding discussion of the major uncertainties in the analysis and "what should we know for assessing risks" is provided.

495 Addressing Concerns About Wild Foods Safety in Alaska Following Radiation Releases in Japan L. Verbrugge, US Fish and Wildlife Service, Anchorage Fish and Wildlife Field Office; L. Castrodale, State of Alaska, Dept of Health and Social Services, Division of Public Health, Section of Epidemiology; R. Klein, Alaska Dept of Environmental Conservation, Division of Environmental Health. Many Alaskans rely heavily on wild foods for subsistence, especially Alaska Natives and others that live in remote rural areas with no road access. Following the March 2011 radiation releases from the Fukushima Daiichi nuclear power plant in Japan, state and federal agencies in Alaska received questions from the public about whether radiation was making wild foods unsafe to eat. An inter-agency workgroup with expertise in health, wildlife, and the environment was formed to evaluate the public's concerns and to provide information. Air monitoring revealed that radiation levels reaching Alaska through the air were very small, and the US Food and Drug Administration provided helpful information about the safety of the commercial food supply in the United States. Alaska's workgroup carefully evaluated the potential risk posed by birds that overwinter in or migrate through Japan on their way to breeding grounds in Alaska. Wildlife agencies compiled a list of migratory birds in Alaska categorized by migration pattern/risk of exposure, environmental toxicologists evaluated scientific literature to assess the fate and behavior of several important radionuclides in the environment, and health officials assessed potential health risks and provided health-related advice. The interagency team worked together to develop joint information materials that were posted to the Internet. The team found that the likelihood of encountering a bird with dangerous levels of radiation in Alaska while subsistence hunting is very slight, for a number of technical reasons that will be presented.

497 Modeling Radionuclide Bioaccumulation in Aquatic Foodwebs that Receive Episodic or Pulse Releases: Steady State or Biokinetic? D.J. Rowan, Atomic Energy of Canada Ltd., Environmental Technologies Branch. Episodic or pulse releases of radionuclides and other contaminants to aquatic ecosystems are common, with releases from the damaged reactors at Fukushima an extreme example. However, the effects of episodic releases on bioaccumulation remain poorly understood. This likely stems from the lack of data on contaminant concentrations in water and biota prior to a release, during a release and after a release. Without prior knowledge of the timing of a pulse release, an ongoing, detailed time series study of contaminant concentrations in an aquatic food web would have to serendipitously straddle a pulse release and include its contaminant(s). While conducting a detailed time series study of cesium isotopes in a pelagic food web, several small pulse releases of Cs-137 occurred, yielding an unusual data set that consists of two isotopes of the same element under steady state (stable cesium, Cs-133) and non-steady state (radioceisum, Cs-137) conditions. Cesium enters aquatic food-webs through direct uptake by primary producers, followed by trophic transfer to higher trophic levels. This provides a unique opportunity to compare the performance of steady state and biokinetic approaches. Stable cesium was used to calculate bioaccumulation factors (BAFs) for weekly to bi-weekly collections of zooplankton, smelt (age-class composites) and walleye (individual fish) and to parameterize a biokinetics model. I compare the predictions of steady state and biokinetic models with respect to observed Cs-137 concentrations in fish over the eight month study period. The biokinetic, mechanistic food web model predicts a range of Cs-137 concentrations that encompasses observed concentrations in Ottawa River pygmy smelt (Osmerus spectrum) and walleye (Sander vitreus), describes temporal variation due to pulse releases and handles the complexity of a partially mixed source term. The steady state approach exhibits poor predictive capability during the entire eight month study period even though the BAFs used were not generic, but were derived from the same samples.

498 Modeling the Bioaccumulation Potential of Cesium 137 in a Marine Food Web of the Northwest Pacific, Canada J.J. Alava, Simon Fraser Univ, Resource & Environmental Management; F.A. Gobas, Simon Fraser Univ, School of Resource and Environmental Management (Faculty of Environment), Simon Fraser Univ. The Fukushima nuclear emergency provoked by the tsunami that impacted the north east coast of Japan on March 11, 2011, emerged as a high priority looming threat due to the risk of radioactive contamination in the global ocean and biodiversity. On April 11, The Fukushima nuclear plant reached the severity level 7, the same as the 1986 Chernobyl nuclear disaster. One of the most persistent isotopes produced and expected to be released by this kind of nuclear accidents was Cesium 137 (^{137}Cs), with a physical half life of 30 years. In an effort to assess the fate, accumulation and health effects of ^{137}Cs in marine organisms of the Northwest Pacific after the Fukushima nuclear disaster, we assessed the bioaccumulation potential of ^{137}Cs by testing steady state and time-dependent bioaccumulation models in an offshore food web that included fish-eating, resident killer whales (*Orcinus orca*) as one of the major top predators of the marine ecosystems in British Columbia, Canada. The steady stated model showed that concentrations of ^{137}Cs predicted in the male killer whale were approximately three orders of magnitude higher relative to its major prey, Chinook salmon, and > 13,000 times higher compared to phytoplankton. The time-dependent model showed that after 30 days of radioactive spillage, the ^{137}Cs concentrations accumulate gradually over time in high trophic level organisms (salmon and killer whales), which exhibited low concentrations likely driven by slow intake rates, while it bioaccumulates at faster uptake rates in low trophic level, gill ventilating organisms (phytoplankton, zooplankton, benthic invertebrates and planktivorous fish), exhibiting concentration about one to two orders of magnitude greater than that in killer whales. At 9125 days (25 years), the predicted concentrations of ^{137}Cs accumulate in a higher degree in killer whales, being >2 orders of magnitude greater than that predicted in Chinook salmon and 10,000 times higher relative to phytoplankton. The levels of ^{137}Cs predicted in biota (shellfish and fish) exceeded well above the ^{137}Cs action level for commercial food/beverage of 1000 Bq/kg established by the Canadian Guidelines for Consumption following a Nuclear Emergency.

500 The Only Certainty is Uncertainty: Parameter, Model, and Scenario Uncertainties in Radioecology I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center; F. Carini, Universita Cattolico; C. Lu, MIT. Modelling is widely used to predict the fate of radionuclides in ecosystems following accidental releases. Understanding uncertainty associated with modelling is therefore an important aspect not only of conducting analysis consistent with current regulatory guidance, but also of gaining stakeholder and decision-maker trust in the process and confidence in the results. In the framework of the BIOsphere Modeling and ASSessment (BIOMASS) program, the International Atomic Energy Agency (IAEA) developed several scenarios that described specific cases of radionuclide releases, and then tasked individual modelers or groups of modelers with the prediction of contaminant fate and transport in ecosystems. The BIOMASS Fruits Working Group undertook modelling studies to identify and investigate significant areas of uncertainty in modelling radionuclide transfer to fruit, with particular attention to "modeller uncertainty," i.e., differences in problem formulation, model implementation and parameter selection originating from subjective interpretation of the problem at hand. Two different exercises were carried out: model-model intercomparisons, where only the differences among model predictions were evaluated, and model-data

intercomparisons, where model predictions were compared to measured field data. This presentation will summarize Parameter, Model and Scenario uncertainty resulting from multiple modelling exercises from the BIOMASS framework. The results show that even for the simple and well-defined scenario of radionuclide accumulation in agricultural fruits (relative to more complex ecosystems), the differences in model predictions may be as high as five orders of magnitude for short term predictions following the acute radionuclide deposition. Comparisons with other fields and authors perspectives on modelling for regulatory risk assessment will be discussed.

501 Why We Still Need Data for Radioecological Modeling K. Higley, Oregon State Univ, Nuclear Engineering and Radiation Health Physics; D. Bytwerk, E. Houser, Oregon State Univ. Radioecologists are damned by their own apparent success in the proliferation of tools for assessment of dose from radiological releases. In addition to human exposure and dose assessment is an area that is still evolving: radiological dose assessment for nonhuman biota. Until recently dose calculation to species other than humans were regarded as unnecessary in radiological assessments. Transport and exposure pathways were evaluated predominantly for biota present in the human food chain. Changes in philosophy regarding protection of the environment, as well as the need to be more comprehensive in assessing impact have forced a reconsideration of this approach. However, biota dose assessment is in its infancy, and made more difficult because of the complex nature of food webs in nature. The requirement to make predictions of radionuclide transfer at many trophic levels in an ecosystem in order to fully assess uptake and exposure of a particular species is formidable. Dose assessment of non human biota is still evolving, and the tools are still be developed and debated. Two recent events have underscored the importance of data collection for radioecological modeling for both humans and biota. First, the publication by the International Atomic Energy Agency (IAEA) of two documents – IAEA TECDOC 1616 (2009) "Quantification of Radionuclide Transfer in Terrestrial and Freshwater Environments for Radiological Assessments, and Technical Reports Series No. 472 (2010) "Handbook of parameter values for the prediction of radionuclide transfer in terrestrial and freshwater environments" illustrate that with the exception of a few very well studied radionuclides such as 137Cs, 90Sr, and 131I there are substantial data gaps in our knowledge of environmental transfer of radionuclides. Secondly, the events resulting from the nuclear plants in Fukushima Daiichi Japan highlight our need to quickly and accurately forecast near term environmental behavior of radionuclides so as to help limit both radiological and economic impacts. Specifically, increased accuracy in our models could help better delineate "embargo" zones for the purpose of restricting agricultural activities to limit consumption of contaminated foodstuffs and to provide some degree of certainty to farmers. Such efforts need to be made quickly and as precisely as possible – particularly in circumstances such as in Fukushima where the releases were in advance of the growing season for many crops.

502 Arsenic Toxicity to Juvenile Fish: Effects of Exposure Route, Arsenic Speciation, and Fish Species R.J. Erickson, USEPA, Mid-Continent Ecology Division; D.R. Mount, US Environmental Protection Agency, ORD; J. Fernandez, USEPA, Research Chemist; T. Highland, J.R. Hockett, USEPA, Mid-Continent Ecology Division; D. Hoff, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division; C. Jenson, USEPA, Mid-Continent Ecology Division. Arsenic toxicity to juvenile rainbow trout and fathead minnow was evaluated in 28-day tests using both dietborne and waterborne exposures, both inorganic and organic arsenic species, and both a live diet and an arsenic-spiked pellet diet. Effects of inorganic arsenic on rainbow trout growth were elicited when dietary concentrations were >10 µg As/g dwt, but no effects of dimethylarsinate, monomethylarsonate, and arsenobetaine on growth were observed at dietary concentrations at least 10-fold higher. Exposure of the live diet organisms to either arsenite or arsenate resulted in similar relationships of fish growth to dietary concentration, because arsenate was reduced to arsenite in the diet. For arsenite, dietborne exposure growth effects were similar whether a live or pellet diet was used. Waterborne exposures of rainbow trout to ≥16 mg As/L of arsenate resulted in both growth reductions and mortality, but these water concentrations were much greater than those needed to contaminate live diet organisms enough to elicit growth effects. When growth effects were based on accumulation in the fish, waterborne and dietborne exposures showed similar dosimetry and were roughly additive. Fathead minnows were more sensitive than trout to mortality from waterborne exposure, but less sensitive to growth effects from dietborne exposure.

503 Effect of Allometry on Predicted Steady State Metal Accumulation P. Paquin, HDR|HydroQual; R. Mathew, Moffatt & Nichol; R. Santore, HDR|HydroQual. Kinetic models are frequently used to predict the bioaccumulation of trace elements in aquatic organisms. These models are commonly applied in steady state mode to evaluate tissue residue concentrations, bioconcentration factors (BCFs), bioaccumulation factors (BAFs), and the like. The approach is based on an underlying assumption that the kinetic coefficients used in the evaluation remain constant over time. In contrast to this assumption, it has frequently been shown that several important model coefficients conform to allometric relationships. As such, kinetic coefficients such as those related to metal uptake rate from water, metal assimilation efficiency from food, ingestion rate of food and growth rate may vary with organism size. The result is that the presumably constant values for such coefficients are actually transient in nature. That is, they will change over time as an organism grows. It has also been found that BAFs observed in nature can vary with the metal concentration in water. It is for these reasons that the predicted BAFs and steady state tissue concentrations are likely to be somewhat illusory under real world conditions. A time variable bioaccumulation model that was developed for bivalves will be used to assess the importance of the preceding considerations when predicting steady state tissue residue levels for copper.

504 Biologically-mediated Flux of Trace Metals from Streams to Riparian Spiders: A Large Scale Survey in Mineralized Alpine Ecosystems J.M. Kraus, T. Schmidt, D. Walters, R. Wanty, R. Zuellig, C. Stricker, P. Lamothe, US Geological Survey. Trace-metal contamination of aquatic ecosystems is a major health and environmental concern globally. In the Rocky Mountains, geologic processes and mining can strongly alter the distribution and bioavailability of metals within streams, reducing aquatic insect production (g C/m2/yr) and increasing metal body burdens. Here we use a large scale (4,488 km2, ~30 streams) survey to examine whether these effects on stream macroinvertebrates can cascade across ecosystem boundaries to alter neighboring terrestrial ecosystems in the Central Colorado Mineral Belt. We ask how bioavailable metals in stream alter metal concentrations and emergence production of aquatic insects, and the metal body burdens and biomass of riparian web-building spiders (Tetragnathidae). Because aquatic insects emerge from streams as adults, metals bioaccumulated in their bodies may negatively affect terrestrial spiders by reducing the biomass of available aquatic prey and by increasing their metal exposure. Results presented will highlight how geology, human disturbance, and ecological responses of stream and riparian biota determine fluxes of aquatically derived metals to terrestrial food webs. This study quantifies transport mechanisms and potential effects of aqueous metals on terrestrial ecosystems to better understand direct/indirect exposure and risks to riparian consumers posed by upstream mining activity. Implications for stream and riparian management in the national forests and parks where this study takes place are discussed.

505 Cadmium, Zinc, Manganese and Calcium Transport in a Stream Insect (*Hydropsyche sparna*): Interactions, Anomalies and Adsorption M.D. Poteat, North Carolina State Univ, Dept of Environmental and Molecular Toxicology; M. DiazJaramillo, Universidad de concepcion; D.B. Buchwalter, North Carolina State Univ, Dept of Environmental and Molecular Toxicology. Despite their ecological dominance and prevalent use as ecological indicators, the trace element physiology of aquatic insects remains poorly studied. While work with fish and crustaceans strongly suggests that Cd and Zn are transported apically through Ca-related transport systems, few studies with insects are available for comparison. Ca is largely thought to afford protection against Cd and Zn uptake and toxicity. Mn, a Ca analog, could also conceivably offer protection via competition for uptake or via the formation of oxide phases, which are known to be sinks for other metals. Here we used a radiotracer approach to examine interactions among Cd, Zn, Ca, and Mn. At environmentally relevant concentrations (2.7 nM Cd and 45.9 nM Zn), Cd and Zn did not compete for uptake, suggesting ample transport capacity consistent with a calcium or bulk cationic transport system. At extreme concentrations (8.9 µM Cd and 15.3 µM Zn), Cd accumulation was unaffected by the presence of Zn whereas Zn accumulation rates were 58% slower in the presence of Cd. Surprisingly, accumulation rates of Cd and Zn were remarkably similar under low Ca (31 µM) and high Ca (1.3 mM) concentrations. External Mn concentrations (up to 18.2 µM)

decreased adsorption of Cd and Zn in a concentration dependent manner, but did not alter absorbed concentrations of these elements. Comparisons of rinsing protocols to examine metal adsorption profiles revealed an association of Cd and Zn with oxide phases on the insect body surface. The addition of a 0.1 M ascorbate rinse to a 0.05 M EDTA rinse typically removed 18.5±8.7% more Cd and 13.8±4.7% more Zn than the EDTA rinse alone. Pharmacological blockers of Ca transport were used to examine Ca, Cd, and Zn uptake routes. L-type Ca channel blockers verapamil and nifedipine along with plasma membrane Ca-ATPase inhibitor carboxyeosin had no influence on Ca, Cd, or Zn uptake rates at concentrations up to 100 µM. Ruthenium red, a Ca-ATPase inhibitor, significantly decreased Ca absorption by 53% at 10 µM and by 93% at 100 µM. At 100 µM, ruthenium red significantly reduced total Zn accumulation rates and final internalized concentrations by 89% and 80%, respectively, and reduced total Cd accumulation rates by 87% and internalized concentrations by 71%. These results suggest that Zn and Cd do traverse a Ca-ATPase transport system, but that ambient Ca only exerts minor influence in Cd and Zn uptake.

506 Chronic Nickel Bioaccumulation, Sub-cellular Fractionation and Essential Ion Disruption in Two Teleosts: The Round Goby and the Rainbow Trout E.M. Leonard, U. Banerjee, J. D'Silva, C.M. Wood, McMaster Univ, Biology. The Tissue Residue Approach (TRA) is a relatively new concept that predicts toxicity as a function of metal levels within the organism at an organ or cellular level. The aim of this model is to determine a range of tissue residues that cause harmful effects on organisms due to multiple routes of entry (i.e., waterborne and/or dietary exposures). Therefore, round gobies (Neogobius melanostomus) and rainbow trout (*Oncorhynchus mykiss*) were exposed to a joint waterborne and dietary nickel (Ni) exposure for 30 days and were sampled on days 0, 2, 4, 10, 20, 30 for whole-organ bioaccumulation, sub-cellular fractionation and essential ion homeostasis. Sub-cellular fractionation of the individual organs was conducted to assess internal Ni processing and distribution within the cells. Ni bound to the organelles and heat-denaturable proteins are considered the Metal Sensitive Fraction (MSF) and Ni bound to the metal rich granules and metallothionein like-proteins are considered detoxified and part of the Biologically Detoxified Metal (BDM). Round gobies were approximately two times more sensitive than rainbow trout to a 30-day Ni exposure. There was no effect of Ni on growth in either teleost. The general trend of Ni accumulation was the gills>kidney>gut>liver. In the gills there was an initial increase in Ni burden followed by a recovery back to control levels by day 30 in both species. Ni bioaccumulation in kidney tissue increased over time in both species. In round gobies, this significant increase was correlated to the highest mortality at 50 µmol Ni/L. Sub-cellular fractionation of round goby gills showed significant Ni accumulation in the organelles over time which caused a ~13% increase of Ni in the MSF and a ~10% decrease of Ni in the BDM. Overall, mortality in the round goby may be related to Ni bioaccumulation in the kidney and an increase of Ni in the MSF of the gills. In gobies, acute Ni exposure led to a 50-80%, ~60% and ~58% decrease in gill Ca, Mg and Na levels, respectively. Gill essential ion concentrations returned to control values by day 30. Kidney ion homeostasis was maintained over the 30 day exposure. Additionally, a comparison between rainbow trout and round gobies will be discussed in terms of Ni bioaccumulation, sub-cellular analysis and essential ion disruption in the liver and gut. (NSERC Strategic Grant, Rio Tinto Alcan and Environment Canada).

507 Copper Uptake by Sodium Transporters and its Distribution in the Blue Crab *Callinectes sapidus* Acclimated to Low Salinity C.d. Martins, M.B. Jorge, M.M. Giacomin, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas; C. Wood, McMaster Univ, Dept of Biology; A. Bianchini, Universidade Federal do Rio Grande – FURG, Instituto de Ciências Biológicas. In vivo and in vitro studies were performed to evaluate copper flux through sodium transporters and its organ-specific distribution in the blue crab *Callinectes sapidus* acclimated to low salinity (2 ppt) . At low salinity, the blue crab hyperosmoregulates with a major ion uptake. For the in vivo tests, adult crabs were exposed (6h) to 1 µM of ^{64}Cu in artificial seawater and in a sodium free media, both at 2 ppt, with the following apical blockers: amiloride (100 µM) and furosemide (120 µM). For the in vivo tests, isolated gills were perfused (4h) with a saline solution corresponding to hemolymph and incubated with a saline solution corresponding to seawater at 2 ppt with amiloride or furosemide and 1 µM of ^{64}Cu. Samples of the incubation media and hemolymph (in vivo) or perfusate (in vitro) were collected over the respective experimental period. The efficiency of amiloride and furosemide in blocking sodium uptake in vivo and in vitro was first checked by adding ^{24}Na in the exposure media. Results from sodium flux in vivo and in vitro showed that both amiloride and furosemide, in less extent, are able to block sodium uptake. Copper uptake from water in both artificial seawater and sodium free media did not change with presence of blockers, at a rate of approximately $3.0x10^{-4}$ $\mu mol.g^{-1}.h^{-1}$ in all treatments. In vitro experiments with isolated-perfused gills also showed that amiloride and furosemide are not able to block copper influx. Concerning copper organ-specific distribution, in vivo tests showed that ^{64}Cu was primarily accumulated in the gills, exoskeleton and carapace rather than in the hemolymph, hepatopancreas, or other internal tissues. According to the presented findings, copper seems to be incorporated by blue crabs through other transporters than those responsible for sodium uptake. Alternatively, it is possible that copper uptake occurs essentially via specific copper transporters in *C. sapidus* since a significant amount of this metal is required for the respiratory pigment of crustaceans, hemocyanin. Moreover, our results indicate that gills are a key target organ for copper accumulation and that following its entry into the hemolymph it is distributed to organs where it will not be so harmful. This phenomenon may be a detoxification response as copper accumulated in carapace can be lost during molting. (Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), International Development Research Centre (IDRC))

508 Food Rationing Affects Dietary Selenium Bioaccumulation and Life Cycle Performance in the Mayfly *Centroptilum triangulifer* J.M. Conley, North Carolina State Univ, Dept of Environmental and Molecular Toxicology; D.H. Funk, Stroud Water Research Center; D.B. Buchwalter, North Carolina State Univ, Dept of Environmental and Molecular Toxicology. Selenium effects in nature are mediated by the relatively large bioconcentration of aqueous Se by primary producers and smaller, yet critical, dietary transfers to primary consumers. These basal processes are then propagated through food webs to higher trophic levels. Here we quantified the movement of dissolved Se (as selenite) to periphyton, and used the resultant periphyton as a food source for conducting full life-cycle dietary Se exposures to the mayfly *Centroptilum triangulifer*. Periphyton bioconcentrated Se ~2200-fold from solution in a log-linear fashion over dissolved Se concentrations ranging from 1.1 to 23.1 µg L^{-1}. We examined the influence of two feeding ration levels (*1x* and *2x*) on trophic transfer, tissue Se concentrations, maternal transfer, and functional endpoints of mayfly performance. Mayflies fed a lesser ration (*1x)* displayed greater trophic transfer factors (mean TTF, 2.8 ± 0.4) than mayflies fed *2x* rations (mean TTF, 1.1 ± 0.3). In *1x* exposures, mayflies exhibited significant ($p < 0.05$) reductions in survivorship and total body mass at dietary [Se] ≥ 11.9 µg g^{-1}, reduced total fecundity at ≥ 4.2 µg g^{-1}, and delayed development at ≥ 27.2 µg g^{-1}. Mayflies fed a greater ration (*2x*) displayed reduced tissue Se concentrations (apparently via growth dilution) relative to *1x* mayflies, with no significant effects on performance. These results suggest that the influence of Se on mayfly performance in nature may be tied to food resource availability and quality. Furthermore, nutritional status is an important consideration when applying laboratory derived estimates of toxicity to risk assessments for wild populations.

509 Uptake of Platinum Group Elements by the Marine Phytoplankton *Chlorella stigmatophora*, Their Fate and Effects L. Shams, Univ of Plymouth, School of Geography, Earth and Environmental Sciences, Univ of Plymouth, School of Geography, Earth and Environmetal Sciences; A. Turner, M. Brown, G. Millward, Univ of Plymouth. Very little information exists on the marine biogeochemistry of Rh, Pd and Pt, or the platinum group elements (PGE), an emerging group of contaminants whose principal emissions are associated with the abrasion of the catalytic converter in motor vehicles and chemotherapy drugs discharged in hospital wastes. In this study, PGE were added individually and in combination to cultures of the marine microalga, *Chlorella stigmatophora*, and the accumulation of metal was established under varying conditions (pH, algal biomass, PGE concentration, time). Under all conditions the extent of accumulation was in the order: Rh > Pd >> Pt. In short-term (24-h) exposures, accumulation isotherms were quasi-linear up to PGE concentrations of 30 mg L^{-1}, although Pd displayed convexity, hence saturation of available binding sites, at greater concentrations. The pH did not have a great impact on PGE accumulation, with Rh displaying a moderate increase in accumulation and Pd a moderate reduction with increasing pH. More important, all PGE displayed a significant reduction in accumulation on a weight-normalized basis with

increasing concentration of algae, an effect not reported for metal-marine algal interactions previously in the literature. Longer-term experiments showed that the rates of both overall accumulation and internalization were greatest for Pd and least for Pt. Consistent with this observation, the toxicity to *C. stigmatophora* evaluated by both pigment content and growth rate, was significantly greater for Pd. Differences in the biogeochemical behaviours among the PGE are attributed to differences in their aqueous speciation in seawater, different affinities for the algal surface, different tendencies to cross the cell membrane, and especially with regard to Pd and Pt, differences in the rates of these interactions. Because the environmental concentrations of PGE are predicted to increase with increasing emissions from vehicles and hospitals, the results of this study make an important contribution to an improved understanding of the likely effects and fates of these emerging contaminants in the marine environment. The results are also more generally important to an improved understanding of the interactions of trace metals with microalgae in seawater.

510 Soil Ingestion as a Pathway of Exposure to Lead in Ground-feeding Songbirds W.N. Beyer, US Geological Survey, Patuxent Wildlife Research Center; B. Spears, US Fish and Wildlife Service, Northern Idaho Field Office; J. Hansen, US Dept of Energy, Richland Operations Office. Documented lead poisoning of birds has generally been the result of ingestion of lead shot or sinkers. In mining areas such as the Coeur d'Alene River Basin in Idaho, however, waterfowl have been poisoned from incidental ingestion of lead in contaminated sediments. We investigated soil ingestion as a potential pathway of exposure to 205 ground-feeding songbirds at the same site. Based on the aluminum content measured in ingesta of these birds, we estimated surprisingly high rates of soil ingestion, about 20% in American robins (*Turdus migratorius*) and 17% in song sparrows (*Melospiza melodia*). Almost all of the lead ingested by these species was associated with soil rather than the soil-free diet. Swainson's thrushes (*Catharus ustulatus*), which feed higher than the two other species, ingested an estimated 1% soil in their diets. Based on activity of the enzyme ALAD and on analyses for lead in blood and livers, we concluded that many of the robins and song sparrows from the most contaminated sites were exposed to toxic concentrations of lead. Species of songbirds not normally feeding on the ground would be expected to have low exposures to lead. Assessments on wildlife exposed to lead should include soil or sediment ingestion as a pathway of exposure, rather than rely solely on biomagnification estimates.

511 What Can We Learn About Exposure and Effects of Rodenticides to Nontarget Wildlife from Investigations Following Broad Scale Conservation Use? N. Golden, US Fish and Wildlife Service, Environmental Contaminants Program; P. Dunlevy, USDA/APHIS Wildlife Services; S. Ebbert, US Fish and Wildlife Service, Alaska Maritime National Wildlife Refuge; C. Swift, US Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office. The frequency of anticoagulant rodenticide detection in wildlife has led the US Environmental Protection Agency to impose restrictions on the sale and use of these pesticides aimed at reducing exposure to nontarget organisms. While the curbing of residential and commercial use is being pursued, anticoagulant rodenticides, particularly diphacinone and brodifacoum, remain a common tool of government agencies and non-governmental organizations in the US for the control of invasive species for conservation purposes. In particular, eradication of invasive rodents from islands has become a high-profile conservation tool for habitat restoration, and rodents have been eradicated from hundreds of islands worldwide using rodenticides. In order to expose all target individuals to lethal doses, rodenticides are often applied to these islands at rates that are much higher than have been used in commensal or agricultural settings, and exposure to nontarget organisms present in and around the application area is nearly impossible to avoid. As such, these applications can serve as a means to investigate exposure pathways and adverse effects associated with these rodenticides that would be difficult to gather from other registered uses, including pathways that are not always predicted based upon our prior knowledge of rodenticide properties or animal behavior. Data generated from recent post-eradication monitoring and investigations of nontarget mortality reveal new information about diphacinone and brodifacoum, that when combined with laboratory studies, can influence not only the development of future eradication efforts, but potentially risk assessments for other uses of anticoagulant rodenticides. Consolidation of this data and identification of data gaps can also serve to guide the prioritization of areas for further investigation.

512 Mercury in Waterfowl from a Contaminated River in Virginia D.A. Cristol, College of William & Mary, Professor of Biology, College of William & Mary, Dept of Biology; L. Savoy, D. Evers, Biodiversity Research Institute; C. Perkins, Univ of Connecticut, Center for Environmantal Sciences and Engineering; R. Taylor, Texas A&M Univ, Trace Element Research Laboratory; C. Ramos, College of William & Mary. Many bodies of water around the world are contaminated with mercury from historic industrial and mining activities or ongoing atmospheric deposition, resulting in numerous fish consumption advisories. In contrast, concerns about mercury have only rarely led to waterfowl consumption advisories. In contrast with fish, waterfowl are free to disperse, so hunters and wildlife managers do not know whether waterfowl at a pristine site have spent time at a contaminated site elsewhere. We sampled tissue mercury concentrations of mallards, wood ducks, and Canada geese at a site contaminated with mercury, during the breeding and hunting seasons. We found that most mallards, some wood ducks, and very few Canada geese, had bioaccumulated mercury to levels that posed a risk to their health and the health of hunters who might consume them. We also documented through leg band recovery records that mercury-exposed waterfowl from this contaminated site were harvested by hunters, both locally and as far as 1054 km away. Our results suggest the need for more proactive sampling of waterfowl for mercury, and likely other bioaccumulating contaminants, in order to allow hunters to make more informed choices about consumption risks.

513 Immunological and Reproductive Health Assessment in Herring Gulls and Black-crowned Night Herons in the Hudson Raritan Estuary K. Grasman, Calvin College, Dept of Biology, Calvin College, Dept of Biological ; K. Echols, T. May, P. Peterman, R. Gale, C. Orazio, US Geological Survey, Columbia Environmental Research Center. Previous studies have shown inexplicable declines in breeding colonial waterbirds within western New York, New Jersey Harbor between 1996-2002, and elevated concentrations of polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated biphenyls (PCBs) in double-crested cormorant (*Phalacrocorax auritus*) eggs. This study assessed the immunological health and reproductive success of herring gulls (*Larus argentatus*) and black-crowned night herons (*Nycticorax nycticorax*) in lower New York Harbor during 2003 and evaluated associations between these endpoints and contaminants. In pipping gull embryos, lymphoid cells were counted in the thymus and bursa of Fabricius (sites of T and B lymphocyte maturation). The phytohemagglutinin (PHA) skin response assessed T cell function in gull and heron chicks. In vitro lymphocyte proliferation was measured for adult and prefledgling gulls. Reference data came from the Great Lakes and Bay of Fundy. Reproductive success of gulls was poor, with only 0.68 and 0.5 chicks/nest surviving to three and four weeks after hatch, respectively. The mean number of developing lymphoid cells was reduced 51% in the thymus and 42% in the bursa of gull embryos from New York Harbor. In vitro lymphocyte assays demonstrated reduced spontaneous proliferation, reduced T cell mitogen-induced proliferation, and increased B cell mitogen-induced proliferation in gull chicks from New York Harbor, but no alterations in adults. The PHA skin response was suppressed 70-80% in gull and heron chicks. Strong negative correlations ($r = -0.95$ to -0.98) between the PHA response and dioxins and PCBs in gull livers was strong evidence to suggest that these chemicals contribute significantly to immunosuppression in New York Harbor waterbirds.

514 Dietary Exposure of Mink (*Mustela vison*) to Fish from the Upper Hudson River, New York, USA: Effects on Reproduction, Offspring Growth and Mortality S.J. Bursian, Michigan State Univ, Dept of Animal Science; J.W. Kern, R.E. Remington, Kern Statistical Services, Inc.; J.E. Link, Michigan State Univ, Dept of Animal Science; S.D. Fitzgerald, Michigan State Univ, Dept of Pathobiology and Diognostic Investigation. The upper Hudson River is contaminated with polychlorinated biphenyls (PCBs) from Ft. Edward, NY, USA to New York City. The major sources of PCBs were capacitor manufacturing facilities at Ft. Edward and Hudson Falls, NY. Field studies indicate that wild mink (*Mustela vison*) collected in the vicinity of the Hudson River have hepatic concentrations of PCBs equivalent to concentrations associated with reproductive impairment in ranch mink experimentally exposed to PCBs. The mink is a commonly selected ecological receptor in studies at sites involving aquatic habitats with elevated concentrations of PCBs. A study was conducted to evaluate the health effects of feeding ranch mink diets containing PCB-contaminated fish from the Hudson River. In the present report, the effects of PCBs on adult reproductive performance and offspring growth and mortality through

31 wks of age are discussed. Diets contained 2.5% to 20% Hudson River fish, providing 0.72 to 6.1 µg ∑PCBs/g feed (5.1 to 38 pg toxic equivalents [TEQs]/g feed). The number of stillborn kits per litter was significantly increased by dietary concentrations of 4.5 µg ∑PCBs/g feed (28 pg TEQs/g feed) and greater. Mortality of 6-wk-old kits was significantly increased by dietary concentrations of 2.8 µg ∑PCBs/g feed (19 pg TEQs/g feed) and greater and body mass was significantly reduced by 1.5 µg ∑PCBs/g feed (9.9 pg TEQs/g feed) and greater. Between 6 and 10 wks of age, 4 (7.8%), 6 (20%), 33 (87%), 8 (89%), 15 (100%), and 2 (100%) animals in the control and 0.72, 1.5, 2.8, 4.5 and 6.1 µg ∑PCBs/g feed groups, respectively, died. The 7 juvenile deaths that occurred from 10 wks of age to termination of the trial (31 wks of age) were 1 in the 0.72 µg ∑PCBs/g feed group, the remaining 5 in the 1.5 µg ∑PCBs/g feed group and the remaining juvenile in the 2.8 µg ∑PCBs/g feed group. The dietary concentration predicted to result in a 20% increase in kit mortality (LC20) at 6 wks of age was 0.34 µg ∑PCBs/g feed (2.9 pg TEQs/g feed). The corresponding maternal hepatic concentration was 0.80 µg ∑PCBs/g liver (13 pg TEQs/g liver). The conclusions and opinions presented here are those of the authors and do not represent the official position of any of the funding agencies, the Hudson River Trustees or the United States.

515 Endocrine Disruption in Smallmouth (*Micropterus dolomieu*) and Largemouth Bass (*M. salmoides*) on National Wildlife Refuges in the Northeast USA A.E. Pinkney, US Fish & Wildlife Service, Chesapeake Bay Field Office; C.P. Guy, USFWS, Chesapeake Bay Field Office; L.R. Iwanowicz, V.S. Blazer, USGS, Leetown Science Center; A. Major, K. Munney, USFWS, New England Field Office; A. Secord, USFWS, New York Field Office; S. Mierzykowski, USFWS, Maine Field Office; S. Lingenfelser, USFWS, Virginia Field Office; C. Stern, T. Kubiak, USFWS, New Jersey Field Office; K. Patnode, USFWS, Pennsylvania Field Office. Members of our team previously reported a high (33% to 100%) prevalence of intersex, specifically testicular oocytes, in smallmouth bass (*Micropterus dolomieu*) in the Potomac River basin, USA. From 2008 through 2010, the US Fish and Wildlife Service and US Geological Survey conducted an On-Refuge Investigation on National Wildlife Refuges (NWRs) in the Northeast USA. Our goal was to evaluate the extent and magnitude of endocrine disruption (including intersex) in smallmouth and largemouth bass (*M. salmoides*) in rivers and impoundments on or adjacent to 21 NWRs. If possible, river sampling included an upstream/downstream design. One area was near a suspected source of endocrine-disrupting chemicals such as wastewater treatment plants (WWTPs) and pulp and paper mills and the other area was remote. Ten male and ten females were captured and necropsied per area. Endpoints were gonad histopathology (including intersex), and plasma hormone and vitellogenin (Vtg) concentrations. Grab samples of ambient water or WWTP effluent were collected, extracted and screened for total estrogenicity via a bioluminescent yeast estrogen screen. Intersex was observed in male smallmouth bass at all sites; however the prevalence and severity differed, in some cases substantially between upstream and downstream sites. Intersex was more prevalent in smallmouth vs. largemouth bass. Vtg was infrequently detected in the plasma of male fish; however, at some locations the median concentration exceeded 1 mg/ml indicating exposure to estrogens. Neither intersex prevalence nor severity correlated with plasma Vtg. Estrogenicity was only above the level of detection in WWTP effluent samples. We will utilize the results to advise refuge managers on land management issues and in commenting on permits for new and expanded point sources.

516 The Montara Well Release – One Year of Fish Health Monitoring C. Rawson, Curtin Univ, Dept of Environment and Agriculture; M. Gagnon, Curtin Univ, Dept of Environment and Agriculture, Curtin Univ (Bentley Campus), Dept of Environment and Agriculture, Curtin Univ, Environment and Agriculture. From August to October 2009 an estimated 22,800 barrels of oil and gas condensate were accidentally discharged from the Montara well head to the Timor Sea raising immediate economic, political and environmental concerns. The spill was controlled after seventy-four days, after which a monitoring program to assess the extent of environmental impacts of the well release was enacted. As part of this program, commercially important fish species were collected during three sampling trips spanning 12 months following the release. A suite of physiological indices (condition factor, liver somatic index and the gonadosomatic index), biomarkers (biliary polycyclic aromatic hydrocarbon (PAH) metabolites, liver integrity measured by serum sorbitol dehydrogenase activity (SDH), oxidative DNA damage) and histological examination were used to evaluate the short and long-term impacts of exposure to petroleum hydrocarbons on fish health. In presenting these results we discuss the continuing importance of ecotoxicology in establishing rapid methods for testing the short- and long-term impacts of acute exposure to industrial contamination events related to the expanding Australian resource sector.

517 A Transferable Measurement Matrix for Assessing Injury Using as Ecosystem Approach D. Evers, Biodiversity Research Institute; D. Cristol, College of William and Mary; A. Condon, J. Schmerfeld, US Fish and Wildlife Service; D. Yates, A. Jackson, L. Savoy, Biodiversity Research Institute. The Natural Resource Damage Assessment and Restoration (NRDAR) on the South River, Virginia is a collaborative effort between the Trustees and the responsible party that has followed an ecosystem approach in evaluating the potential injury to trust resources from the historical release of mercury into the river system. Various taxa were examined, emphasizing species within invertivore and piscivore foodwebs. Multiple researchers and experts have been involved in these investigations, and through the NRDAR process, have also been able to answer basic research questions related to mercury exposure and effects in wildlife. Researchers have studied reproductive endpoints, growth and development, behavior, and other sublethal effects. While the primary intent of a NRDAR investigation is to quantify injury in a particular case, the approaches and findings have potential to be more widely applied. As a result of these studies, we have developed a transferable, measurement matrix that is adaptable for assessing injury based on differing taxa, foraging guilds, and other spatially-explicit attributes of potential NRDAR sites across the United States.

518 Predicting the Sensitivity of Avian Species to the Embryotoxic Ffects of Polychlorinated Biphenyls (PCBs) Using a Luciferase Reporter Gene Assay G.E. Manning, R. Farmahin, Univ of Ottawa, Dept of Biology; S.P. Jones, D. Crump, Environment Canada, National Wildlife Research Centre; S.W. Kennedy, Univ of Ottawa, Dept of Biology, University of Ottawa, Dept of Biology, Environment Canada, National Wildlife Research Centre. Avian species differ in sensitivity to the embryotoxic effects of polychlorinated biphenyls (PCBs). This complicates environmental risk assessments for these chemicals. Avian toxic equivalency factors (TEFs) have been established by the World Health Organization and are applied in the risk assessment of mixtures of dioxin-like compounds (DLCs), including polychlorinated dibenzo-*p*-dioxins (PCDDs), dibenzofurans (PCDFs) and certain PCBs. However, TEFs do not account for differences in species sensitivity to DLCs, and may not accurately predict DLC toxicity in all avian species. A luciferase reporter gene (LRG) assay was developed in our laboratory to measure aryl hydrocarbon receptor (AHR)-mediated cytochrome P4501A (CYP1A) induction in COS-7 cells transfected with different avian AHRs. The assay reliably predicted the embryotoxicity of PCDD/F congeners in 3 model avian species with varying sensitivity to DLCs. Although other assays have been used to measure CYP1A induction using primary hepatocyte cultures, the LRG assay can predict DLC toxicity in rare and endangered species since it requires only the AHR sequence of the species of interest. In the present study, the LRG assay was used to predict 1) the sensitivity of 76 avian species to the embryotoxic effects of PCB 126 and 2) the potency of PCB 126 relative to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) in these species of interest. COS-7 cells were transfected with AHRs representative of different avian species and dosed with 0.003 to 3000 nM PCB 126 or TCDD. Concentration-response curves for luciferase activity in COS-7 cells transfected with 9 of the 15 AHRs of interest have been characterized and the results indicate that avian species sensitivity to CYP1A induction by PCB 126 is dependent on the identity of 2 amino acids present in the AHR ligand binding domain. These results confirm previous findings that avian species can be grouped into 3 general classes of sensitivity to DLCs based on the identity of these amino acids. Future studies will investigate differences in species sensitivity to the effects of PCB 77, 105 and 118. The data from this study regarding the sensitivity of wild avian species to PCB-induced transactivation will be useful in site-specific risk assessments of DLC-contaminated sites.

519 Differential Expression of Liver Regulatory Genes with Embryonic PCB Exposure M.E. Barton, Univ of Maryland, Animal and Avian Sciences; K. Dean, Univ of Lethbridge, Neuroscience, Univ of Maryland, post-doctoral research fellow; M. Ottinger, Univ of Maryland, Dept of Animal and Avian Sciences. Biomarkers of exposure and effect provide valuable indices of potential damage to an organism or population exposed to

environmental contaminants. However, wild populations are often exposed to complex mixtures of compounds and there are life stage and species differences in sensitivity. Several well-established biomarkers, such as the induction of hepatic cytochrome P450 monooxygenases, have been used to measure exposure. Few data are available on the use of gene expression for selected responsive genes as a sensitive and biologically meaningful index of PCB exposure. Previously, we reported results using a customized microarray in which hepatic gene expression profiles were examined in response to embryonic PCB exposure in Japanese quail. These data were indicative of potentially useful biomarkers of both exposure and effect. Differentially expressed genes were those involved in glycolysis, xenobiotic metabolism, replication, protein degradation, and tumor regulation, including cytochrome P450 1A5, cytochrome b5, NADH-cytochrome b5 reductase, glutathione-S-transferase, fructose bisphosphate aldolase, glycogen phosphorylase, carbonic anhydrase, and DNA topoisomerase II. Because these physiological functions are potential targets of PCB exposure, this current study compared effects of embryonic exposure to PCB 126, PCB 77, or two environmentally relevant mixtures of PCB congeners on gene expression in Japanese quail liver. Embryos were dosed in ovo on embryonic day 0 via air cell injections, with comparative untreated, sham, and vehicle control groups. Embryonic death was tracked during incubation and eggs were allowed to hatch. Hatchlings were sacrificed within 24 hours of hatching; livers were immediately collected, snap frozen on liquid nitrogen, and stored at -80°C until RNA extraction. Expression levels for genes of interest were screened using real time quantitative polymerase chain reaction (qPCR). An assay for ethoxyresorufin-O-deethylase activity was also run for confirmation of induction of this canonical downstream biomarker. The conclusions and opinions presented here are those of the authors, they do not represent the official position of any of the funding agencies, the Hudson River Trustees or the United States. Support from US Fish and Wildlife Service and the Hudson River Trustees.

520 Expression Pattern of DNA Damage Response Genes Revealed by 55K Microarray Upon UV-B Irradiation in the Copepod, *Tigriopus japonicus* J. Lee, Hanyang Univ Graduate School, Dept of Chemistry. Ultraviolet-B (UV-B) radiation affects the genome stability of aquatic organisms by absorption of certain wavelength at the molecular level. Recently, extensive gene information has been identified from the intertidal copepod, *Tigriopus japonicus*. Here, we developed a 55K (54,254 genes) oligomicroarray and tested its usefulness to identify the effect of single dose of UV-B irradiation (12 kJ/m2) on transcriptomes of the copepod *T. japonicus*. A total of 35,361 spots were identified to be significantly modulated on the 55K oligomicroarray by hierarchical clustering after exposure to UV-B irradiation over 48 h (6, 12, 24, and 48 h). Of them, 1,300 and 588 genes were observed to be up-regulated and down-regulated at all time points, respectively. Particularly, it was observed that several genes involved in DNA repair mechanism were significantly modulated in the UV-B-exposed *T. japonicus* by microarray and quantitative real-time RT-PCR analysis. In detail, UV-B irradiation specifically up-regulated some genes in non-homologous end-joining (NHEJ), homologous recombination (HR), base excision repair (BER), and mismatch repair (MMR) pathways. On the other hand, a majority of down-regulated genes was representatives for the nucleotide excision repair (NER) mechanism. These results demonstrated that DNA damage would be induced by UV-B irradiation in this species, resulting in reliable induction or repression of various DNA repair mechanism on UV-B-induced DNA damage. In this report, we suggest that a high density microarray-based approach for risk assessment of UV-B irradiation would be useful to elucidate the mechanistic analysis in a non-model organism. This study could also provide a better understanding of molecular mechanisms of cellular protection against UV-B-induced stress.

521 Al2O3 Nanoparticles Effect the Growth, Development, and miRNA Expression Profile in *Nicotiana tabacum* C. Burklew, East Carolina Univ, Dept of Biology; B. Zhang, East Carolina Univ, Dept of Biology, East Carolina Univ, Biology, East Carolina Univ, Dept of Biology. Nanoparticles are small objects that are approximately 1 to 100 nanometers in diameter and are being increasingly used in industry due to their unique properties such as their small size and large surface area. Nanoparticles can be used in coatings for products, colorants, food additives, pharmaceuticals, cosmetics, and paints, therefore residues from their use may be increasingly released into the environment as the use of these products also increases. Currently, nanoparticles have become one major environmental issue and have become a major environmental pollutant. However, to date, few experiments have been conducted to investigate the effect nanoparticles may have on plant growth and development. It is important to study the effects nanoparticles have on plants and its molecular mechanism because they are stationary organisms that cannot move away from environmental stresses like animals can, therefore they must overcome these stresses by molecular routes such as altering gene expression. microRNAs (miRNA) are a newly discovered, endogenous class of post-transcriptional gene regulators that function to alter gene expression by either targeting mRNA for degradation before it is translated or by preventing the ribosome from translating mRNAs into proteins. miRNAs have been shown to mediate abiotic stress responses such as drought and salinity in plants by altering gene expression, therefore our aim in this study was to classify if certain miRNAs play a role in plant response to Al_2O_3 nanoparticle stress. In this study we exposed *Nicotiana tabacum* (tobacco) plants (an important cash crop as well as a model organism) to 0%, 0.1%, 0.5%, and 1% Al_2O_3 nanoparticles and found that as exposure to the nanoparticles increased, the average root length, leaf count, and the germination rate of the seedlings significantly decreased. We also found that miR395, miR397, miR398, and miR399 showed an extreme increase in expression during exposure to 1% Al_2O_3 nanoparticles compared to the other treatments and the control, therefore these miRNAs may play a key role in mediating plant responses to heavy metal stress in the environment. The results of this study show that Al_2O_3 nanoparticles have a negative effect on the growth and development of tobacco seedlings and that miRNAs may play a role in the ability of plants to withstand heavy metal stress in the environment.

522 Identification of Whole Cytochrome P450 (CYP) Genes from the Copepod, *Tigriopus japonicus* and Their Modulation Upon Exposure to Pollutants J. Lee, Hanyang Univ, Dept of Chemistry, Hanyang Univ Graduate School, Dept of Chemistry; D. Hwang, Hanyang Univ, Dept of Molecular and Environmental Bioscience. The cytochrome P450 superfamily is a large and diverse group of enzymes. P450 gene expression, protein levels, and P450 mediated metabolism of xenobiotics are induced by PAHs in marine invertebrate species. Thus, the regulation of P450 enzyme activity may play a central role in the adaptation of animals to environmental pollutants. To understand the effects of marine pollutants and the cellular responses, we indentified a nearly entire set of the cytochrome P450 (CYP) gene superfamily in the intertidal copepod, *Tigriopus japonicus*. To obtain *T. japonicus* CYP genes, we searched for CYP genes from *T. japonicus* local genome databases (25.56 Gb) sequenced by the genome analyzer, GS-FLX-Titanium and Solexa. We obtained 34 full length CYP genes from *T. japonicus*. To determine the phylogenetic placement of CYP genes, we performed a phylogenetic analysis using maximum likelihood and the Bayesian method comparing with diverse other organisms. The *T. japonicus* CYP genes were clustering with well known vertebrate CYP clans, CYP2, 3, 4, and mitochondrial clans, respectively. We further analyzed specific expression patterns of 34 CYP transcripts in developmental and different sexual stages. Expression patterns of CYP transcripts after exposure to marine pollutants (e.g., heavy oil spillage, endocrine disruptors, and nanoparticles) were also analyzed by quantitative real-time RT-PCR. Differentially modulated expression patterns of CYP transcripts suggest that these invertebrate CYPs are involved in defenses and detoxification mechanisms against marine pollutants. Overall, this is the first report to characterize nearly the entire CYP gene superfamily expressed in this marine copepod. Our studies are helpful in expanding knowledge on the innate roles of CYPs in the metabolism of xenobiotics and in the physiology of marine invertebrate in general.

523 Differential Life-stage Response to Common Endocrine Disruptors in Two Endangered Species, Atlantic Salmon and Shortnose Sturgeon T. Duffy, S. McCormick, Conte Anadromous Fish Research Center, USGS. Atlantic salmon (*Salmo salar*) and shortnose sturgeon (*Acipenser brevirostrum*) are endangered anadromous fish that spawn in rivers, and offspring develop in their natal stream before migrating out to sea or moving into estuaries. Therefore, these species may be exposed to wastewater effluent during early life-history stages, potentially impacting survival and development. Little is known about differential life-stage sensitivity to environmental endocrine disrupting compounds (EDCs) in these species, but this knowledge is crucial to conservation and protection under the Endangered Species Act. The purpose of this research was to determine differential life-stage sensitivity to three common endocrine disrupting chemicals in Atlantic salmon and shortnose sturgeon. We carried out short-term (four- day)

exposures using three doses each of nonylphenol (NP), 17β-estradiol (E2) and 17α-ethinylestradiol (EE2) on four life-stages; embryos, yolk-sac larvae, feeding fry and 1+ year-old juveniles of both species. Differential sensitivity was compared using a common biomarker of exposure to EDCs, vitellogenin (Vtg, a precursor egg protein). For each species we validated an enzyme-immunoassay (EIA) measurement of plasma or whole body Vtg and quantitative real-time PCR measurement of Vtg gene transcription. No dose-dependent mortality occurred in our exposures, indicating that sub-lethal impacts are necessary endpoints to determine which life-stages are most sensitive to common EDCs. The impact of exposure to estrogenic compounds on plasma Vtg and Vtg transcription at four developmental stages of Atlantic salmon and shortnose sturgeon will be presented.

524 Genetic Biomarkers of Developmental Atrazine Exposure Indicate Disruption of Neuroendocrine Function, Cell Cycle Regulation and Carcinogenesis G. Weber, Purdue Univ, School of Health Sciences; S. Lewis, S. Peterson, M. Sepulveda, J. Freeman, Purdue Univ. Endocrine disrupting chemicals (EDCs) are exogenous agents that alter endocrine system function and are associated with a myriad of diseases. Atrazine, an herbicide commonly applied to agricultural areas throughout the Midwest and a common contaminant of potable water supplies, has been implicated as an endocrine disruptor and potential carcinogen. The specific adverse health effects associated with atrazine exposure and the underlying molecular mechanisms of these effects are not well defined. Several described endocrine disruptors often act as mimetics of ligands or hormones that competitively bind to targeted receptors such, as the estrogen and androgen receptors, and subsequently enhance or suppress the corresponding pathway(s). However, to date the molecular mechanism through which atrazine exerts its effects is not fully understood. In an effort to elucidate the toxic mechanisms of action, we exposed zebrafish embryos to 0.3, 3, and 30 parts per billion (ppb) atrazine shortly after fertilization through 72 hours post fertilization (hpf). A portion of the larvae were collected at the end of the treatment period and prepared for global gene expression analysis and morphological analysis. Gene expression data revealed 61 gene targets were significantly altered in the 0.3 ppb concentration while the 3 ppb and 30 ppb concentrations had 202 and 198 gene targets altered, respectively. Interestingly, there was 66% overlap between the 3 and 30 ppb treatment groups with 132 of these gene targets found in both of these treatments. Subsequent gene ontology and molecular network analysis indicated an enrichment of genes associated with neurological disease and neuroendocrine development in the 0.3 ppb gene set. Moreover, in the two higher atrazine treatments (3 ppb and 30 ppb) the altered gene expression profiles were enriched with several gene targets associated with cell proliferation and cancer development. Upon thorough analysis of this genomic data, a subset of genes with prominent roles in reproductive function and cancer has been chosen for targeted analysis in a subset of adult individuals developmentally exposed to atrazine and then allowed to mature under normal conditions. Alteration of these targets in adult individuals will support our hypothesis that developmental exposure to atrazine will elicit a unique transcriptomic signature from which relevant biomarkers of exposure can be identified and used in subsequent molecular analyses.

525 Is There a Relationship Between Environmental Contaminant Levels, DNA Damage and Fertility Hormones in Bottlenose Dolphins? E. Pulster, Mote Marine Laboratory, Senior Chemist; L. Schwierzke-Wade, Mote Marine Laboratory; D. Wetzel, Mote Marine Laboratory, Aquatic Toxicology; J. Reynolds, Mote Marine Laboratory. Environmental contaminants are monitored globally, however, the effects of these measured levels are still relatively unknown. Although laboratory tests and selected analyses with wild animals have suggested that exposure toward organic contamination can have significant sublethal effects on marine mammals there has been a lack of empirical data about the effects of organic contaminants on cetaceans. This study attempts to link DNA damage in blood samples as well as levels of fertility hormones in free-ranging male bottlenose dolphins from along the coast of southeastern Georgia (USA) to body burdens of environmental contaminants. Supporting evidence indicates differences in fertility peptide hormone averages for male adults between the two locations along the coast of Georgia, where anti-Müllerian hormone (AMH) concentrations were statistically lower in St. Simons Sound (mean 650 ng mL-1) than Sapelo (mean 850 ng mL-1). These results suggest potential reproductive impairment in marine mammal populations in close proximity to heavily contaminated areas. Future health assessments of species status or stock status must include additional investigations into sublethal stressors to properly manage or conserve species.

526 An Overview of the Current Regulatory Framework for Environmental Assessment of PCPs in the US and the EU M. Sharma, T. Verslycke, Gradient. In the last decade, several studies have reported concentrations of personal care product (PCP) ingredients in various environmental media, particularly in surface waters. In addition, effects data are increasingly reported in the scientific literature, as greater resources are expended to better understand the environmental safety of "chemicals of emerging concern." In this milieu of increased scrutiny regarding environmental safety, it is appropriate to examine the adequacy of the current regulatory framework for assessing the environmental safety of personal care product ingredients. This presentation will provide an overview of the current regulatory framework for conducting environmental safety assessments of PCP ingredients in the US and in the EU and other existing US/EU regulatory statutes that are relevant in the context of safety evaluations of PCP drug and cosmetic ingredients. We will also evaluate the scientific adequacy/challenges associated with the current regulatory framework and potential regulatory changes in the near future.

527 The Environmental Risk Assessment of Major Surfactants Used in Consumer Products – History and Watershed Studies Validation S. Dyer, The Procter & Gamble Company, Central Product Safety, The Procter & Gamble Company, Miami Valley Innovation Center. The surfactants linear alkylbenzene sulfonates (LAS), alkyl sulfates (AS), alkyl ethoxylate sulfates (AES) and alcohol ethoxylates (AE) are among the highest volume and most environmentally studied chemicals used in consumer products. Over the past 3 decades, studies conducted by suppliers, formulators and trade associations (e.g., American Cleaning Institute (ACI), formerly known as the Soap and Detergent Association) have obtained definitive fate and effects data in a variety of environmental media at appropriate levels of biological scale. This presentation consolidates data from lab and field based studies to provide an overall perspective on the environmental risk of each of these chemicals as well as a complex mixture. Such a perspective is especially pertinent in today's scientific climate as these chemicals are often listed as "contaminants of emerging concern". Due the long history of study, it is quite apparent that these chemicals are neither "emerging", that is – new to the world of analytical detection, nor a "concern", that is – pose a significant adverse risk to receiving water biology. These chemicals are designed to clean, hence are sorptive to organic carbon as well as biological surfaces. Due to these properties extensive fate studies have been conducted where their removal in wastewater could be predicted based on laboratory studies and then verified via field-based monitoring studies. Monitoring results provided needed validation data for the development of the national watershed model: GIS-ROUT, recently rebranded by ACI as iSTREEM. Each of these surfactants are typically used in consumer products as mixtures of homologues of various alkyl chainlengths, phenyl positions (i.e., LAS) and ethoxylates (AES and AE). Quantitative structure-activity relationships have been developed that has enabled the assessment of these complex chemicals as mixtures. Further, these QSARs have been verified at the population and community levels via several experimental stream studies. Due to the large effects database, species sensitivity distributions (SSDs) have been also verified via experimental stream studies. The final validation of the safety of these chemicals has come most recently via watershed-based studies where a focus on both overlying water and sediment biota have been studied in the upper Midwest (Indiana, Ohio) and in Texas (Trinity River).

528 The Environmental Assessment of Fragrance Materials D. Salvito, Research Institute for Fragrance Materials , RIFM; A. Lapczynski, Research Institute for Fragrance Materials, Inc., Research Institute for Fragrance Materials, Inc, Environmental Specialist. Fragrance materials are used in a wide variety of consumer products. These include soaps and detergents, fabric conditioners, shampoos, cosmetics, fine fragrance, and other personal care products. Among other functions desired by consumers within these products, they often play an important role in signaling to consumers the effectiveness of a product; and, thus, have an impact on the sustainable use of the consumer product as a whole. The environmental risk and hazard of these materials have been studied and reported in the literature (see for example, Salvito, Senna and Federle, 2002). The fragrance materials industry has recently expanded its self-regulatory IFRA Standards to include management measures for environmental risk and hazard. Reported here will be a

summation of testing and research programs to assess environmental impacts of fragrance materials, the application of the IFRA Environmental Standards, and a strategy for progressing this program.

529 An Aquatic and Terrestrial Ecological Risk Assessment for Triclosan T. Barber, ENVIRON International Corp.; M. Bock, P. Fuchsman, J. Lyndall, Environ International; M. Capdevielle, Colgate-Palmolive. Triclosan is an antimicrobial compound used in personal care products in concentrations ranging from 0.1% to 0.3% active ingredient by weight. The primary migration pathway to the environment is via "down the drain" disposal. The conceptual site model included product use, sewage conveyance to wastewater treatment plants, discharge of treated effluent to receiving waters, and production of secondary sewage sludge, which may be applied to land as biosolids. An ecological risk assessment was conducted to evaluate the potential effects of triclosan in the aquatic and terrestrial environments under various exposure scenarios. Given the range of environmental variability, a probabilistic fugacity and bioaccumulation model that explicitly considered the range of potential environmental conditions (e.g., population density, watershed size, wastewater treatment plant removal efficiency, receiving water characteristics, agricultural practices) provided a more complete picture of triclosan in the environment. Predicted environmental concentrations in water, sediment, soil, and tissue were compared to available environmental data. The risk characterization compared the exposure concentrations, body burdens, dietary concentrations, and doses to ecotoxicity benchmarks developed from values published in the open literature and proprietary studies. The comprehensive nature of this work was able to place potential concerns about triclosan in the environment into proper context, identify important exposure factors and data gaps, and prioritize future research needs.

530 Simulated Use and Wash-off Release of Decamethylcyclopentasiloxane Used in Personal-care Products T. Gouin, Unilever, Safety and Environmental Assurance Centre; R. van Egmond, C. Hastie, C. Sparham, Unilever. Given recent concerns regarding the environmental fate of decamethylcyclopentasiloxane (D5), as highlighted by the proposed designation of D5 as persistent and bioaccumulative, as defined under the Canadian Environmental Protection Act, and its potential inclusion in the Canadian Toxic Substances List, assessing the use and potential release to the environment is important for better understanding its environmental safety. A recent Canadian survey reported that D5 is the dominant cyclic volatile methylsiloxane (cVMS) ingredient used in personal-care products (PCPs), with concentrations observed at 680 mg/g in an antiperspirant product. Models that attempt to simulate the use and release of D5 in relation to consumer habits can help identify products that may represent significant sources. In this study, we have performed a sensitivity analysis aimed at better assessing sources of D5 used in PCPs. Probability distributions are defined for inclusion levels of D5 used in different PCP categories, varying from categories defined as leave-on, such as skin creams, antiperspirants, and deodorants, to wash-off, such as liquid soaps, shampoos and conditioners. This information is then combined with knowledge about consumer habits to quantify distributions of amounts being discharged to waste-water treatment plants. This analysis thus provides an assessment of product categories and consumer habits that contribute the most to influent levels.

531 Determination of the Levels of Synthetic Musk Compounds in the United States National Rivers and Streams Using Gas Chromatography/Mass Spectrometry L.I. Osemwengie, United States Environmental Protection Agency, Environmental Chemistry Branch, United States Environmental Protection Agency, National Exposure Research Laboratory; W. Sovocool, United States Environmental Protection Agency, Environmental Chemistry Branch; J. Lazorchak, United States Environmental Protection Agency, Ecological Exposure Research Division; A. Batt, United States Environmental Protection Agency. In 2008-2009, the USEPA and their partners collected fish during a probabilistic survey of 700 navigable waters in the contiguous US under the National Rivers and Streams Assessment program (NRSA), a subset of which were 183 urban river sites. Urban river site fish fillets were analyzed for the occurrence and extent of selected contaminants of emerging concern (CEC), including pharmaceuticals and personal care products. Fish fillets were analyzed for synthetic musk compounds to estimate the potential human exposure during consumption of fish collected from navigable waters of the United States. Approximately 2 g of fish homogenate was surrogate fortified and accelerated solvent extracted with alumina in a stainless steel cell. Gel permeation chromatography was then performed on each fish sample extract. The resultant extracts were then subjected to a further cleanup step using amino propyl cartridges (SPE). These samples were extracted and analyzed by GC/MS for select synthetic musk compounds and nitro musk metabolites, i.e., Galaxolide, Tonalide (polycyclic musks), Musk Xylene, Musk Ketone (nitro musk compounds), Amino musk ketone, and 4-amino musk xylene (nitro musk metabolites). Upon analysis of 220 fish fillet samples, the polycyclic musks were found in varied concentrations, 756 ng/g to non-detect, while the nitro musk compounds were found either in low concentrations (

532 Expanding the Knowledge on Organic UV Filters in the Environment: Occurrence, Removal and Toxicity P. Gago-Ferrero, IDAEA-CSIC, Environmental Chemistry; M. Badia-Fabregat, UAB; A. Olivares, B. Pina, IDAEA-CSIC, jordi girona, jordi girona; P. Blanquez, UAB, Enginyeria. Química, jordi girona; T. Vicent, UAB; G. Caminal, IQAC (CSIC-UAB), Biocatàlisi Aplicada, jordi girona; S. Diaz-Cruz, IDAEA-CSIC, Environmental Chemistry; D. Barcelo, ICRA, Environmenta Chemistry, ICRA, Catalan Institute for Water Research, IDAEA-CSIC, Environmental Chemistry Dept. Modern societies depend on a large number of chemicals. Once discharged from industrial and urban sources, they may ultimately enter wastewater. Most of them may be to some extent eliminated during water treatment. However, those not removed may be present in residual concentrations in the receiving ecosystem. Among them, organic UV absorbing compounds are of particular interest due to the raised concern about harmful effects of sunlight; they have been increasingly used in the last decades. This group of additives is worldwide used in many personal care products (sunscreens, cosmetics, hair sprays), in which they amount up to 25% of the total product weight. These chemicals enter the environment either indirectly, via WWTP effluents, or directly, through human recreational activities. There is still limited information about the occurrence, fate and effects of UV filters in the environment, although several of them are known to display estrogenic activity, affect the thyroid axis and reproduction. Moreover, it is documented that UV filters can be bioaccumulated in organisms and concentrated on solid matrices. In this study, environmental concentrations of largely used UV filters and their metabolites were determined, highest levels corresponding to sewage sludge samples with concentrations up to 9.17 ug/g dw. Since biological conventional treatments in WWTP are not effective at degrading most UV filters, new approaches need to be tested. Two of them are assessed in the present work for their elimination. Photodecomposition might be regarded as one of the most important abiotic factors affecting the fate of sunscreen agents in the environment and photocatalysis has been suggested as an effective method to degrade organic pollutants. Biodegradation by the fungus Trametes versicolor is considered as a promising alternative to conventional aerobic bacterial degradation, as it is able to metabolise a wide range of xenobiotic compounds. Results obtained by applying both treatments evidenced the high degradation yields achieved by the biodegradation approach. Toxicological assays performed to determine the endocrine disrupting and dioxin-like activities of selected UV filters and their metabolites, indicated that lower EC50 values were obtained for degradation products, ranging from 0.058 to 0.61 mg/L. The toxicity profile upon the biological treatment was also estimated. The outcome demonstrated the suitability of the method to eliminate the estrogenic activity.

533 Effects of a Chronic Lower Range of Triclosan Exposure to Stream Mesocosm Communities C. Nietch, USEPA, Office of Research and Development, National Risk Management Laboratory, Water Supply Water Resources Division, US Environmental Protection Agency, Water Supply Water Resources Divison; E. Quinlan, Georgia Gwinnett College; J. Lazorchak, United States Environmental Protection Agency, Ecological Exposure Research Division; C. Impellitteri, US Environmental Protection Agency, Water Supply and Water Resources Division. An environmentally relevant range of doses for the common antimicrobial agent triclosan (2,4,4'-trichloro-2'-hydroxydiphenyl ether) were selected for exposing stream mesocosm communities after a 28 day colonization period with water from a natural wadeable stream. Two mesocosms served as controls while five others were exposed to 0.1, 0.5, 1.0, 5.0, and 10 ug/L Triclosan. The dosing period lasted for 56 days, was designed to simulate a continuous, therefore, chronic point-source discharge to a receiving stream potentially already stressed from organic/nutrient enrichment during the summer low-flow period, and had continuous through-flow with potential for biotic renewal. Sixty six biotic-abiotic parameters were measured throughout the study to provide a comprehensive assessment of triclosan's potential impact on stream biotic

structure and system function. Triclosan's antimicrobial properties were observed first in a dose-response relationship for periphytic bacteria cell densities, but this was not significant until 21 days of exposure. The effect persisted for an additional seven days, but by the 35th day a proliferation in cell densities had occurred across all mesocosms. This coincided with a seemingly natural increase in the periphytic cyanobacteria abundance. By the end of the dosing period bacteria cell densities along with cyanobacteria appeared stimulated in the low doses but were significantly depressed in the two high doses relative to the controls. Similar was the trend across doses for periphytic chlorophyll, ash free dry mass, and nematode densities. The changes to periphytic structure were not significant enough to produce concomitant or subsequent effects in nutrient biogeochemical-based functional indicators, community oxygen metabolism, or the inhabiting macroinvertbrates. However, endpoints for a litter-bag decomposition assay suggested lower fungal biomass, decreased import of nitrogen, and overall lower decay rate in doses 1.0 ug/L and above. Antibiotic resistance increased over the controls was found to be different at concentrations as low as 1 ug/L. Taken together the results suggest that persistent low-levels of triclosan exposure have ecologically relevant consequences for the base of the stream food chain but these may not cascade for significant functional relevance in already stressed systems.

534 Modeling and Measurement of Climatic and Biologic Control of Gaseous Air-forest Canopy Exchange of Semivolatile Organic Contaminants J.A. Perlinger, Michigan Technological Univ, Dept of Civil & Enviromental Eng.; L. Nizzetto, Norwegian Institute for Water Research; M.D. Rowe, US Environmental Protection Agency. Semivolatile organic contaminants enter the environment through primary emissions, but due to their persistence and volatility, once in the environment they are susceptible to multiple volatilization-deposition steps with environmental media. The surfaces presented to the atmosphere by canopies are ideal for passive uptake and re-emission of the chemicals, and these processes are controlled by climatic and biologic factors. Here, the controls are assessed through implementation and validation of a chemical partitioning model in a physiological and energy balance model for forest canopies. Diurnal and seasonal variability in air-canopy exchange flux, net yearly transfer of chemical from air to canopy, and the forest filter effect under potential climate and land use management scenarios are examined. In addition, the flux estimates are used to determine the chemical sensor resolution required to measure air-canopy exchange flux using the modified Bowen ratio and relaxed eddy accumulation micrometeorological techniques.

535 Air-Water Exchange Fluxes and Mass Transfer Coefficients for PCBs on the Hudson River A.L. Sandy, Rutgers, the State Univ of New Jersey, Dept of Environmental Science; L. Rodenburg, Rutgers, the State Univ of New Jersey, Dept of Environmental Sciences; J. Guo, R.J. Miskewitz, Rutgers, the State Univ of New Jersey, Dept of Environmental Science; W.R. McGillis, Columbia Univ, Lamont-Doherty Earth Observatory. In this study, micrometeorological approaches, using turbulent transport measurements, were used to calculate air-water exchange fluxes and mass transfer coefficients (MTCs) for polychlorinated biphenyls volatilizing out of the heavily contaminated Hudson River. The study was conducted during July 2008 on the Hudson River estuary near the Tappan Zee Bridge. Volatilization PCB fluxes were calculated using the modified Thornthwaite-Holzman equation. Values of friction velocity and atmospheric stability were calculated using the Aerodynamic Gradient and Eddy Correlation techniques. MTCs were determined using these turbulent fluxes divided by the corresponding dissolved phase concentrations. The median MTCs ranged from 0.29 for hexachlorobiphenyls to 2.2 m/d for monochlorobiphenyls with a propagated uncertainty of about 70%, lower than in previous studies. These field measurements differ by as much as a factor of 23 from predictions based on the widely-used Whitman two-film model.

536 "Old" and "New" Flame Retardants in the Great Lakes Basin A. Salamova, Indiana Univ, School of Public and Environmental Affairs, Indiana Univ, SPEA; M. Venier, Indiana Univ, School of Public and Environmental Affairs, Indiana Univ; R.A. Hites, Indiana Univ, School of Public & Environmental Affairs. Amina Salamova*, Marta Venier, and Ronald. A. Hites School of Public and Environmental Affairs, Indiana Univ, Bloomington, Indiana 47405 USA Email contact: asalamov@indiana.edu Due to environmental concerns, the use of most polybrominated diphenyl ethers (PBDEs) was banned by the European Union and phased out in the United States in 2004. Perhaps as a result, there seems to be a shift to using non-regulated flame retardants, and several "new" flame retardants have been recently detected in the environment. Here we present temporal and spatial trends in SPBDE, decabromodiphenylethane (DBDPE), 1,2-*bis*(2,4,6-tribromophenoxy)ethane (TBE), hexabromobenzene (HBB), and pentabromoethylbenzene (PBEB) concentrations in air (vapor and particle phases) and in precipitation at the five United States Integrated Atmospheric Deposition Network sites located in the Great Lakes basin. These samples were collected from January 2005 to December 2009, inclusive. Overall, Chicago and Cleveland had the highest concentrations of SPBDEs in both air and precipitation, suggesting a strong urban atmospheric source of these pollutants. This urban effect could also be observed at the rural Sturgeon Point site. The other two remote sites, Sleeping Bear Dunes and Eagle Harbor, have the lowest concentrations of these contaminants. Following this pattern, TBE and DBDPE have highest levels at urban Chicago and Cleveland. The spatial pattern for HBB and PBEB was surprising: highest levels of these compounds were detected at the rural site in Sturgeon Point and at the remote site in Eagle Harbor, respectively. The sources of HBB and PBEB at these sites are not known. The temporal trends of SPBDEs, DBDPE, HBB, PBEB, and TBE were investigated using harmonic regression applied to concentrations in all three phases at all the sites combined together, which allowed us to look at the overall temporal behavior of these compounds in the Great Lakes region.

537 Polybrominated Diphenyl Ethers (PBDEs) in the Atmosphere Surrounding Two WWTPs in Tuscany (Italy) A. Cincinelli, Univ of Florence, Chemistry Dept; T. Martellini, Univ of Florence; K. Jones, LEC, Lancaster Univ. Polybrominated diphenyl ethers (PBDEs) constitute an important group of brominated flame retardants that have been extensively produced and used in numerous everyday products. The market demand for PBDEs has been dominated by three major industrial formulations (penta, octa, deca-BDE mixtures), which are mixtures of tetra- to deca-congeners at various proportions. The penta and octa formulations were banned in Europe in 2004, deca-BDE was also prohibited by July 2008. PBDEs enter the waste water treatment plants (WWTPs) from a variety of sources including urban and agricultural run-off, domestic wastewater, industrial point discharges, etc. and can be released to the atmosphere by volatilization and aerosol formation generated by bursting bubbles produced by the diffused aeration systems that provide oxygen to the microbial flora in the activated sludge processes. Thus, wastewater treatment processes are often overlooked as responsible for the emission of PM10 and associated pollutants. In this study, we collected PM10 samples in the atmosphere (downwind and upwind) surrounding two waste water treatment plants (WWTPs) in Tuscany (Italy), between 2004 and 2006, in order to determine the atmospheric occurrence and distribution of PBDEs and investigate WWTPs as source of these pollutants to the atmosphere. PBDEs concentrations were compared to those found in samples taken simultaneously at reference sites that were not influenced by the WWTPs. Particulate and gas-phase samples were also collected to evaluate not only the gas-particle partitioning of PBDE, which is fundamental for assessing their fate and human exposure, but also to evidence temporal variations. Moreover, the risk of potential adverse health risks was calculated using the mean measured concentrations.

538 Analysis of Veterinary Growth Promoters in Airborne Particulate Matter by Liquid Chromatography Mass Spectrometry B.R. Blackwell, Texas Tech Univ/TIEHH, Environmental Toxicology, Texas Tech Univ, Environmental Toxicology; Q. Cai, Texas Tech Univ, TIEHH, Environmental Toxicology; M. Buser, Oklahoma State Univ; B. Johnson, Texas Tech Univ, Animal and Food Sciences; G.P. Cobb, P.N. Smith, Texas Tech Univ/ TIEHH, Environmental Toxicology. Veterinary growth promoters are widely used throughout the United States in livestock production. In beef production, steroid hormones are administered to an estimated 90% of cattle. These include the synthetic steroids trenbolone acetate and melengestrol acetate, as well 17β-estradiol. Given the endocrine-modulating activity of steroid growth promoters, a sensitive and reliable analytical method is needed to detect trenbolone, melengestrol acetate, estradiol and related residues in environmental matrices. We have developed a method that incorporates solid phase extraction (SPE) and liquid chromatography-tandem mass spectrometry for the simultaneous determination of trendione, trenbolone, melengestrol acetate, estrone, and estradiol in airborne particulate matter (PM) samples. PM was collected on 47 mm Zefluor filters. Sample preparation involved shaking extraction in methanol followed by cleanup on

Strata-X and Florisil SPE cartridges. Analytes were separated using reversed-phase liquid chromatography on a Kinetex PFP column. Column effluent underwent atmospheric-pressure chemical ionization (APCI) followed by detection using a triple-quadrupole mass spectrometer in SRM mode. 17β-trenbolone-d3, melengestrol acetate-d3, and estradiol-d5 were used as internal standards. Due to high noise levels interfering with estrone and estradiol determination, estrogens were derivatized using pentafluorobenzyl bromide. Detection limits, recovery, and repeatability of all target compounds will be presented and discussed in detail.

539 Estimating Hourly Passive Sampler Mass Transfer Rates and Concentrations in an Urban Landscape Using a Numerical Weather Prediction Model N.T. Petrich, S.N. Spak, Univ of Iowa, Civil & Environmental Engineering; C. Stanier, Univ of Iowa, Chemical and Biochemical Engineering; Z.L. Rodenburg, Univ of Iowa, Civil & Environmental Engineering; G.R. Carmichael, Univ of Iowa, Chemical & Biochemical Engineering; K.C. Hornbuckle, Univ of Iowa, Dept of Civil & Environmental Engineering. Polyurethane foam (PUF) passive air samplers represent an inexpensive and practical way to sample semivolatile organics compounds and their spatial gradients over urban areas. However, canonical methods for estimating concentrations from passive sampling assume constant empirical mass transfer rates and temperature, which add unquantified uncertainties in temporal representativeness to concentrations estimated from raw sampled mass. These methodological choices currently limit the ability to calculate and constrain uncertainty in estimated concentrations, and to directly compare passive sampler concentrations with time-resolved concentrations from active sampling methods and chemical transport models. Here we present an alternative method for estimating hourly flow rates, mass transfer coefficients, and concentrations—including average concentration at a reference temperature—from first principles using hourly meteorology (temperature, wind direction, and wind speed) simulated by the Weather Research and Forecasting (WRF) model. This method is applied to gas and aerosol polychlorinated biphenyl (PCB) congeners at an urban passive sampling network in Chicago, Illinois during 2008. We evaluate the importance of sampler height and orientation, temperature, sub-gridscale turbulent mixing, internal fluid dynamics within the PUF housing, and PUF air concentration gradients. Effects of model spatial resolution are considered using nested WRF simulations on 12 km, 4 km, and 1.33 km grids over the city. Spatial variability in mass transfer coefficients and concentrations are compared with results from canonical empirical methods, and temporal variability evaluated through comparison with cotemporaneous concentrations from high volume air samplers.

540 Modeling Assessment of Environmental Fate, Latitudinal Distribution and Long Range Transport of Decamethylcyclopentasiloxane (D5) S. Xu, Dow Corning Corporation, Health and Environmental Sciences. Decamethylcyclopentasiloxane (D5), a major ingredient in personal care products, has been shown to be mainly distributed in the air compartment due to its high air/water partition coefficient although small fraction of it may also partition to the fresehwater sediment near the point of release. The airborne D5 has an average atmospheric half-life of 6.9 days and thus may travel a long distance in the air. The environmental fate of this chemical in a regional environment has analyzed by fugacity modeling. Objective of this study was to assess the environmental fate of D5 in a global scale and to determine its global distribution and long range transport potential (LRTP). The environmental fate and global distribution of D5, the travel distance of D5 in air and water, and the deposition of airborne D5 to surface media in the remote region were estimated using both GloboPOP model and a global average chemical fate model: the OECD tool for screening Pov and LRTP (or the Tool). All simulations were conducted using the default values of the model for compartment dimensions and properties. The chemical specific data inputs, including physiochemical properties and the release scenarios, were either experimental values or the best estimation based on the experimental data. Generally, that D5 behaves as a degradable and highly hydrophobic flier with little potential to be transported to, and accumulated in, the remote surface media. For example, > 99 % of D5 was degraded after 10 years of continuous release. The majority (97.7%) of the non-degraded 1% of D5 was distributed in the global atmosphere. The Arctic contamination potential for D5 is > 3.8 orders of magnitude lower than that for Gamma-Hexachlorohexane and PCB 28, two POP reference materials. When all the results from both models were considered, it was concluded that most of D5 will be degraded in three latitudinal zones of the Northern hemisphere where they are released. Although some of it may be transported to the remote atmosphere such as the Arctic, the airborne D5 has very low potential to be transferred to the remote surface media and ecosystem.

541 Organosiloxane Compounds in Urban and Rural Air R. Yucuis, Univ of Iowa; K.C. Hornbuckle, Univ of Iowa, Dept of Civil & Environmental Engineering. The organosilicon compounds octamethylcyclotetrasiloxane (D4), decamethylcyclopentasiloxane (D5), and dododecamethylcyclohexasiloxane (D6) are widely used in household goods and personal care products. Due to their prevalence and chemical behavior, cyclic siloxanes have been targeted for study as possible persistent organic pollutants. We have applied active and passive methods to collect airborne siloxanes in urban and rural environments and analyzed the samples using the internal standard method (internal standard tetrakis trimethyl-siloxysilane, M4Q) and gas chromatography with electronic impact mass detection. Quality assurance metrics included sample replicates, field and laboratory blanks, laboratory background measurements, sampling media breakthrough, instrument linearity, and spike recoveries. The method was applied onboard the EPA R/V Lake Guardian, in urban Chicago, and in rural and suburban Iowa. We have found siloxanes to be present in every environment tested but much greater in concentration and variability in urban environments. Concentrations of D4, D5, and D6 over Lake Michigan near Chicago averaged 30, 230, and 9.3, respectively.

542 How Weirs in Agricultural Drainage Ditches Alter Conditions for Sediment Accumulation and Phosphorus Retention E. Usborne, Mississippi State Univ, Wildlife, Fisheries and Aquaculture; R. Kroger, Mississippi State Univ, Dept of Wildlife, Fisheries and Aquaculture, Mississippi State Univ. Agricultural phosphorus loads, carried by surface runoff through ditches, contribute to eutrophication. Low grade rip rap weirs potentially reduce phosphorus (P) from entering primary aquatic systems by slowing water flow through drainage ditches, allowing sediments to settle out and P to sorb to soil. Weirs have the potential to alter the pH and hydraulic residence time within the ditch system, thereby affecting P retention by ditch soils. A laboratory experiment was conducted in microcosm chambers to simulate this effect. Ditch sediments collected between Portageville, MO and Vidalia, LA were inundated for three day, three week, and three month treatments. Average pH within the microcosms decreased from 6.960 to 6.876 over three days. Over three weeks and three months, pH increased from 6.960 to 7.075 and from 6.960 to 7.266 respectively. Two field studies were conducted in order to compare experimental data with field data and record sediment deposition rates. One field study, measuring weirs of varying maturity, shows sediment accumulation behind a weir structure to be twice as much as ditches without weirs. A second field study is monitoring individual weirs monthly after installation to detect seasonal differences in weir effects on sediment deposition and P retention. Total P and P fractions are being measured on the sediment samples collected from the lab and field. Preliminary results show longer inundation treatments and older weirs have larger concentrations of iron phosphate. Predicting time periods between soil P saturation and sediment accumulation limits will allow us to inform farm managers of optimal times to dredge ditches for greatest P retention efficiency.

543 Nature and Estimated Toxicity of Polar Compound Mixtures Measured in Groundwater at Petroleum Release Sites and Reported as TPHd/DRO D. Zemo, Zemo & Associates; K. OReilly, Exponent; R. Mohler, A. Tiwary, R. Magaw, K. Synowiec, Chevron Environmental Technology Company. Both petroleum hydrocarbons and polar non-hydrocarbons are measured as "TPHd/DRO" using EPA Method 8015 unless a silica gel cleanup (SGC) is used. Sources of polar compounds include (1) natural organics, (2) petroleum biodegradation byproducts (metabolites), (3) sampling/lab contamination (e.g., phthalates), or (4) non-petroleum chemicals. Work since the mid 1990s has shown that a large proportion of organics in groundwater at sites with biodegrading petroleum are polar compounds. The polar compounds occur within and downgradient of the source area and within the area of aerobic and anaerobic biodegradation, and therefore have been assumed to be primarily biodegradation byproducts. Some regulatory agencies have been hesitant to allow SGC of samples to separate hydrocarbons from polars because of uncertainty regarding the nature and toxicity of compounds removed by the SGC. This study provides a better understanding of the potential composition of polars in groundwater based on knowledge of metabolic pathways and actual analytical results. This

work summarizes what is known about the human toxicity of the major classes of polar compounds found in groundwater, compiled from numerous published sources. It provides analytical results from groundwater samples collected at multiple sites with biodegrading petroleum that (a) identify and quantify specific polar compounds of potential human toxicity concern; and (b) tentatively identify polar compounds present using two-dimensional gas chromatography mass spectrometry (GCxGCxMS). In summary, this study shows that the polar compounds present are primarily organic acids and alcohols, with lesser amounts of phenols, aldehydes and ketones. The human toxicity of these chemical classes varies from "non-toxic" to "low to moderate". The overall toxicity of the mixture present in groundwater at these sites is characterized as "low" based on the relative proportions of the classes. The mixture of polar compounds present in groundwater at these sites has lower toxicity than dissolved aromatic hydrocarbons, and does not pose a significant risk to human health. Results also confirm that water quality objectives developed based on hydrocarbons should not be applied to the polar compounds, and a SGC should be routinely used to separate hydrocarbons from polar compounds if TPHd/DRO analysis is required.

544 PAH Reaction Rates with Peroxy-Acid Treatment: Prediction of Reactivity Using Local Ionization Potential J. Shoulder, C. Brenemann, Rensselaer Polytechnic Institute, Chemistry and Chemical Biology; M. Nyman, Rensselaer Polytechnic Institute, Dept of Civil and Environmental Engineering. Property-Encoded Surface Translator (PEST) descriptors have been found to be highly correlated with the degradation rates of polycyclic aromatic hydrocarbons (PAHs) by the peroxy-acid process. Reaction rate constants (k)in hr^{-1} for nine PAHs (e.g., acenaphthene, anthracene, benzo[*a*]pyrene, benzo[*k*]fluoranthene, fluoranthene, fluorene, naphthalene, phenanthrene, and pyrene) were determined by a peroxy-acid treatment method that utilized acetic acid, hydrogen peroxide, and a sulfuric acid catalyst to degrade the polyaromatic structures. Molecular properties of the selected nine PAHs were derived from molecular structures optimized at B3LYP/6-31G* and HF/6-31G* levels of theory. Properties of molecular energy, adiabatic and vertical ionization potential (IP), highest occupied molecular orbitals (HOMO), HOMO/lowest unoccupied molecular orbital (LUMO) gap energies and HOMO/singly occupied molecular orbital (SOMO) gap energies were not correlated with rates of peroxy-acid reaction. PEST descriptors were calculated from B3LYP/6-31G* optimized structures and were found to have significant levels of correlation ($r^2 = 0.787$) with k. PIP Min described the minimum local average ionization potential on the surface of the molecule and was found to be most related to k of the selected PAHs used in this investigation. PEST technology appears to be an accurate method in predicting reactivity for the selected PAHs and could prove to be a valuable asset in building treatment models and in effective remediation design for PAHs and other organic contaminants in the environment. Therefore, this technique could potentially save time and expense in treatment design and implementation.

545 Photosensitized Transformation of Acetochlor and Isoproturon by Chromophoric Dissolved Organic Matter M. Langlois, L. Weavers, The Ohio State Univ, Dept of Civil and Environmental Engineering and Geodetic Science; Y. Chin, The Ohio State Univ, Dept of Geological Sciences. The phototransformation of agricultural products in wetlands is strongly influenced by chromophoric dissolved organic matter (CDOM), a well-studied and important process by which absorbed light causes the production of reactive oxygen species (ROS) in illuminated, aerated waters. We investigated the photolysis of two broadleaf herbicides, acetochlor (AC) and isoproturon (IP), in water from four US wetlands (an agricultural wetland in Ohio [OH], Kawai Nui wetland in Hawaii [HW], the Everglades in FL [EV], and Okefenokee Swamp in GA [OK]). Wetland waters spiked with the target herbicides were irradiated in a solar simulator (Suntest CPS+) and analyte concentrations monitored over time. Further, UV-vis absorbance of CDOM in our samples and dissolved oxygen (DO) were also monitored at time points throughout the experiment to determine the relationship between photobleaching and herbicide degradation. Indirect photolysis of AC was slow; even across chemically diverse waters ([DOC]: 7-190 mg C/L, pH 3.5-9, [Fe] = 1.1- 28 mM, [NO_3] < 7.5 mM) with consistent half-lives at $t_{1/2} = 1.8 \pm 0.3$ d. Quenching of the reaction by t-butanol as well as dramatically higher rates in photo-Fenton-enhanced low-pH water strongly indicate a hydroxyl radical (OH•) mediated pathway. The similarity of O_2 consumption between control (no-herbicide) and AC-spiked samples indicate that CDOM is the main source of photochemical oxygen demand in sunlit waters. Conversely, IP actually contributed both to DO loss and to changes in UV-vis absorbance in irradiated waters, indicating that it and DOM are directly involved in O_2 consumption. These data suggest that O_2 is involved in quenching activated IP intermediates. Rate constants for both herbicides in these wetland waters do not correlate strongly to any one chemical or optical property of the sampled waters, indicating that it is difficult to predict the photochemical behavior of these type of herbicides based upon the chemical constituents in natural waters.

546 Environmental Fate of Flame Retardant Chemicals and Triclosan in Biosolids-amended Soil E.F. Davis, H.M. Stapleton, Duke Univ, Nicholas School of the Environment. Disposal of biosolids as a nutrient-rich soil amendment is a growing trend in the United States. However, these biosolids are not regulated for organic contaminants that may not be fully removed during wastewater treatment; thus, extensive land application of biosolids may enhance the bioaccumulation and transport potential of these compounds. This study was undertaken to determine the fate of chemicals of emerging concern in biosolids-amended soil in a controlled greenhouse experiment. Our objective was to determine whether a suite of brominated and chlorinated flame retardants as well as the antimicrobial agent triclosan would be accumulated by alfalfa (*Medicago sativa*) grown in the amended soil and/or undergo transformation reactions over time. Biosolids were collected from a wastewater treatment plant in Durham, North Carolina in July of 2010. In a 90-day controlled experiment conducted in the Duke Univ research greenhouse in the summer of 2010, pots of soil were amended with biosolids at three different levels (0% (control) and approximately 10% and 30% by volume). Alfalfa was grown in the amended soil and each treatment was prepared in triplicate; unplanted controls were also prepared. At predetermined time points, subsamples of soil and above- and below-ground plant biomass were collected and frozen until analysis. A suite of chemicals have been detected in the biosolids as well as in the three soil treatments from Day 0 of the experiment, including polybrominated diphenyl ethers (PBDEs), 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (TBB), di(2-ethylhexyl)-2,3,4,5-tetrabromophthalate (TBPH), tris(1,3-dichloro-2-propyl)phosphate (TDCPP), Dechlorane Plus and 5-chloro-2-(2,4-dichlorophenoxy)phenol (triclosan). Triclosan was the dominant contaminant detected in the biosolids (3125±226 ng/g dw) followed by PBDEs (2784±180 ng/g dw), TDCPP (1557±112 ng/g dw), TBPH (548±49 ng/g dw), TBB (297±39 ng/g dw) and Dechlorane Plus (22±4 ng/g dw). Concentrations of triclosan in the amended soil treatments on Day 0 ranged from ΣPBDEs ranged from 2 to 1687 ng/g dw and TDCPP ranged from 73 to 581 ng/g dw. Soil and alfalfa samples from the remaining time points are currently being analyzed for these compounds and their known degradation products. Contaminant concentrations over time in soil and alfalfa biomass as well as the formation of degradation products will be presented.

547 Pesticides in Guttation Droplets Following Seed Treatment – Field Studies D. Schenke, Julius Kühn-Institute, Institute for Ecological Chemistry, Plant Analysis and Stored Product Protection; I. Joachimsmeier, J. Pistorius, Julius Kühn-Institute, Institute for Plant Protection in Field Crops and Grassland; U. Heimbach, Julius Kühn-Institute. The European Council Regulation (EC) 1107/2009 defines that plant protection products shall only be approved if under the proposed conditions of use there is no unaccetable risk for honeybees. An exposure assessment is a precondition for the terrestrial ecotoxicological risk assessment. According to the Guidance Document on Terrestrial Ecotoxicology (SANCO/10329/2002 rev 2 final) realistic exposure conditions should be taken into account if soil applied systemic plant protection products (e.g., applied as seed dressing) have a very high oral toxicity. Some data are available for transport of systemic compounds in the xylem to pollen or nectar but not for excretion via guttation droplets. Guttation takes place at high humidity and lack of transpiration. The droplets are excreted at the end of the xylem veins at leaf edges. In certain circumstances guttation may be a potential water source for water collecting bees and bees may potentially exposed to systemic compounds used as seed coating. The frequency and duration of guttation were observed at major crop species under middle european climate conditions at field stations in Berlin and Braunschweig from April to August 2010. Rarely droplets were found on leaves of sugar beet, potato, onion, carrot and pea. The first guttation droplets in maize, cereal, oilseed rape und cucumber were seen at emergence and beginning of leave development. These crops guttated with high frequency. Spring barley and oat showed guttation at leaf edges until booting and winter wheat until the end of heading. Guttation

stopped in winter oilseed rape at fruit development and in spring oilseed rape at emergence of inflorescence. Maize und cucumbers excreted guttation droplets up to the ripening of fruit and seeds. Grass on field boundaries guttated also often combined but good distinguishable with presence of dew. Guttation droplets from agricultural crops sown with pesticide coated seeds were sampled for analysis. Special studies were designed to examine the influence of different rates of pesticides on maize seeds on the concentration of the neonicotinoids imidacloprid, clothianidin and thiamethoxam in guttation droplets. The concentration of clothianidin in guttation water was also analysed after use of the same rates per ha as point (coated seed) and as row in furrow application (granulate).

548 The Sky is Falling: Evaluating the Potential Impact of Soil Deposition from Static Rocket Testing on Crop Plants W.J. Doucette, Utah State Univ, Utah Water Research Laboratory; S. Mendenhall, L. McNeill, J. Chard, Utah State Univ. Static testing of reusable solid rocket motors (RSRMs) at the ATK Promontory site can displace large amounts of soil that become entrained in the combustion cloud. As the cloud cools, the soil drops on the surrounding area (typically within a 3-5 mile radius) that includes farmland, rangeland, low-density residential housing and a wildfowl management area. This deposition material, referred to as Test Fire Soil (TFS), is different from the original soils due to its exposure to the elevated temperatures and the aluminum oxide and hydrochloric acid rocket fuel combustion products. Local residents and farmers have observed TFS being deposited on their gardens, fields, and crops and have expressed concerns regarding the potential impact of this material. To address these concerns, we conducted growth and uptake studies in a controlled greenhouse environment. Corn and alfalfa were grown to for a minimum of 45 day or until maturity, in columns of soil with and without the addition of TFS material. Water and fertilizer were applied to simulate local field applications. Leachate if generated was analyzed for Cl, Al and other elements. Three treatments were evaluated: 1) soil without the addition of TFS, 2) soil completely mixed with 5-10% TFS and 3) soil with TFS applied to soil surface after 45 days of plant growth. Analysis of soil and plant tissue was conducted periodically throughout the study to determine if there was a significant difference between crops grown in soil and those exposed to TFS. The potential impact of the TFS on plant health was also evaluated by comparing plant growth and nutrient content between the treatments. In addition to soil uptake, the impact of deposition through direct contact between the TFS and above ground (foliar) portions of the plants was also evaluated.

549 Volatilization of Trichloroethylene from Trees and Soil: Measurement and Scaling Approaches W.J. Doucette, Utah State Univ, Utah Water Research Laboratory; H. Klein, J. Chard, B. Bugbee, R. Dupont, Utah State Univ; B. Plaehn, Parsons. Phytoremediation, using fast growing trees like poplars and eucalyptus, has been promoted as a low cost, sustainable remediation alternative for the clean up of shallow groundwater contaminated with volatile chlorinated solvents like trichloroethylene (TCE). Volatilization from leaves and trunk (phytovolatilization) is thought to be a primary mass removal mechanism with trees also reported to enhance soil volatilization. However, quantifying this mass removal on a field scale is challenging. The focus was to develop a simple, low-cost approach for measuring the volatilization of TCE from leaves, truck and soil and to use the measurements to estimate TCE removal from phytoremediation demonstration sites at Travis and Fairchild Air Force Bases (AFBs). Tree cores, collected using an increment borer and analyzed using headspace chromatography/mass spectrometry (GC/MS), were used to determine the relative TCE concentrations within the plume beneath the trees and estimate the TCE mass within each tree. Volatilization from leaves was measured by enclosing several leaves inside a flow-through glass chamber continuously purged with air to maintain normal transpiration and temperature. Air exiting the chamber was sampled using sorbent tubes and analyzed for TCE by thermal desorption GC/MS. Humidity probes, placed at the chamber entry and exit, were used to determine transpiration. Volatilization of TCE from tree trunk and soil surfaces was measured by enclosing a known area within a small stainless steel chamber. Fans mixed the air in the chamber that was recirculated through sorbent tubes to continuously remove TCE. After a known time interval, the sorbent tubes were analyzed for TCE. Using the volatilization measurements, a Thiessen polygon approach was used to estimate the removal of TCE at Travis (839 g/yr) and at Fairchild AFBs sites (18 g/yr) with the majority associated with leaf and soil volatilization. It was also observed that volatilization of TCE from the soil surface was greater inside the planted areas than outside. Based on estimates of TCE mass in the groundwater below the sites at Fairchild and Travis AFBs, volatilization removed 5 and 50%, respectively. The lower removal at the Fairchild site was not surprising since the average TCE groundwater concentration was approximately 10 times lower than at the Travis AFB site and the growing season is shorter by a factor of two.

550 PBDEs, PCBs, and DDT in Resident Backyard Birds of Suburban and Rural Areas Near Washington D.C. C. Orazio, US Geological Survey, Columbia Environmental Research Center; N. Diggs, Smithsonian Migratory Bird Center, National Zoological Park, Smithsonian Conservation Biology Institute; P. Peterman, US Geological Survey, Columbia Environmental Research Center; S. Tan, C. Grimm, Smithsonian National Zoological Park, Center for Species Survival; K. Feltz, K. Echols, US Geological Survey, Columbia Environmental Research Center; P. Marra, Smithsonian Migratory Bird Center, National Zoological Park, Smithsonian Conservation Biology Institute. Residue levels of polybrominated diphenyl ethers (PBDEs), organochlorine pesticides, and PCBs were measured in eggs of northern cardinals (Cardinalis cardinalis) from several neighborhoods surrounding the Washington DC area to determine if there are location-specific exposure patterns for these chemicals in resident birds. The diet of the cardinal consists mostly of fruits and seeds (and water) throughout the year with the summer diet including insects. Eggs were collected in May 2008 from 5-6 first-brood nests within each neighborhood. Neighborhoods included Arlington VA (suburban), Takoma Park MD (suburban), Greenbelt MD (managed suburban community), Dunkirk MD (semi-rural estate homes), West Friendship MD (semi-rural), and Whitehall MD (rural farming community 70 mi NE of DC). Nest locations were generally separated from each other by at least 100 yards from within a 10-20 acre area. Egg contents were solvent extracted, purified, and analyzed by GC/MS and GC-high resolution MS. Within each neighborhood, PBDE concentrations and congener patterns in the eggs were similar. PBDEs 47, 99, 100, and 209 were the predominant PBDE congeners detected in the eggs. Total-PBDE levels in suburban eggs were higher (with the exception of Arlington) as compared to rural areas. The highest levels of PBDE- 47 and PBDE-209 were found in an egg from Greenbelt: 3.08 and 3.25 ng/g wet weight (ww) or 57 and 53 ng/g lipid weight basis, respectively. Residues of p,p'-DDE were detected in eggs from all areas, with suburban areas having higher levels that ranged from < 2 to 569 ng/g ww. Levels of p,p'-DDT were below detection (< 0.1) in eggs from the three more rural neighborhoods tested, while p,p'-DDT ranged from 0.5 to 16 ng/g ww with the exception of two suburban eggs: one from Takoma Park with 127 ng/g ww and one from Greenbelt with 1130 ng/g ww. The DDT/DDE ratios in these two eggs (4:1 and 2:1) suggested a recent DDT-contaminated diet, either from foraging in a DDT contaminated area or from DDT-contaminated seed in a backyard bird feeder. We measured egg shell thickness, but saw no correlation to the high DDT levels in these two eggs. Total-PCB in eggs from the three suburban neighborhoods ranged from 11 to 21 ng/g ww, whereas the rural area levels were < 5ng/g. Levels of chlordane were higher in eggs from older suburban neighborhoods, likely from related to lingering termiticide treatment of home foundations.

551 Comparison of PCBs in East Chicago, IN and Columbus Junction, IA in Indoor and Outdoor Air T. Schulz, Univ of Iowa, Dept of Civil & Environmental Engineering, IIHR-Hydroscience and Engineering; C. Stanier, Univ of Iowa, Chemical and Biochemical Engineering; P. Thorne, J. Dewall, Univ of Iowa, Occupational and Environmental Health; K.C. Hornbuckle, Univ of Iowa, Dept of Civil & Environmental Engineering. We have deployed and collected polyurethane foam based passive samplers (PAS-PUF) at residential homes in two communities: East Chicago, Indiana and Columbus Junction, Iowa. At each residence, a sampler was deployed inside the home and outside the home. The samples have been extracted and analyzed for the full suite of polychlorinated biphenyls (PCBs). Higher levels were expected to be found in East Chicago compared with Columbus Junction due to a higher level of current and historical industrial activity in Northwest Indiana relative to rural Iowa. However, preliminary results indicate that the two communities do not have statistically significant differences in outdoor air concentrations. Total PCB masses quantified in indoor air are fairly similar to outdoor, but when transformed to air concentrations using published sampling rate constants, they are calculated to be approximately three times the outdoor concentration. Congener distributions are examined

to elucidate sources of PCBs from building materials and/or nearby industrial activity.

552 Spatial Distribution of Chlordane and PCB Congeners in Soil in Cedar Rapids, Iowa, After a 500-year Flood A. Martinez, Univ of Iowa, Dept of Civil & Environmental Engineering,and IIHR-Hydroscience and Engineering; N.R. Erdman, Z.L. Rodenburg, Univ of Iowa, Civil & Environmental Engineering; P. Eastling, IIHR- Univ of Iowa Civil and Environmental Engineering, IIHR- Univ of Iowa Civil and Environmental Engineering; K.C. Hornbuckle, Univ of Iowa, Dept of Civil & Environmental Engineering. After the largest flood on record occurred in Cedar Rapids, Iowa (June 2008), we measured chlordane and polychlorinated biphenyls (PCBs) in surficial soils. Chlordane compounds, including trans-chlordane (TC), cis-chlordane (CC) and trans-nonachlor (TN), ranged from 0 to 7500 ng g-1 d.w., with an average and standard deviation of 130 ± 920 ng g-1 dry weight (d.w.). These chlordane concentrations are about 100 times larger than background concentrations and could be due to historical residues from residential applications of the chlorinated insecticide. ΣPCBs concentrations ranged from 3 to 1200 ng g-1 d.w., with an average and standard deviation of 56 ± 160 ng g-1 d.w. The concentrations and PCB congener patterns strongly suggest local use as the major explanation of their presence in Cedar Rapids soils: concentrations are ~ 1 order of magnitude higher than background worldwide soil concentrations; and the individual congener profiles observed in the samples are very different from each other and dissimilar to Aroclor mixtures. Overall, the soils are enriched in penta-, hexa- and heptachlorobiphenyls (85%) and exhibit some evidence of environmental weathering from volatilization and/or aerobic biodegradation. Soil toxic equivalency quantities (TEQs) in Cedar Rapids are similar to those reported elsewhere, but 2 order of magnitude lower that a PCB Superfund site. Although the flooding severely affected the industries and residential areas of Cedar Rapids, no spatial trends in PCBs or chlordane was detected that could be attributed to chemical transport during to the flood, which has been seen in other similar studies.

553 Background Concentrations of Dioxin in Urban Soils Throughout the United States: A Review of Academic and Government Literature Values M.K. Lambert, Univ of Rhode Island, Graduate School of Oceanography, USEPA, OSRTI, Environmental Scientist; M. Berg, USEPA, Office of Superfund Remediation and Technology Innovation. Dioxin is a problematic environmental contaminant due to its persistence, its high toxicity at low concentrations, and its potential to bioaccumulate. Improvements in analytical technologies have lowered the detection limits for measuring dioxin and contributed to an understanding that dioxin is a ubiquitous soil contaminant. An EPA survey of rural soils throughout the US indicated an average rural soil concentration of 1.76 pg TEQ/g (SD = 2.47). Long-range transport, via atmospheric deposition, is the dominant source for dioxin at many of the rural sites studied. Urban background values are more difficult to define due to the proximity of a variety of sources and multiple transport mechanisms. The purpose of this project was to compile published urban background levels of dioxins in soils, provide a national perspective on urban dioxin levels, and highlight important gaps in our knowledge. Much of the data available for the US comes from state funded studies and background studies at individual Superfund sites. Urban residential soil concentrations, as reported by several state funded studies, ranged from 0.1 to 20 pg TEQ/g soil and were similar to values reported for residential soils in other developed countries. Industrial land use soils varied over three orders of magnitude, up to ~1,000 pg TEQ/g.

554 Metal Contamination in Street Dust: Levels, Trends, and Fate in Urban Watersheds L.A. Benedict, J. Barilone, N. Chouinard, M. Neidig, Univ of Southern Maine, Chemistry; L. Fox, Univ of Southern Maine; L. Benedict, AMEC. Street dust is defined as fine-grained solids with particle sizes < 500 µm that are found on roadways, parking lots and/or sidewalks. Street dust is predominantly composed of locally derived material (e.g., soils) and is heavily influenced by anthropogenic activities such as driving, construction and demolition, and combustion (e.g., burning). During rain events street dust is transported from impervious surfaces into urban watersheds typically through managed storm water disposal networks. Small-scale urban watersheds are particularly sensitive to contaminated storm water run-off transported from impervious surfaces. Contaminated street dust also poses a human health risk for individuals as the fine-grained particles can easily become airborne and can be inhaled or inadvertently ingested by adults and children during outdoor activities. This study focused on the determination of levels, fate and trends of various metals found within street dust samples collected from paved areas (e.g., streets and parking lots) in the Casco Bay Watershed in southern Maine. Metal analysis was conducted using an x-ray fluorescence spectrometer. Reported concentrations were evaluated in three sample sets based on the area in which the samples were collected; commercial areas, school areas and residential areas. Average levels of Cu, Zn, Cr, and As were highest in samples collected in commercial areas, likely a result of higher traffic and operations of businesses adjacent to sample sites. Conversely, levels of these four metals were lowest in samples collected from residential areas. Levels of Pb were highest in residential areas, correlating with a higher historical use of lead paint. Samples collected in school areas had levels of Cu, Zn, Cr, and As between those reported for the commercial and residential groups, likely due to the high amount of idling that occurs during drop off and pick up times for schools. This project also focused on the potential of contaminants found in street dust to impact a small-scale urban watershed with a high percentage (28%) of impervious surface and over 90% commercial use. Samples were collected from areas with varying traffic patterns and use. Samples collected from roadways with higher traffic patterns and longer periods of vehicle idling had significantly higher levels of Cu, Zn, and Cr, than those samples collected from areas with little to no idling or with low traffic patterns.

555 Transport of PCBs, PBDEs, PAHs, and Polycyclic Musks via Urban Tributaries to Lake Ontario, Canada M. Robson, Univ of Toronto; P.A. Helm, Ontario Ministry of the Environment, Environmental Monitoring and Reporting Branch; G. Kaltenecker, B. Gilbert, Ontario Ministry of the Environment; L. Melymuk, M. Diamond, Univ of Toronto; C. Brimacombe, T. Chen, T. Kolic, E. Reiner, Ontario Ministry of the Environment. Urban rivers continue to deliver contaminants such as the legacy polychlorinated biphenyls (PCBs) and current/recent-use chemicals to receiving waters like the Great Lakes where they may persist, bioaccumulate, and impact biota. To investigate the relative roles of urban contaminant fate pathways (atmospheric deposition, tributary, municipal wastewater) to adjacent waterbodies, using Toronto, Canada and Lake Ontario as examples, we measured concentrations for a suite of organic compounds of varying uses and sources and estimated stream loadings. This presentation highlights results for the urban tributary pathway. Water concentrations of PCBs, polycyclic aromatic hydrocarbons (PAHs), polybrominated diphenylethers (PBDEs), and polycyclic musks (PCMs) were determined at base flow and in wet weather conditions in Toronto, Ontario, Canada in 2007 through 2009. Median (maximum) concentrations at downstream sites ranged from 2.2-6.7 (19-144) ng/L for SPCBs, 100-950 (1700-19300) ng/L for SPAHs, 5.1-6.6 (25-46) ng/L for SPBDEs, and 29-1800 (53-5800) ng/L for SPCMs. Regression analysis indicated a strong correlation with suspended sediments for PAHs and PCBs (R2 of 0.59-0.85 and 0.36-0.75, respectively), while correlations were weaker for PBDEs and musks (R2 of 0.01-0.59 and 0-0.55, respectively), depending on the site. This suggests that the reservoir for PCBs and PAHs are predominantly soils and sediments within the watersheds, while sources are more varied for the current-use PBDEs and musks. Contaminant loads to Lake Ontario were calculated using USGS's LOADest. Estimated average annual loads were 2200 kg/yr for SPAHs, 42 kg/yr for SPCMs, and 8 kg/yr each for SPCBs and SPBDEs. On a mass basis, the tributaries were the most important pathway for SPAHs, contributing 60% of loads compared to atmospheric and wastewater pathways from urban Toronto. In comparison the tributaries were estimated to contribute 40% for SPBDEs, 20% for SPCBs, and 4% for SPCMs. Urban tributaries are important contributors of compounds with urban sources to adjacent aquatic environments.

556 Predicting Urban Scale Atmospheric PCB and PBDE Emissions and Fate Using the BLFM-MUM Model S.A. Csiszar, Univ of Toronto, Dept of Chemical Engineering and Applied Chemistry; S. Daggupaty, Environment Canada, Science And Technology Branch; L.E. Melymuk, Univ of Toronto, Dept of Chemical Engineering and Applied Chemistry; S. Verkoeyen, Univ of Toronto; M. Robson, Univ of Toronto, Dept of Geography; A. Giang, Univ of Toronto; P. Helm, Ontario Ministry of Environment; M.L. Diamond, Univ of Toronto, Dept of Geography and Dept of Chemical Engineering and Applied Chemistry. An atmospheric transport model coupled with a local scale (5×5 km^2) multi-box multimedia fate model (together referred to as BLFM-MUM) has been developed to estimate chemical emissions and fate in urban areas. The model is illustrated

here through a case study of PCBs and PBDEs in Toronto. Toronto was estimated to contain ~440 tonnes of PCBs in 2006 and ~240 tonnes of PBDEs in 2010. The spatial mass inventories were used to estimate air emissions on a local scale with a total PCB emission of ~150 kg y^{-1} or 0.4 g y^{-1} kg^{-1} inventory for the entire city. These emissions accounted for air concentrations measured at various sampling sites across the city suggesting that neighbouring areas do not significantly contribute to Toronto PCB and PBDE levels. The downtown core had the largest chemical inventories which accounted for ~90% of the total urban PCB emissions. In addition to emissions, local meteorology contributed to concentration gradients measured across the city. The coupled model also simulated interactions between air and the city via various urban media such as soil and films that coat impervious surfaces. The model predicted that a large proportion of chemical becomes diluted within the city's air as modeled air concentrations are at least ~4 times lower at non-downtown sites and are even lower outside the city. The chemical that is not diluted in the air may act as a source to other urban media. We estimate that 45% of the chemical that is deposited to the city is transferred to impervious surface films which is mostly mobilized via storm water.

557 What We Found in Our Backyard M.L. Diamond, Univ of Toronto, Dept of Geography and program in planning, Univ of Toronto, Dept of Geography; P.A. Helm, Ontario Ministry of the Environment, Environmental Monitoring and Reporting Branch; S.A. Csiszar, Univ of Toronto, Dept of Chemical Engineering and Applied Chemistry; L. Melymuk, Univ of Toronto, Dept of Chemical Engineering and Applied Chemistry, Univ of Toronto, Dept of Chemical Engineering and Applied Chemistry; M. Robson, S. Verkoeyen, Univ of Toronto, Dept of Geography and program in planning; S. Backus, S. Daggupatty, L.M. Jantunen, Environment Canada. We found a lot in our backyard! This presentation summarizes results from our multi-year, multi-agency effort to quantify what's in our backyard and how it moves from emission source in our city to our backyard, urban surface waters and beyond. Focussing on PCBs, PBDEs, PAH and PCMs (polycyclic musks), we measured concentrations in air, soil, urban rivers and final effluent from waste water treatment plants in Toronto. As expected, air concentrations showed strong urban-rural gradients, with the gradient related to patterns of chemical use and thus emissions. For example, Melymuk found that PCB emissions can be explained by major emissions from the downtown core and radial dilution from the core. Robson sound a strong correlation between PCM air concentrations and population density. PBDE air concentrations were related to a spatial inventory of PBDEs in Toronto prepared by Verkoyeon. Robson and Helm estimated that loadings from urban rivers were greatest for PAH, followed by PBDEs and PCBs. Concentrations were closely correlated with that of total suspended solids. The greatest loadings of all compounds from rivers occurred during storm events. Emissions from Toronto's waste water treatment plants were greatest for PCMs, followed by PBDEs, PCBs and PAH. Finally, Csiszar and Daggupaty tightly coupled the mesoscale boundary layer forecast meteorology model (BLFMPOP) and the Multimedia Urban Model (MUM) which was used to estimate spatially resolved emissions and fate of PCBs and PBDEs. Model results provided a mechanistic explanation for the observations discussed above that were based on the measurement campaign.

558 Development of Transcriptomics-based Biomarkers for Selected Endocrine Disrupting Chemicals in Zebrafish (*Danio rerio*) R. Wang, USEPA; D. Bencic, USEPA, Office of Research and Development; A. Biales, USEPA, Office of Research and Development, National Exposure Research Laboratory; R. Flick, USEPA, Office of Research and Development, National Exposure Research Laboratory; J.M. Lazorchak, USEPA, Office of Research and Development, National Exposure Research Laboratory, Molecular Ecology Research Branch; D.L. Villeneuve, USEPA, Mid-Continent Ecology Division; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division. Genome-wide transcriptional profiling by microarrays provides a powerful platform for gene expression-based biomarker discovery.Â After their wide acceptance in human disease diagnosis, prognosis, and drug discovery, these gene signatures are increasingly being adopted for environmental toxicology applications as well.Â Built upon our previous work in zebrafish of reverse-engineered transcription factor (TF) networks and their statistical linkage to various treatment conditions of endocrine disrupting chemicals (EDCs), a systematic, computationally-intensive search using genetic algorithm coupled with support vector machine was conducted for candidate gene signatures capable of distinguishing individual chemical treatment conditions from their controls.Â Microarray data from zebrafish brain (male, female, or combined), ovary, and testis were analyzed.Â The search within each tissue type was either confined to hundreds of individual TF networks significantly associated with EDCs of differing mechanisms/modes of action, or across the entire genome.Â In agreement with our previous findings, tissue type was found to be critical to biomarker search.Â Brain yielded most candidate gene signatures, followed by ovary and testis. Â By chemical, prochloraz had the greatest number of candidates, then flutamide, fipronil, and enthinyl estradiol.Â A subset of these candidates will be evaluated using an independently derived microarray dataset generated from additional EDC-exposed zebrafish samples.

559 Transcriptomic Responses to Metal Bioaccumulation in the Blue Mussel *Mytilus edulis* H.C. Poynton, US Environmental Protection Agency, Molecular Indicators Research, Univ of Massachusetts-Boston, Environmental, Earth and Ocean Sciences; W.E. Robinson, Univ of Massachusetts-Boston, EEOS Dept; B.J. Blalock, Univ of Massachusetts, Boston, Environmental, Earth, and Ocean Sciences; R.E. Hannigan, Univ of Massachusetts, Boston, Dept of Environmental, Earth and Ocean Sciences. In the Northeastern United States, the blue mussel *Mytilus edulis* is the primary species utilized for monitoring the bioaccumulation of toxicants along the coast. The NOAA National Status and Trends "Mussel Watch" Program has monitored tissue concentrations of contaminants in this species for over thirty years; however, as the list of potential contaminants grows, the ability to measure concentrations in a targeted manner is becoming cost prohibitive. Bioassays which are able to screen for pollution and predict the presence of chemical contaminants are needed. We created a 3500 gene *M. edulis* oligonucleotide microarray to determine gene expression patterns that correlate with the bioaccumulation of cadmium and lead. We performed four week exposures to 0.54 μM Cd and 0.54 μM Pb and a mixture of both metals and monitored gene expression in the gill after one week, two weeks and four weeks. Metal bioaccumulation was also measured in the gill, digestive gland and whole body soft tissue at these time points. Transcriptomic patterns after two weeks reveal distinct expression profiles for the two metals with the mixture profile most closely resembling the Cd profile, possibly due to competition for uptake between the two metals or increased toxicity of Cd. As expected, metallothionein biomarker genes MT-10 and MT-20 were induced in the Cd and mixture exposures confirming the validity of the transcriptomic approach. Analysis of the one week and four week time points will enable us to determine if gene expression profiles of more chronically exposed organisms directly correspond to the levels of metals accumulated in their tissues.

560 Epigenetic Effects of Methylmercury on DNA Methylation in Fish, Mammals, and Birds J. Head, Univ of Michigan, Cooperative Institute of Limnology and Ecosystem Research, Univ of Michigan, Cooperative Institute for Limnology and Ecosystem Research; D. Nam, Univ of Michigan, Dept of Environmental Health Sciences; J. Rutkiewicz, Univ of Michigan; K. Mittal, Univ of Michigan, Dept of Environmental Health Sciences; N. Basu, Univ of Michigan, Dept of Environmental Health Sciences, Univ of Michigan, Dept of Environmental Health. We are interested in studying the epigenetic effects of environmental contaminants in natural populations. Alterations in patterns of DNA methylation are termed 'epigenetic' because they cause heritable changes to gene expression that occur outside of changes to the DNA sequence itself. We previously reported that relatively low levels of methylmercury are associated with a decrease in global DNA methylation in mammalian brain tissue. This decrease was observed in wild polar bears and captive mink, and was accompanied by a suppression of DNA methyltransferase (DNMT), the enzyme that maintains DNA methylation. Here we expand upon this work by assessing the relationship between methylmercury exposure and global DNA methylation in multiple tissue types (liver, muscle, brain) and species (mammals, fish and birds). Global DNA methylation ranged from 53% in chicken to 87% in yellow perch. No significant differences in DNA methylation were observed among tissue types for a given species. The effect of methylmercury on DNA methylation may be limited to certain species or tissues. For example, no effect of methylmercury was detected in yellow perch liver or muscle. Ongoing work will characterize the effects of methylmercury on DNA methylation in chicken tissues. By taking a multi-species, multi-tissue approach we hope to add weight of evidence to our initial findings and also gain a deeper understanding of the mechanisms behind contaminant-induced alterations to DNA methylation across ecologically-relevant organisms.

562 Identification and Characterization of Reptilian Cytochrome P450 1A: Sequencing, Expression, and Inducibility of CYP1A5 in Sea Turtles C. Godard-Codding, The Institute of Environmental and Human Health/ Texas Tech Univ, Assistant Professor, Texas Tech Univ/The Institute of Environmental and Human Health, Assistant Professor; S. Wiggins, Texas Tech Univ/The Institute of Environmental and Human Health; J. Goldstone, Woods Hole Oceanographic Institution; J. Flanagan, Houston Zoo; B. Higgins, NOAA/NMFS. The loggerhead sea turtle (*Caretta caretta*) is currently listed as threatened under the Endangered Species Act. It faces threats from anthropogenic sources including exposure to environmental contaminants such as polycyclic aromatic hydrocarbons (PAHs). The metabolism and toxicity of these and other xenobiotics are poorly known in this species and in reptiles in general. This knowledge gap limits our understanding of the impact of environmental pollution on the health and survival of sea turtles and thus our ability to conserve and manage them. The cytochrome P450 1A1 (CYP1A1) enzyme plays a key role in the metabolism and activation of PAHs to their carcinogenic metabolites in mammals and may be involved in the bioactivation of PAHs in reptiles as well. A CYP1A protein has been detected in some reptiles; however, the full length CYP1A gene has not yet been sequenced in turtles or any other reptilian species to the best of our knowledge. Clones isolated from the liver of three species, the loggerhead (*Caretta caretta*), Kemp's ridley (*Lepidochelys kempii*) and green sea turtles (*Chelonia mydas*), were identified and named as CYP1A5 by the P450 Nomenclature Committee. Reptilian CYP1A5 share between 58-67% amino acid sequence identity with mammalian and amphibian CYP1As and between 65-79% amino acid sequence identity with avian CYP1As. Tissue distribution and expression of CYP1A5 was detected by quantitative reverse transcription polymerase chain reaction (qRT-PCR) in all loggerhead tissue types tested (heart, kidney, liver, lung, muscle, ovary, and skin). CYP1A1 and CYP1A-like induction is commonly used as a biomarker of exposure to PAHs and PHAHs in wildlife, but its relevance in sea turtles and other reptiles has not yet been validated. We investigated the CYP1A5 inducibility at the gene expression level using primary skin fibroblast cultures established in our laboratory. The cells were exposed to benzo[*a*]pyrene (B[*a*]P) for 72 hours and CYP1A5 induction by this prototypical PAH was detected by qRT-PCR. The present study confirms that CYP1A exists in reptiles and that sea turtle CYP1A5 is inducible by a xenobiotic known to induce CYP1A in other species.

564 The Effect of CYP1A Inhibition on Embryotoxicity of Weak Aryl Hydrocarbon Receptor Agonists in *Fundulus heteroclitus* and *Danio rerio* D. Brown, B. Clark, L. Van Tiem, Duke Univ, Nicholas School of the Environment ; K. Johnson, Duke Univ, Howard Hughes Program; R. Di Giulio, Duke Univ, Nicholas School of the Environment. The aryl hydrocarbon receptor (AHR) is a ligand-activated transcriptional regulator that mediates many of the toxic effects of dioxin-like compounds and many polycyclic aromatic hydrocarbons (PAHs). Strong AHR agonists, such as some polychlorinated biphenyls and dioxins, cause severe cardiac teratogenesis in fish embryos. We have shown that moderately strong PAH agonists such as benzo[*a*]pyrene and b-naphthoflavone cause similar cardiac teratogenesis when coupled with a CYP1A inhibitor such as fluoranthene (FL). We sought to determine if weaker agonists are capable of causing cardiac deformities following inhibition of CYP1A with FL. *Fundulus heteroclitus* (killifish) and *Danio rerio* (zebrafish) embryos were exposed to weak AHR agonists (carbaryl, phenanthrene, 2-methylindole, 3-methylindole, indigo, and indirubin) at equimolar concentrations (100 nM and 1 μM). The agonists were assessed for their relative potency as inducers of CYP1 and capacity for inducing cardiac teratogenesis. CYP1 induction was measured via the in vivo ethoxyresorufin-O-deethylase assay at 96 hpf. Indirubin, Indigo, and carbaryl were the strongest CYP1 inducers in killifish embryos showing significant differences from the control treatment. In contrast, 3-methylindole, carbaryl, and 2-methylindole caused the highest CYP1 activity in zebrafish. These equimolar exposures did not cause deformities. Agonists were then coupled with FL to assess if CYP1A inhibition could induce cardiac deformities. Killifish cardiac deformities were assessed at 144 hpf, and zebrafish cardiac deformities were measured at 96 hpf. FL by itself did not cause deformities, but co-exposure with some weak agonists resulted in cardiac teratogenesis. Cardiac deformities were significantly increased in the indigo + FL and indirubin + FL groups in killifish embryos, whereas FL enhanced the teratogenicity of 2-methylindole, carbaryl, phenanthrene, and 3-methylindole in zebrafish. Current studies are employing knockdown of AHR2 in both species. AHR2 has been shown previously to mediate the embryotoxicity of weak and moderate agonists. P42-ES10356.

565 Modulation of Lipid Levels and Cellular Homeostatic and Apoptotic Responses in Salmon Hepatocytes is a Novel Aspect of PFOSA Toxicity A.M. Wagbo, Norwegian Univ of Science and Technology (NTNU), Biology; M.V. Cangialosi, Univ of Messina; R.J. Letcher, Carleton Univ, Dept of Chemistry, Environment Canada, Science and Technology Branch, Ecotoxicology and Wildlife Health Division, Science and Technology Branch, Environment Canada, Great Lakes Institute for Environme, Canadian Wildlife Service; G. Dugo, Univ of Messina, Biology; A. Arukwe, Norwegian Univ of Science and Technology (NTNU), Dept of Biology, Norwegian Univ of Science and Technology (NTNU), Biology. Available toxicological evidence indicates that perfluorinated organic compounds (PFCs) alter normal peroxisomal lipid oxidation and cellular function in mammalian in vivo and in vitro studies. The neutral perfluorooctane sulfonamide (PFOSA) has received little attention over the years, but recent evidence show that PFOSA can be metabolically degraded at a slow rate and is a potent mediator of oxidative stress and cell death. The primary objective of the present study was to investigate the effects of PFOSA on cellular functions and lipid homeostasis (including b-oxidation) in salmon in vitro primary hepatocyte system. Primary salmon hepatocytes generated by two-step perfusion technique were exposed to PFOSA at 2, 20 and 50 μM for 0, 12 and 24 h. Fatty acids (FAs) and lipids were determined by GC-MS, fatty acid elongase (FAE), desaturase-5 (FAD5) and desaturase-6 (FAD6) and PPARs (a, b and g) and acyl coenzyme A (ACOX-1), glyceraldehyde 3-phosphate dehydrogenase (GAPDH), autophagy gene (ATG) 5, beclin-1 and bcl-2 19 kD interacting protein 3 (bnip3) mRNA expression were analyzed using qPCR. Our data showed that PFOSA produced a time- and concentration-dependent significant alteration of FA profiles. PFOSA produced changes in FA composition that predominantly involved decrease (at 24 h) and increase (at 48 h) in fatty acid methyl esters (FAMEs), MUFA, total PUFA, (n-3 and n-6) PUFA. Particularly, an increase of g and a-linolenic acid [ALA; 18:3(n-6 and n-3)], eicosapentaenoic acid [EPA; 20:5(n-3)] and arachidonic acid (ARA: 20:4 n6) with associated increase in FAE, FAD5 and FAD6 mRNA expression were observed after PFOSA exposure, while docosadienoic acid [DCA; 22:2(n-6)] was significantly decreased. PFOSA produced apparent concentration-dependent increase of PPARα and PPARg, while PPARb was not affected. The level of GAPDH mRNA declined at 24 h. ATG-5 was not significantly affected, while at 12h exposure, the levels of beclin-1 was increased and decreased at 20 and 50 μM, respectively. Our data also showed that PFOSA produced an increase in the levels of bnip3. In general, these responses indicate that PFOSA evoke deleterious effect on cellular lipid homeostasis and b-oxidation and responses that regulate cellular homeostasis and apoptosis in salmon hepatocytes.

566 Evaluation of the Immunological Effects of Oil Sands-influenced Surface Waters Using a Rainbow Trout In Situ Bioassay S.A. McNeill, N.S. Hogan, Canadian Rivers Institute, Univ of Prince Edward Island, Dept of Biology; C.J. Arens, M.R. Vandenheuvel, Canadian Rivers Institute, Univ of Prince Edward Island. The Athabasca oil sands deposit located in northeastern Alberta is the largest single oil reserve in the world, containing over 700 billion barrels of bitumen. The reclamation of the mined area will introduce new aquatic habitat that may be influenced by organic and inorganic compounds associated with oil sands. A 21 day in situ bioassay was conducted with rainbow trout (*Oncorhynchus mykiss*) co-exposed to oil sands-influenced surface waters and pathogen-associated molecular patterns in the form of inactivated *Aeromonas salmonicida* (*A.s.*). Rainbow trout were stocked in 1 m^3 constructed cages at three sites: (1) Mildred Lake, a reservoir receiving only Athabasca River water, used as the reference site; (2) South Bison Pond, a drainage basin that has received unextracted oil sands-contaminated overburden; and (3) Demonstration Pond, a constructed pond containing oil sands mature fine tailings capped with fresh water. After acclimation, trout were tagged and injected with either phosphate buffered saline (control) or formalin-inactivated *A.s.* Trout were sacrificed and processed 21 days post-injection. Some mortality was observed in rainbow trout caged in the Demonstration Pond and opacity of the eyes indicated that this may have been due to gas bubble formation as the pond is consistently gas supersaturated. Rainbow trout from the Demonstration Pond showed reduced total leukocytes as compared to the other two sites. The *A.s.* treatment itself caused an overall elevation of leukocytes. Demonstration Pond fish also showed increased fin erosion as evaluated by a fin erosion index. There were

no significant differences in liver weight, spleen weight or condition factor across the treatments. Results will be discussed with regards to fish exposure as measured by water chemistry, bile fluorescent metabolites, and liver monoxygenase activity.

567 Long-term Changes in Disease Incidence and Biochemical Indicators of Exposure in Yellow Perch (*Perca flavescens*) Exposed to Oil Sands-Affected Waters N.S. Hogan, Canadian Rivers Institute, Univ of Prince Edward Island, Dept of Biology; L.J. Phalen, M.R. van den Heuvel, Univ of Prince Edward Island, Dept of Biology. Large quantities of affected water and solid materials from oil sands mining in northern Alberta, Canada must eventually be incorporated into the reclaimed landscape. This material contains a mixture of organic and inorganic compounds, specifically elevated salt levels, naphthenic acids and traces of polycyclic aromatic hydrocarbons (PAHs). To examine the potential effects of oil sands-influenced aquatic systems on fish health, studies were conducted during 1995-1997 and 2008-2010 whereby yellow perch were captured from a nearby reservoir, Mildred Lake, and placed two experimental ponds: South Bison Pond, a drainage basin that has received unextracted oil sands-contaminated overburden or Demonstration Pond, a constructed pond containing oil sands mature fine tailings capped with fresh water. Liver mixed-function oxygenase activity as measured by 7-ethoxyresorufin-O-deethylase (EROD) activity was highest in fish from experimental ponds and this pattern was consistent across all sampling years. Bile fluorescence measurements showed a gradient of oil sands-associated exposure with the two experimental ponds being elevated over the source population of perch, and over other local perch populations. In both sets of studies, two disease pathologies were observed in yellow perch: fin erosion caused by an as yet unidentified pathogen, and lymphocystis that was confirmed using a diagnostic real-time PCR method. In early studies (1995-1997) both pathologies were most prevalent in the South Bison Pond; however, in the recent studies (2008-2009), disease was substantially more prevalent in the Demonstration Pond and corresponded with a decrease in total white blood cells. Changes in pond chemistry over the past decade allow for some inferences to be made as to causal agents. Naphthenic acids have decreased in the Bison Pond over the duration of studies while increasing in the Demonstration Pond due to tailings densification. As the concentrations of inorganic compounds in the ponds are similar, temporal changes in naphthenic acid levels appear to correlate best with incidence of disease pathologies, an effect that may be related to a contaminant-induced immune suppression. However, the precise chemical makeup of the organic material, including the identity of the fluorescent bile metabolites is not yet fully understood. The causative agents and their thresholds for immunological effects will dictate further research directions.

568 Toxicity of Untreated and Ozone-treated Oil Sands Process-Affected Water (OSPW) to Early Life Stages of the Fathead Minnow (*Pimephales promelas*) Y. He, Univ of Saskatchewan, Toxicology Centre, Univ of Saskatchewan, PHD student; S.B. Wiseman, M. Hecker, Univ of Saskatchewan, Toxicology Centre; P. Jones, Univ of Saskatchewan, School of Environment and Sustainability; A. Moustafa, N. Wang, L. Perez, Univ of Alberta, Dept of Civil and Environmental Engineering; M.G. Din, Univ of Alberta, Dept of Cival and Environmental Engineering; J.W. Martin, Univ of Alberta, Laboratory Medicine and Pathology, Univ of Alberta, Dept of Lab Medicine and Pathology, Univ of Alberta, Dept of Public Health Science; J.P. Giesy, Univ of Saskatchewan, Biomedical Veterinary Sciences & Toxicology Centre, Michigan State Univ, Dept of Animal Science. Great volumes of oil sands process-affected water (OSPW) are produced annually by the oil sands industry in North Eastern Alberta, Canada. OSPW is stored in on-site tailings ponds due to a no-release policy implemented as the result of concerns about the potential toxicity and remediation of this process water. Ozonation may be a promising and effective method for remediation of OSPW, by reducing concentration of naphthenic acids, which are considered the primary toxic constituents in OSPW. However, further work is needed to fully evaluate the effectiveness of ozonation in reducing the toxicity of OSPW and to ensure that ozonation does not impart toxicity upon OSPW. This study examined the effects of untreated and ozone-treated OSPW on the early life stage (ELS) of fathead minnow (*Pimephales promelas*). Embryo mortality rates, spontaneous embryo movement, hatching success, and incidences of hemorrhage, pericardial edema, and spinal malformation were examined. Exposure to OSPW significantly increased the incidence of embryo mortality (56 ± 14%), compared to that for control and ozone-treated OSPW (2.1 ± 4.2% and 23 ± 14%, respectively) ($\rho <$ 0.05, the same below). Exposure to OSPW also significantly increased the rate of spontaneous embryo movement at 26 hpf (49 ± 5.5 movements/min), compared to 25 ± 2.3 movements/min in control and 29 ± 3.8 movements/min in ozone-treated OSPW. Exposure to OSPW resulted in a greater incidence of immature hatching, with the cumulative hatching rates of 15 ± 4.2%, 31 ± 8.0%, and 69 ± 8.0% at 48, 72, and 96 hpf, respectively, while at the same time points the cumulative hatching rates were 2.1 ± 4.2%, 8.3 ± 12%, and 29% ± 20% in ozone-treated group. No embryos hatched until 120 hpf in control. Finally, exposure to OSPW also resulted in greater incidences of hemorrhage (50 ± 6.8%), pericardial edema (56 ± 14%) and spinal malformation (38 ± 11%), compared to ozone-treated group (13± 4.8%, 6.3 ± 8.0%, and 6.3 ± 4.2%). No malformations were observed in control. Overall, the results suggest that exposure to OSPW can negatively impact early embryo development of the fathead minnow, and ozonation of OSPW attenuated the observed toxicity towards ELS of fathead minnow. The mechanisms of the observed effects of OSPW are currently under investigation and will be discussed.

569 Using Synchronous Fluorescence Spectroscopy to Prioritize Environmental Samples for High Resolution Mass Spectrometry in Canada's Oil Sands R.A. Frank, Environment Canada, AEPRD, Univ of Guelph, Dept of Env. Biology & Toxicology; G. Bickerton, J. Headley, M. McMaster, M. Hewitt, Environment Canada. The oil sands of northern Alberta, Canada contain an estimated 170 billion barrels of recoverable crude oil, second only to Saudi Arabia's 264 billion barrels. These proven Alberta reserves only account for approximately 10% of the total crude contained within the oil sands deposits and as technology improves, future production possibilities could make Canada the world leader in oil supply. However, the rapid expansion of oil sands development, especially within the past 10 years, has raised many concerns regarding the potential impacts on the environment and communities downstream of oil sands development. Extensive research is currently underway to identify a "chemical fingerprint" capable of differentiating oil sands materials originating from natural sources of bitumen from industrial sources, such as leachate from tailings ponds, entering surface waters. Differentiation of oil sands materials is critical to both industry and regulators alike, as accurate monitoring of potential pollution is currently quite difficult. Recent advancements in high resolution mass spectrometry analyses are beginning to allow for the elucidation of specific classes of compounds as well as some individual structures contained within complex mixtures of oil sands organic acids. Due to the high costs associated with high resolution mass spectrometry, a screening method using synchronous fluorescence spectroscopy (SFS) to prioritize samples for further analysis was developed. Following the identification of a unique SFS fingerprint for oil sands organic acids, a large number of samples collected from the Athabasca River and its tributaries, basins containing oil sands process-affected water (OSPW), groundwater interceptor wells near basins containing OSPW, and groundwater wells and seeps along the banks of the Athabasca River and its tributaries have been screened. This enabled the identification of specific classes of compounds as fingerprinting candidates for determining tailings seepage using high resolution mass spectrometry.

570 Identification and Toxicity of Individual Naphthenic Acids S.J. Rowland, Univ of Plymouth, School of Geography, Earth and Environmental Sciences, Univ of Plymouth, SoGEES; C. West, Univ of Plymouth, SoGEES; A. Scarlett, Univ of Plymouth, School of Earth, Ocean & Environmental Science; D. Jones, Univ of Plymouth, School of Geography, Earth&Environm. Science. Schindler[1] has called for the debate on the environmental consequences of oil sands exploitation in Canada to be based on solid science. Kean[2] has labelled aspects of the current debate, "eco-alchemy". Although the acute impacts of oil sands process water have sometimes been dramatic, experimental evidence for the acute toxicity of the so-called 'naphthenic acids' has been mainly gathered from assays of incompletely characterised extracts of the water. Clearly the toxic constituents need to be identified and assayed. We show how numerous of these acids in oil sands process water and petroleum-derived naphthenic acids can be identified by comprehensive two-dimensional gas chromatography-mass spectrometry. We then show how synthesis of dozens of such acyclic to tricyclic acids and measurement of their toxicities to the bioluminescent bacterium, *Vibrio fisheri* allows assessment of their toxic effects. We also used a computer model to predict their toxicities to the water flea, *Daphnia magna*. Both are well-accepted toxicological screening endpoints. The results show how toxic some of the naphthenic acids really are and reveal the influence of hydrophobicity

and aqueous solubility on the toxicities. Comparison with measured toxicities of other known, but more minor, constituents of oil sands process water, such as polycyclic aromatic hydrocarbons and alkylphenols, helps place these toxicities into a wider context. 1.Schindler, D. Tar sands needs solid science. Nature 2010, 468, 499-501. 1. 2.Kean, S. Eco-alchemy in Alberta. Science 2009, *326*, 1052-1055.

571 Tracking the Sources of Naphthenic Acids in the Athabasca River and its Tributaries J.W. Martin, Univ of Alberta, Laboratory Medicine and Pathology, Univ of Alberta, Dept of Lab Medicine and Pathology, Univ of Alberta, Dept of Public Health Science; J.P. Benskin, AXYS Analytical Services Ltd; M.S. Ross, Univ of Alberta, Dept of Laboratory Medicine & Pathology; E. King, Univ of Alberta. Highly specific and sensitive analytical methods have recently evolved for accurately characterizing the complex mixture of organic acids in oil sands process water (OSPW), including naphthenic acids (NAs). Here we report the application of HPLC-high resolution mass spectrometry to background water samples in the oil sands region. Samples (1 L) were collected in Fall 2010 at sites upstream and downstream of industrial activity and were preserved with methanol, and by freezing. Sampling locations included the main Athabasca River, upstream and downstream of industrial activity, and also smaller tributaries in the open-pit mining region. The North Saskatchewan River was also sampled, in Edmonton, for comparison. Samples were extracted by acidification and liquid-liquid extraction using an isotopically labeled internal standard for quantification. NA profiles in samples close to human development (i.e., Fort McMurray, or Edmonton) had a prevalence of non-cyclic (Z=0) NAs, presumably owing to emissions of surfactants from municipal waste-water treatment plants. Concentrations in the main stem of the Athabasca River were low, immediately upstream of industrial activity, but NAs were detectable downstream at several sites. The upstream headwaters of small tributaries to the Athabasca River had very low NA concentrations, but at the mouth of these rivers (where they join the Athabasca River) NA concentrations were detectable. NA profiles of natural water samples were compared to OSPW, and data will be discussed with respect to differentiating natural sources of NAs from anthropogenic emissions of OSPW.

572 A Comparison Between Carboxyl Groups Quantifications for Different Naphthenic Acids Using the Linear Programming Technique and the FT-IR Spectroscopy A.M. Moustafa, Univ of Alberta, Dept of Civil and Environmental Engineering; S. Kang, Kyung Hee Univ, Dept of Civil Engineering; S. Smith, Wilfrid Laurier Univ, Faculty of Science; J. Wang, M.M. Gamal El-Din, Univ of Alberta, Dept of Civil and Environmental Engineering. Naphthenic acids (NAs) are the major toxic compounds from the bitumen extraction industries in northern Alberta. In NAs, carboxylic functional groups are attached to unspecified alicyclic compounds with different molecular weights. The FT-IR spectroscopy is one of the popular quantification method for NAs by the detection of the carboxylic acids through their carbonyl stretch C=O. Also this quantification is generally used for the assessment of the solution toxicity. The purpose of the current study is to quantify the actual concentrations of carboxylic functional groups for different sources of NAs samples. The quantification techniques performed using the Linear Programming Method (LPM) and compared to the FT-IR results. 50 mg/L NAs solutions were prepared from the refined Merichem NAs, the Fluka NAs, the OSPW-extracted NAs and the Cyclohexanecarboxylic acid. All concentrations were confirmed using the FT-IR spectroscopy, but only 40 mg/L of the Cyclohexanecarboxylic acid was detected. The evaluation of their toxicity was performed using the basic protocol of the Microtox bioassay. The concentration of the carboxylic functional groups for all NAs sources were secondly evaluated using the Linear Programming Method (Cox et al. 1999). Results showed that both Merichem and Fluka NAs have almost the same concentration of carboxylic functional groups $3.3X10^{-4}$ mM, and the same toxicity as well. The extracted NAs from OSPW showed only $1.15X10^{-4}$ mM of carboxylic functional groups concentration which equal to one third of Merichem's and Fluka's. Toxicity of NAs from OSPW was 50% of Fluka and Merichem. On the other hand, the carboxylic functional groups concentration for the Cyclohexanecarboxylic acid was $3.92X10^{-4}$ mM, which is equal to the prepared concentration with no toxicity at all. This study introduced LPM as an efficient method for NAs quantification. LPM technique detects carboxylic groups directly instead of carbonyl groups in the FT-IR method. Also it shows the independency of the toxicity on the total NAs concentration.

573 Dropping Acid at the Synchrotron: Using X-Ray Absorption Spectroscopy to Characterize Naphthenic Acids C.H. Ryan, Canadian Light Source Inc.; N. Toor, Level Science Inc., Environmental Science; M. Gillis, Level Science Inc. ; L. Zuin, Y. Hu, Canadian Light Source Inc,, Experimental Facilities Division; J. Headley, Environment Canada, Water Science and Technology Directorate. The characterization of oil sands acid-extractable organics (AEO), commonly referred to as naphthenic acids (NAs), is a topic of growing interest for the study of their fate and transport in aquatic environments. The principal toxic components in oil sands process-affected waters (OSPW) have not been identified. Reported here is the first account of the application of X-ray absorption near-edge spectroscopy (XANES) for the characterization of the components present within NAs derived from OSPW and surrounding waters. These components are known to interfere with the characterization of NAs using conventional techniques. Emphasis is given to the identification of sulfur components as potential markers for delineating anthropogenic sources of NAs from those that are naturally occurring. The presence of sulfur in different chemical states in OSPW NAs and surrounding waters was confirmed using complimentary beamlines for the sulfur K and L-edges XANES. The qualitative speciation of sulfur suggests large contributions of sulfates, and additional contributions from organosulfur compounds similar to thioethers, benzothiophenes, and sulfoxides. The OSPW NAs XANES were also compared to the spectra obtained from NAs extracted from surrounding waters; upstream, midstream and downstream of oil sands production. A spectral shift was identified in the extracted NAs from upstream to downstream. It suggests a larger organic contribution from the sulfur components within the NAs, as the sample moves downstream.

574 En Route to Developing a Female Reproductive Assessment Scheme for Mammals in the Field L. Tannenbaum, US Army Public Health Command, Environmental Health Risk Assessment Program, US Army institute of Public Health. Direct (reproductive) health status assessment of ecological receptors (mammals) at contaminated sites formally entered the ecological risk assessment (ERA) arena just over a year ago with the Army's patenting of Rodent Sperm Analysis – a method presented at SETAC N.A. meetings in recent years. With reproduction understood by many to be the most sensitive toxicological endpoint for mammals, and arguably being the greatest endpoint of concern in ERA in an overall sense, the need to embellish field-based reproductive assessment is keen. The direct (reproductive) health status assessment approach can be made stronger with the addition of a complementary assessment scheme for female rodents. To that end, a strategy for bringing such a scheme online has been developed. Come hear why "Wild Rodent Ovarian Follicle Counting" ("WROF-C") may well be the way to go. Preliminary WROF-C data might be informing us of a useful and informative threshold-for-effect to apply.

575 Estimating the Potential Significance of Dermal Exposure of Birds, Reptiles, Amphibians, and Mammals to Pesticides T. Crk, E. Odenkirchen, US Environmental Protection Agency, Office of Pesticide Programs, Environmental Fate and Effects Division; T. Purucker, US Environmental Protection Agency, Office of Research and Development; D. Spatz, N. Mastrota, K. Garber, J. Housenger, F. Farruggia, M. Wagman, M. Clock-Rust, V. Woodard, T. Dowen, H. Yingling, US Environmental Protection Agency, Office of Pesticide Programs, Environmental Fate and Effects Division. The Dermal Uptake Screening Tool (DUST v. 1.0) is a model developed by the United States Environmental Protection Agency's Office of Pesticide Programs. The output of the model will be used in the problem formulation phase of ecological risk assessment to assess the potential significance of chemical exposure to the dermis of birds, reptiles, amphibians, and mammals as a result of pesticide application. Exposure estimates are based on pesticide application rate, application method, and biology of the non-target organism. DUST evaluates dermal exposures via contact with soil and foliar residues and interception of spray. Soil exposure estimates for terrestrial wildlife account for contact with soil particulates via dust bathing and treading the soil surface. Dermal contact estimates vary across terrestrial taxa more than for other exposure pathways, for example, amphibian dermal contact from enhanced skin permeability can be a key exposure pathway due to high dermis-soil water uptake rates that allow amphibians to regulate hydration. DUST output is used to establish a rationale in problem formulation to either dismiss dermal exposure concerns for soil residues and other dermal contact routes or support further consideration in data collection and analysis phases of the ecological risk assessment. This presentation

includes the following elements of the model: exposure estimation, preliminary effects endpoint estimation, integration of exposure and effects, decision criteria, model assumptions, and model evaluation.

576 Calculation of Lead Site-specific Soil and Food Ingestion Guideline for Livestock Receptors J. Widmeyer, EBA A Tetra Tech Company, Ecological Risk Assessment; K. Bessie, EBA, A Tetra Tech Company, Soil Science; R.N. Hull, Intrinsik Environmental Sciences Inc. In July 2010, an Environmental Summary Report (ESR) was completed for the Valleyview Land Treatment Facility. Soil lead concentrations exceeded the current Alberta Tier 2 Guideline (70 mg/kg) for the Livestock Soil and Food Ingestion exposure pathway. Considering that the current CCME lead exposure guideline was derived using an avian receptor, quail, it is not only practical but relevant to derive a site-specific guideline for lead for livestock species actually using the site. For the Valleyview Land Treatment Facility there are three herbivorous receptors included in the Soil Quality Guideline (SQG) recalculation: beef cattle, dairy cattle, and domestic chickens. The following information was used to develop a site-specific lead SQG for the ingestion pathway for livestock: Literature-derived exposure parameters including body weight, food ingestion rate, and incidental soil ingestion rate for each receptor; Correlation of plant lead concentrations with soil concentrations to derive a site-specific BCF, and comparison of the site-specific BCF with a literature-derived BCF (using a regression equation); Derivation of 95% UCLM and 80% percentile soil lead concentrations for both ecologically-relevant soil lead samples (upper 20 cm horizon) and all samples (surface to 80 cm depth); ED for livestock receptors – based upon studies with chronic exposure demonstrating sublethal effects; Application of 100% bioavailability for lead in soil; 100% receptor exposure from dietary uptake of onsite soil and vegetation. SQG for receptors were above soil lead maximum, 95% UCLM, and 80% percentile concentrations, whether compared to lead soil concentrations collected from all depths or from the most biologically-relevant depth onsite (top 20 cm). Chicken exposures are driving the SQG; however, the chicken SQG is 9- to 11-fold above the 80% percentile soil lead concentration. Based upon the recalculated SQG, no unacceptable risks exist for beef cattle, dairy cattle, and domestic chickens ingesting soils and vegetation.

577 Development of a Soil Toxicity Test Using Species Native to the Canadian Boreal Wetlands M. Moody, Saskatchewan Research Coucil, Environment Division; R. Scroggins, Environment Canada, Ecotoxicology and Wildlife Health Division. Development of a toxicity test specific to wetland soils of the boreal eco-zone is a priority recognized by governments and legislators in Canada. Thousands of industrial sites, derived particularly from oil and gas production are found in the boreal wetlands. Therefore, tools are needed to demonstrate impacts of produced water spills containing high levels of salts and hydrocarbons. Candidate test species native to three wetland habitats (bogs, fens and shallow water marshes) were chosen to offer an ecologically relevant test battery. Achieving consistent germination and growth in preliminary tests led to adoption of suitable test durations and measurements of growth in soils and peats collected from clean reference sites. Challenges presented by varying nutrient levels in commercial peats and testing in processed or dried substrates will contribute to development of a test method capable of reflecting impacts in vulnerable wetland habitats.

578 A Comparative Study of Multiple Drilling Fluids and Their Relative Terrestrial Toxicity L.K. Arneson, Texas Tech Univ, Dept of Environmental Toxicology, The Institute of Environmental and Human Health (TIEHH), Dept of Environmental Toxicology; D.L. Carr, Texas Tech Univ, Biological Sciences; S. Armstrong, Shell Health – Americas; T. Anderson, Texas Tech Univ, TIEHH, Environmental Toxicology. This study compared the terrestrial toxicity and relative environmental safety of several hydrocarbon-based products developed for land-based drilling. During the drilling process the surrounding terrestrial area can be exposed to drilling fluids as well as the remnants of the drilling process including land disposed drill-cuttings. Comparisons were made between two newly developed gas to liquid (GTL) products and two conventional drilling fluids including a low toxicity mineral oil (LTMO) and a low sulfur diesel (LSD). Acute toxicity tests were performed over a period of 14 days for the earthworm (*E. fetida*) and for germination of alfalfa (*M. sativa*) and a wheatgrass species (*E. lanceolatus*). A saltbush (*A. canescens*) 21-day germination study was also performed. Additionally, a springtail (*F. candida*) 21-day exposure study was performed. GCMS was used to monitor hydrocarbon content in soils. A G-Test of the earthworm results showed that there was a treatment affect ($p << 0.001$, $p << 0.001$, and $p = 0.008$) for freshly spiked, 10° C, and 30° C aged soils. Alfalfa showed no significant difference in germination among drilling fluid treatments,. However, results also showed that wheatgrass germination was affected by drilling fluid treatments. Results showed p-values at $p << 0.0001$, $p = 0.0003$, and $p = 0.77$ for freshly spiked, 10° C, and 30° C aged soils, respectively. Overall, the GTL C10-C22 product showed the least terrestrial toxicity, both the LTMO and GTL C11-C24 showed some toxicity although LTMO was highly toxic to earthworms and wheatgrass germination, and Diesel-treated soils showed the most toxic responses.

579 Cytotoxicity and Interaction of Silver Nanoparticles in *Eisenia andrei* J. Kwak, Konkuk Univ; W. Lee, Konkuk Univ, Konkuk Univ, Dept of Environmental Science; S. Kim, Konkuk Univ; Y. An, Konkuk Univ, Dept of Environmental Science. The cytotoxicity of citrate-coated silver nanoparticles (cAgNPs) and the changes of cAgNPs in biological fluid using *Eisenia andrei* were investigated. The cytotoxicity was measured using the neutral red retention assay (NRR assay), along with mortality, abnormality, and bioaccumulation. Because cAgNPs were adsorbed and aggregated in soil, the survival and abnormal effects of cAgNPs on E. andrei was negligible and low bioaccumulation factors were calculated up to the cAgNPs of 2000 μg/g. However, 7d-NOEC values (lysosomal stability) were 300 μg/g dry soil as a result of NRR assay. Additionally, the effects of silver ions dissolved during exposure duration were not observed. We also dispersed cAgNPs in deionized water, earthworm coelomic fluid (ECF), and artificial lysosomal fluid (ALF) to investigate the changes of cAgNPs in biological fluid contains of electrolytes. As a result, deionized water (D.W.) was more homogeneous distribution than ECF, and ALF. On the other hands, cAgNPs dispersed in ECF shows high ionization and aggregation. This result means that small amounts of cAgNPs can be permeated to earthworms and can be ionized easily, so cAgNPs may cause low toxicity to earthworms exposed cAgNPs.

580 A New Indicator to Evaluate the Toxicity of Contaminants Against Soil Microbial Community V. Shah, Dowling College; V. Walker, N. Kumar, Queens Univ, Dept of Biology. In the field of ecotoxicology, it is hard to compare the toxicity of contaminants to soil microbial community based on the data originating from multiple studies. Using copper, silver and silica oxide nanoparticles as examples, in the study to be presented we will show the use of a new microbial community toxicity indicator (MCTI) to compare the toxicity of various NPs against microbial community. MCTI incorporates the toxicity values measured using culture dependent (total substrate utilization pattern) and culture independent (PCR-DGGE and FAME analysis). The toxicity of nanoparticles was measured against Arctic soil microbial community.

581 Hazard Assessment and Product Recognition Drives Green Chemical Design E.T. Lavoie, US Environmental Protection Agency, Design for the Environment Program, Environmental Protection Agency, Office of Pollution Prevention and Toxics; E. Sommer, US Environmental Protection Agency. Green chemical design can be driven by comparative hazard assessment of chemicals in end use products, enabling identification of safer chemical alternatives. Recognition programs, ecolabels, criteria and standards for greener chemistry, are encouraging 'benign by design' considerations in product development. USEPA's Design for Environment (DfE) program has encouraged "safer chemistry" since 1992 by allowing use of the DfE label on products containing the safest chemicals available for a given functional use (e.g., surfactancy). In the last 6 years the program has used its experience in identifying safer chemicals to generate criteria for safer surfactants, solvents, chelants, fragrance chemicals and cleaning product chemicals in general. The DfE criteria for surfactants, as an example, is based on aquatic toxicity and biodegradation rate and has influenced manufacture of new surfactants by companies such as Dow and BASF where both functionality and toxicity were design considerations. The understanding of existing surfactants on the market, their functionality, cost, chemistry, toxicity, and persistence influenced recognition of the safer surfactants on the market, identified the key characteristics of concern, defined the bar for a 'safer' surfactant and resulted in newly designed surfactants coming to market that encompassed green chemistry principles. DfE reviews ecotoxicity and fate data in addition to human health endpoints before recognizing safer chemicals. SAR based predictive methods and safer chemical design principles are used to fill data gaps, interpret data, and determine which chemistries are not inherently safer, or how chemicals could be designed to degrade. However, encompassing both reduced toxicity and reduced persistence can have contradictory chemical design principles. This presentation will use chemical examples to illustrate criteria development, green design success and ongoing challenges for green industrial chemistry design, based on consideration of multiple health and environmental endpoints.

582 Computational Tools to Guide Design for Degradation and the Development of Preferred Chemicals and Products R. Williams, Environmental Science & Green Chemistry Consulting, LLC; T. Williams, Wesleyan Univ, Chemistry. Emerging market forces highlight the importance of innovating environmentally preferred products and manufacturing methods. Innovations in organic synthesis manufacturing processes have achieved substantial environmental and economic benefits through scientific advances in tools such as greener reactions. Computational tools can inform future innovations in molecular design and formulations that result in environmentally preferred consumer products and specialty chemicals such as pharmaceuticals. Product design scientists apply their knowledge of chemical properties to construct molecular architecture and product formulations with commercially valuable functionality. Green Chemistry Principle # 10 (Design for Degradation, DfD) recommends designing molecular architecture that is both environmentally preferred and functional. Consequently, DfD has been emphasized as a long-term pollution prevention opportunity for, as an example, emerging contaminants such as pharmaceuticals. The nature of chemical product discovery and development establishes the essential role computational tools must play, the nature of the tools and paradigm to be achieved, and the scientific interactions that would be supportive if environmentally preferred chemical products are to play a more prominent role in achieving environmental quality.

583 Identification of New and Existing PBTs by QSPR: A Greener Screening E. Papa, Univ of Insubria, QSAR Res. Unit Environ. Chem/Dep. Structural Functional Biology , Univ of Insubria, DBSF; P. Gramatica, Univ of Insubria, QSAR Res. Unit Environ. Chem. Ecotox./Dep.Structural & Functional Biology. The screening of Persistent, Bioaccumulative and Toxic (PBT) chemicals is still a challenging process for scientists and regulators. The European REACH regulation requires the PBT/vPvB assessment of a substance to be carried out on the basis of the criteria defined in its Annex XIII, and promotes the use of alternative, predictive, in silico methods, such as Quantitative Structure–Activity (Property) Relationships (QSA(P)Rs), in order to minimize the expected high costs of experimental tests necessary for the hazard/risk assessment of chemicals, and to maximize the use of existing experimental data. Furthermore, REACH encourages the substitution of unsafe substances, such as PBTs, with safer alternatives, which is in agreement with the Green Chemistry Principles 2 and 10 (2: design safer chemicals and products, 10: design chemicals and products to degrade after use). Molecular modeling approaches such as QSA(P)R can be successfully applied in "safe Chemical Design", in perfect line with the "benign by design" concept. In this study we describe the development and the possible use of the PBT-Index QSPR model. This robust and externally validated model is based on a multivariate screening approach which ranks chemicals according to their P, B and T properties, and is able to identify PBT-like chemicals only on the basis of their chemical structure. To further evaluate the quality of our approach, the accuracy of our results is compared with other PBT screening approaches (US-EPA PBT Profiler, the Canadian DSL List, and HAF values). A screening by consensus is also proposed, which takes into account the different assumptions characterizing each method considered for the comparison (i.e., chemical structure, partitioning and cut off criteria), and gives a more realistic assessment of the potential PBT behaviour of chemicals from different perspectives. Finally, case studies showing the possible "green" application of the proposed QSPR model to screen PBTs, their alternatives or large lists of structures are also presented. The PBT-Index QSPR model is proposed as a hazard screening tool, applicable also by regulators, for the early identification and prioritization of not yet known PBTs. This "green", structurally–based, model is applicable to identify alternatives to PBTs among the existing chemicals, or to screen libraries of unsynthesised candidates through a "safe by design" (drug design-like) approach.

584 Chemists Provide Solutions, Green Chemists Solve Problems N. Gathergood, Dublin City University, School of Chemical Sciences; R. Gore, D. Coleman, M. Ghavre, M. Gurbisz, T. Hayes, I. Beadham, Dublin City University; L. Myles, S. Connon, University of Dublin, Trinity College; B. Quilty, Dublin City University; M. Spulak, Charles University; T. Garcia, IIQAB-CSIC. Last year Paul Anastas published a review highlighting recent applications of the 'Twelv Principles of Green Chemistry' proposed in the seminal book 'Green Chemistry: Theory and Practice'. In these publications both academia and industry are shown a new approach to environmental protection. The core concept presented was that it is better to 'reduce than treat' waste. One of the reasons that the chemical ind has great interest in Green Chemistry is the financial benefits. By developing greener and cleaner methods and processes, that inherently generate less waste, the costs associated with waste disposal can be reduced. Industry can reduce their environmental impact as well as increase profitability. In their book, Anastas and Warner proposed the 'Twelve Principles of Green Chemistry' primarily to inspire chemists to create environmentally less damaging synthetic methodologies. Our own research team in Dublin encompasses a variety of these green chemistry principles to realise environmentally friendly organic synthesis for industry. Concurrent assessment of the performance of a new chemical or class of reaction with its potential environmental impact enables our group to focus investigations on 'safer' and green reaction methodologies. The development of reactions with high atom economy, to reduce waste products, combined with low toxicity and biodegradable reaction media, is one example of our benign-by-design philosophy. Selected recent examples from our investigations in t fields of ionic liquids, organocatalysis and drug discovery will be presented.

585 Assessment of Health Impacts in Munitions Research, Development, Testing and Evaluation: A Phased Approach M.S. Johnson, US Army Institute of Public Health, Health Effects Research Program; W.S. Eck, US Army Institute of Public Health, Health Effects Research Program. Sustaining range operations while maintaining force health is vital to our National security. Current research is underway focused in discovering munition constituents that have a negligible environmental health impact. Determining the potential for adverse environmental health effects requires an interdisciplinary approach that must be phased coincident with munition design. They must be applied in a logical, tiered way consistent with the research, development, and engineering level of effort. This process will enable researchers to determine and refine environmental health properties throughout development--through modeling and simulation in the early stages and testing in the later stages. Researchers will use this knowledge to identify and mitigate potential environmental health risks at each stage of development. Details of the process are provided and examples presented.

586 Targeted Design of a New Effective and Biodegradable Active Pharmaceutical Ingredient K. Kümmerer, Leuphana Univ Lüneburg, Instistue for Sustainabae and Environmental Chemistry; G. Marano, Calvatis GmbH; E. Frei, M. Wiessler, Deutsches Krebsforschungszentrum. The products of

the chemical and pharmaceutical industries are ubiquitous in everyday life. For a long time, production of chemicals and pharmaceuticals was associated with heavy pollution of the environment and serious health effects. During the second half of the last century, such impact was reduced tremendously – at least in developed countries by proper measures such as effluent treatment and containment. In the meantime it has been learned that the products themselves i.e., the desired molecules and not the unwanted ones originating from side reactions are present in the environment because of intended use and pose a risk on humans and the environment. In the past pharmaceuticals and chemicals that have been used were optimized for stability. This is the reason why they are present in the environment. For a sustainable use of chemicals and pharanmceuticals, the aim is to have molecules intentionally designed for efficacy and efficiency as well as fast and complete mineralization in the environment. In a combination of experimental work and in silico tools we have optimized a new pharmaceutical lead structure in terms of efficiency of the pharmaceutical active ingredient and improved biodegradability in the aquatic environment after it reaches the aquatic environment in case of incomplete metabolism in patients. The example demonstrates that even pharmaceuticals can be designed that they are active and biodegradable and that benign by design is a promising and important building block of green and sustainable pharmacy (1). The approach and the results of this study will be presented. (1) Kümmerer K., Hempel M. (Eds.) (2010) Green and Sustainable Pharmacy. Springer, Heidelberg Dordrecht London New York

587 Green Notes for Musks R. Boethling, US Environmental Protection Agency, Office of Pollution Prevention and Toxics, USEPA, Office of Pollution Prevention and Toxins, MC 7406 The design of the molecule itself is the earliest phase in the process of developing useful products. Two of the 12 green chemistry principles, that chemicals should be designed to have minimal toxicity and degrade environmentally to innocuous products, are central to chemical design. Previously we used a series of case studies to show that generalizations about the effects of molecular structure can be used to design small molecules for biodegradability. Here, we extend one of the case studies (synthetic musk fragrances) to a wider range of musks, and address bioaccumulation potential and ecotoxicity in addition to persistence. To this end, we first summarize ready biodegradation data for musks including unpublished data from US Premanufacture Notice (PMN) chemicals. Bioaccumulation potential and aquatic toxicity are then estimated for this set of musks using EPA's BCFBAF, KOAWIN and ECOSAR programs (components of EPI Suite), and the results are used to compare musks across the various structural classes and make inferences about their environmental attributes. Last, the analysis is extended to untested musks including target molecules. In this way, we show how predictive methods and knowledge can be included as additional facets in rational design of small molecules.

588 Does the Colour of Your Chemistry Matter? What Green Chemistry Can Learn from Ecotoxicology M. Hanson, Univ of Manitoba, Dept of Environment and Geography, Univ of Manitoba, Faculty of Environment; K. Solomon, Univ of Guelph, School of Environmental Sciences, Univ of Guelph, Centre for Toxicology, School of Environmental Sciences. The sub-discipline of Green Chemistry has many laudable ideals and precepts, including the aim of reducing the toxicological footprint of chemical processes and products. Eventually though, this idealism runs into a wall of practicality and very necessary pragmatism, especially when examining its aims under an ecotoxicological lens. What might seem simple on paper, e.g., do not use or produce toxic materials, is devoid of real meaning when scrutinized closely, as all things have the potential be toxic, and in different ways to different things. Context matters. What needs to be ascertained in advance is what level of exposure to a contaminant or response as a result of exposure, is deemed scientifically and socially acceptable. For example, pesticides are by their very nature meant to be highly toxic to selected organisms. By defining *a priori* what is and is not acceptable from an ecological perspective, you can develop and market these vital chemical tools with a reduced ecological impact. While Green Chemistry can inform ecotoxicology and risk assessment, more importantly, it needs to better understand these sciences so that it can advocate for more sustainable approaches within chemistry as a whole.

589 The Boston Harbor Project: Documenting an Environmental Success Story A. Rex, Massachusetts Water Resources Authority, Environmental Quality. The Boston Harbor Project began in 1985 with the creation of the Massachusetts Water Resources Authority (MWRA). Spurred by a Federal Court Order, the outcome of a lawsuit against the state for violations of the Clean Water Act, MWRA's task was to design and build modern wastewater treatment facilities serving the 2.5 million people of greater Boston according to a stringent timetable. Over the course of the next 15 years, the practice of discharging sewage sludge to the harbor would end (1991) undersized primary treatment plants would be replaced by a modern secondary treatment plant (1998), and a new, 9.5-mile-long outfall-diffuser system would be bored through bedrock to dilute the treated effluent in the deep waters of Massachusetts Bay (2000). While the new treatment facilities were being built, another major project was initiated to control combined sewer overflows, which were discharging more than 3 billion gallons of raw waste mixed with storm water every year to the shorelines of the harbor and its tributary rivers. To measure the impacts of these multibillion-dollar projects, MWRA began its harbor and outfall monitoring programs in 1989. The harbor data would tell the story of the recovery of an ecosystem, and data collected throughout Massachusetts Bay would provide "before" and "after" comparisons to determine whether the long outfall might adversely affect the ocean around it. Effluent data show that treatment reduced the loadings of many contaminants discharged by more than 80%. Water column bacterial monitoring data show the effect of improved treatment and CSO control. The process of eutrophication appears to be reversing. The benthic community has shown dramatic changes in some parts of the harbor. A great deal has been learned about the process of recovery, and some parts of the harbor ecosystem have recovered more quickly than thought.

590 Twenty Years of MWRA Water Quality Monitoring – Harbor vs. Bay Outfall Observed Trends in Nuisance Species P.S. Libby, Battelle, Environmental Solutions; D.G. Borkman, Univ of Rhode Island, Graduate School of Oceanography; D.M. Anderson, Woods Hole Oceanographic Institution, Dept of Biology. On September 6, 2000, the Massachusetts Water Resource Authority (MWRA) transferred their effluent discharge from Boston Harbor to an outfall in Massachusetts Bay. Limited ecological impact was predicted for the transfer and has been validated by the long-term MWRA monitoring program (1992-2011). After ten years of post-diversion monitoring, changes in the nutrient regimes in the harbor and bay are unambiguous – dissolved inorganic nitrogen (DIN) levels have decreased in the harbor and coastal waters while increasing locally near the bay outfall. In Boston Harbor, the dramatic decrease in DIN has been associated with significant decreases in chlorophyll and particulate organic carbon, lower primary production, and changes in seasonal primary productivity patterns. In the bay outfall area, there is no indication that the higher nutrient loads have translated into significant changes in phytoplankton biomass, whether measured as chlorophyll, particulate organic carbon, or abundance. Contingency Plan thresholds were established to evaluate potential changes in the magnitude of nuisance phytoplankton species blooms. These include *Alexandrium fundyense* a paralytic shellfish poison producing species, *Pseudonitzschia* spp. some of which produce domoic acid, and *Phaeocystis pouchetii*, which is considered a nuisance species due to its potential for very large blooms. Blooms of all three species are observed in Massachusetts Bay and during post-diversion monitoring there have been apparent changes in the frequency, magnitude, and duration of these blooms in the Bay. The major 2005 red tide (*A. fundyense*) renewed interest in the potential effect the outfall may have in exacerbating such blooms, however, associations between the bay outfall and regional phytoplankton blooms have not been observed. This presentation briefly summarizes the overall water quality findings of the MWRA monitoring program, details the trends observed for these three nuisance species, and assess the relative impact of the MWRA outfall on these blooms.

591 Testing for Discharge-related Changes in Massachusetts Bay Infaunal Communities K. Keay, Massachusetts Water Resource Authority; J. Blake, N. Maciolek, AECOM; W. Smith, Temple Univ; D. Dahlen, Battelle. The Massachusetts Water Resources Authority studies benthic communities in Massachusetts Bay as part of an ambient monitoring program required under the National Pollution Discharge Elimination System (NPDES) discharge permit for its offshore effluent outfall, which came online in September 2000. Soft-sediment sampling for contaminants, infauna, and tracers at 23 "nearfield" stations within 7 km of the discharge and 8 reference stations spread from Cape Ann to Cape Cod has been conducted annually since 1992, providing 9 years of baseline sampling and 10 years of discharge monitoring results through August 2010. Testing for the effects of secondary

effluent discharge on sediments and benthic communities in this dispersive and dynamic coastal environment has been challenging. No discharge-associated changes in community composition, abundance, or diversity have been observed, nor have contaminant concentrations increased. Sensitive BACI analyses on contaminant, tracer and infaunal data have confirmed that only levels of the spore-forming bacterium Clostridium perfringens in sediments show strong evidence of an increase related to outfall discharge. MWRA's NPDES permit requires that, as soon as they pass QA/QC checks, raw monitoring data be tested against metrics designed to detect changes from baseline conditions substantial enough to warrant rapid evaluation and notification of regulators. In January 2011, for the first time, infaunal data from MWRA's benthic monitoring exceeded these "thresholds". Two of the four biodiversity parameters monitored, Shannon-Wiener H' and Pielou's J', were slightly higher than the threshold in nearfield sediments. Our ongoing evaluation of these exceedances will be considered and presented. Evaluations conducted as of May 2011 suggest that the 2010 infaunal results reflect natural variation in infaunal community composition and diversity, rather than a discharge-related change in the communities.

592 Boston Harbor Cleanup Brings Back the Benthos R. Diaz, Virginia Institute of Marine Science. Not long ago, nutrient loadings to Boston Harbor were among the highest in the world. A major overhaul of sewage treatment in the area, including treatment upgrades and relocation of an outfall offshore in 2000, was designed to address this problem and clean up the harbor. The cleanup plan resulted in a reduction of organic matter load to the harbor of about 90%. The reduction in carbon loading associated with the outfall relocation led to a shift to more aerobic conditions in the harbor. This shift paved the way for an increase in *Ampelisca* amphipods, which need some level of organic enrichment but better water quality than the "old" Boston Harbor could offer. The cover of amphipod mats increased from < 20% in 1992 to >60% in 1995-1998. As conditions continued to improve, carbon loading fell below the optimum needed to sustain the amphipod mats (the "tipping point" appears to be about 500 g C per m2 per y), and they slowly disappeared, reaching < 20% coverage by 2000 and disappearing by 2005. While they dominated the benthos, amphipod tubes facilitated an increase in biodiversity and bioturbation, which increased the depth of oxidized sediments, improving conditions for other benthic invertebrates. These results highlight the harbor's good news: wastewater treatment improvements have tipped the balance back to good benthic habitats by favoring organisms that enhance bioturbation. However, some areas of the inner harbor, especially near combined sewer outfalls (CSO), have not yet experienced much improvement.

593 Decreases in the Prevalence of Liver Disease in Boston Harbor Winter Flounder M. Hall, Massachusetts Water Resources Authority, Environmental Quality Dept; M. Moore, Woods Hole Oceanographic Institution. The high prevalence of liver neoplasm (tumor) in winter flounder (*Pseudopleuronectes americanus*) collected from Boston Harbor in 1984 was one of several important findings which resulted in the Boston Harbor Project. Since 1991 flounder have been collected from several locations in the Boston Harbor , Massachusetts Bay, and Cape Cod Bay regions during April or early May. The livers of 50 fish from each site are analyzed for various histological markers of disease. Edible meat tissue and liver tissue from 15 fish (3 replicates of 5 fish each) are analyzed for chemical contaminants – mainly organic contaminants in edible meat and organic and inorganic contaminants in livers. Results show a steady decrease in tissue concentrations of organic contaminants at all sites. Metals measured in liver tissue have been highly variable, spatially and temporally, and show no conclusive trends. Liver tumors have not been observed in fish collected from Boston Harbor since 1996. The prevalence of Centrotubular Hydropic Vacuolation (CHV), a precursor to liver tumors, has declined throughout the harbor and western Massachusetts Bay region. The prevalence in harbor flounder is now half of what it was during the early 1990s.

594 A Before-After-Control-Impact Study of Changes in Contaminants in Winter Flounder, Lobster, and Caged Mussels in Massachusetts and Boston Harbor S. Kane Driscoll, M. Edwards, Exponent Inc.; E. Nestler, A. Pembroke, Normandeau Associates. This study addresses various questions related to the Fish and Shellfish component of the Massachusetts Water Resources Authority's (MWRA) Harbor and Outfall Monitoring program for Boston Harbor and Massachusetts Bay. In September 2000, MWRA moved the outfall that discharges wastewater from the MWRA Deer Island Treatment Plant (DITP) in Boston Harbor to a new outfall diffuser system located in Massachusetts Bay 9.5 miles from the DITP. The goal of this study was to examine whether levels of contaminants in fish and shellfish have changed as a result of the relocation of the outfall, and whether current levels of contaminants in fish and shellfish are significantly different among organisms collected from the area of the outfall, Boston Harbor, and reference sites in Cape Cod Bay. A secondary goal was to examine whether current levels of contaminants in the edible tissue of fish and shellfish collected near the outfall present a risk to human health or to the environment. Two approaches were taken to evaluate whether concentrations at the outfall site were significantly different from other locations and times. A before-after-control-impact model was used to assess whether concentrations prior to the relocation of the outfall were significantly different from concentrations after the relocation, and whether the differences were related to the relocation of the outfall. Additionally, data for each year following the outfall relocation were evaluated using an analysis of variance to compare concentrations among locations. As expected, concentrations of some contaminants in caged mussels deployed in the vicinity of the new outfall increased after the effluent was diverted to the outfall in 2000, even after taking into account changes at the control site in Cape Cod Bay. Concentrations of contaminants in lobsters and flounders at the new outfall site did not increase as a result of the relocation of the outfall. Concentrations of most contaminants were below risk-based concentrations, although concentrations of PCBs exceeded a conservative EPA risk-based concentration at all locations, indicating a broader regional distribution of PCBs.

595 The Boston Harbor Project and the Reversal of Eutrophication of Boston Harbor D.I. Taylor, Massachusetts Water Resources Authority, Environmental Quality Dept. Boston Harbor, an urban bay-estuary in the northeast USA, has recently been the site of a large wastewater project that culminated with the diversion of its wastewater discharges offshore. The project, which was widely referred to as the Boston Harbor Project (BHP), provided an opportunity to document the effects of large changes in nutrient inputs on a highly-flushed bay-estuary, of the type common along the northeast coast of North America. Less is known of the effects of enrichment of these types of systems than of the less-flushed bays and estuaries that occur further south. Before the BHP, the total inputs of N and P to Boston Harbor were among the highest for bays or estuaries in the USA. The project decreased the harbor N and P inputs by between 80% and 90%. The large decreases in inputs triggered changes to the harbor water-column and sediments, its seagrass and benthic invertebrate communities, and to its C and N budgets. For certain components of the ecosystem the changes were rapid, and have been sustained through the full 10 years since diversion. For others, the changes have been much slower, and are still underway.

596 Trace Metals in Boston Harbor; a Little More than Two Decades of Observations C. Krahforst, G. Wallace, Univeristy of Massachusetts Boston, Environmental Earth Ocean Sciences. In the mid-1980's, the City of Boston was federally-mandated to implement measures that would return Boston Harbor to standards specified by the US Clean Water Act. The clean-up project began by mitigating direct discharges of municipal wastewater to the Harbor. In1987, sludge disposal to the Harbor ceased. In 2000, the last phase of necessary infrastructure was completed and 61 metro-Boston communities (2.5 million people) began discharging wastewater at a site in Massachusetts Bay located 16 km east of Boston Harbor. At this point, the total cost of the clean-up was $3.9 billion. Noticeable water quality improvements in Boston Harbor were observed shortly after and have been linked to this clean-up effort. However, routine monitoring of some contaminants accumulated by resident *Mytilus edulis* (blue mussel) show Boston Harbor to be well elevated for Pb, Cu, Zn, polyaromatic hydrocarbons, polychlorinated biphenyls, dieldrin, and other classes of compounds when compared to other monitoring sites along the Gulf of Maine (see http://www.gulfofmaine.org/gulfwatch/). Water samples collected during five surveys of 24 stations in Boston Harbor between 1986 – 2002 show most dramatic changes in metal water quality after the sludge discharges were discontinued in 1987. However since that period, during which metro-Boston wastewater underwent improved treatment and direct discharges to Boston Harbor ceased, trace metal concentrations in filtered Boston Harbor water show little or no improvements. While trace metal (Pb, Cu, Zn, Fe) concentrations exhibited predictable spatial variability (water samples from the inner harbor were distinctly higher than outer harbor samples), mean metal concentrations in Harbor water remained remarkably unchanged (Inner Harbor Pb and Cu

concentrations: 0.6 ± 0.12 and 23 ± 3 nmol kg^{-1}, respectively). The results from these surveys will be compared to a recent 2011 Boston Harbor survey to aid assessments of the changing trace metal sources as the Harbor recovers from decades of direct wastewater discharges. These results may also be useful in future ecosystem management considerations. For some contaminants, flux from contaminated sediments in Boston Harbor may be comparable to their loadings from wastewater discharges to the Harbor during the 1990s.

597 Incorporation of WHAM VI Binding Reactions and Metal Sulfide Oxidation Kinetics into TICKET-UWM K.J. Farley, Manhattan College, Civil and Environmental Engineering, Manhattan College, Civil & Environmental Engineering; P.M. McMahon, Manhattan College, Civil and Environmental Engineering; K.J. Rader, Mutch Associates; R.F. Carbonaro, Manhattan College, Civil and Environmental Engineering, Manhattan College, Dept of Civil and Environmental Engineering. The tableau input coupled kinetic equilibrium transport-unit world model (TICKET-UWM) has been developed as a screening model for assessing the combined effects of transport, chemical speciation and kinetics on metal releases to lakes. Chemical speciation reactions in the original model were assumed to follow the Windermere Humic Acid Model Version V (WHAM V). This decision was made in large part based on the use of WHAM V in the Biotic Ligand Model (BLM). In addition, metal sulfides in the model were assumed to oxidize instantaneously upon resuspension in the water column. These two assumptions are currently being re-evaluated as follows. First, a revised parameterization of WHAM, WHAM VI, was developed to provide a better prediction of the competitive reactions of protons and metals with natural organic matter (NOM). The WHAM VI parameterization was therefore incorporated into TICKET-UWM for testing. As part of this evaluation, the WHAM VI, TICKET-UWM results are being compared to metal partitioning data and metal removal rates for Lake Coeur d'Alene, Idaho to serve as a preliminary validation of the model. Second, a review of metal sulfide oxidation rates was performed to provide an overview of oxidation rates for various metal sulfides. A second-order kinetic rate law was added to TICKET-UWM to simulate metal sulfide oxidation in the water column and a comparative evaluation is being performed to determine the overall effect of oxidation kinetics on the cycling and bioavailability of metals in lakes.

598 The Natural and Industrial Cycling of Indium in the Environment S.O. White, H.F. Hemond, MIT, Dept of Civil & Environmental Engineering. Indium is a metal whose production is increasing dramatically due to new uses in the rapidly growing electronics, photovoltaic, and LED industries. Little is known, however, about the natural or industrial cycling of indium or its environmental behavior or toxicology. Such information is needed in order to anticipate and mitigate potential adverse environmental impacts. The combination of materials flow analysis and environmental geochemistry collectively comprise what has been called the "anthrobiogeochemical cycle". When studies of the flow of an element through industry and the environment suggest that its anthropogenic fluxes are becoming comparable to its natural fluxes, Klee and Graedel (2004) have suggested that the element should be flagged for priority study as having potentially harmful effects. This concept is particularly useful for assessing the impact of metals newly introduced to mass industrial use, for many of which the toxicological and ecotoxicological effects have not yet been established. Our studies of the dominant natural and industrial fluxes of indium show that industrial emissions of indium to the environment are already larger than natural emissions, and suggest that metal smelting and coal burning are its primary industrial sources. Because atmospheric releases are thought to be large but are poorly quantified, and because inhalation is thought to be an important exposure pathway for indium, we have studied indium in airborne particulate matter in the Northeastern United States. These studies have shown that indium concentrations in 5 locations from Boston, MA to Rochester, NY vary from below detection limits to 6 pg/m^3. There are significant differences between samples from different locations and over the course of a year. Atmospheric back trajectories generated with NOAA's Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model suggest that the highest indium concentrations come from the north, potentially from smelting operations, while lower concentrations are seen in air traveling from the midwestern US. Further work to correlate indium concentrations with other metals and to obtain smelting emissions data will help to further elucidate the sources of indium to this region.

599 Comparison of Models for Metal Partitioning to Natural Organic Matter: Chemically-based Model and WHAM VI Y.B. Atalay, Cardno Entrix, Civil and Environmental Engineering Dept; R.F. Carbonaro, Manhattan College, Civil and Environmental Engineering, Manhattan College, Dept of Civil and Environmental Engineering; D.M. Di Toro, Univ of Delaware, Dept of Civil Engineering. The WHAM VI model of metal-DOC partitioning was compared to the Excel version of WHAM VI, coded in visual basic with equilibrium constants derived from Irving-Rossotti Linear Free Energy Relationships, IR-LFERs. The Excel version was altered to use Irving-Rossotti slopes, αO, and χOO's for oxygen functional groups to compute all the metal-NOM (Natural Organic Matter) binding constants. The WHAM VI framework including IR-LFERs was called WQL-IR, shorthand for WHAM-EQL-IR, after the MINEQL series of programs. The main issues addressed are the relationships between the WHAM VI and IR-LFER metal-DOC binding constants, and testing WQL-IR by comparing model predictions with WHAM VI, and with field data sets. The model-model comparisons are performed for humic and fulvic acids at widely varying metal ion activities for pH values of 5, 7 and 9 for Ca^{2+}, Cu^{2+} and Cd^{2+} metal ions. Data sets of field measurements for Ca^{2+}, Cu^{2+} and Cd^{2+} were compiled from the literature together with metal vs. metal competition experiments. Comparisons of the WQL-IR models and WHAM VI are presented using model-model and model-field data comparisons.

600 From Exhaust Pipe to Plant: Tracking the Fate of Trace Metal Emissions in Roadside Gardens in Toronto, Canada C. Wiseman, Univ of Toronto, Centre for Environment. Much attention has been paid to the development of more reliable soil quality guidelines which consider the various factors that influence metal speciation and bioavailability. A great deal of what we currently know about soil metal dynamics and speciation has been derived from controlled lab studies, using artificially amended soils. However, some evidence suggests that metals present in field soils, which have undergone natural aging processes, may be less bioavailable. Another issue which has been largely ignored to date is the potential for the direct uptake of metals through atmospheric deposition, in addition to the better known soil-plant uptake route. This research explores these issues as part of a long term study which focuses on the fate of traffic-related trace metal emissions and their uptake by plants grown in Toronto, Canada. Oregano (O. heracleoticum), eggplant (*S. melongena*) and beets (*B. vulgaris*) were cultivated at several locations with predicted variable metal inputs beginning in 2010. Following a microwave-assisted acid digestion procedure, samples are measured using ICP-MS. Preliminary results from the first phase of this study to examine trace element stabilization processes in aging field soils suggest several important trends. First, there is a high degree of variability in traffic-related metal accumulation over time at the site where the soil was remediated. Decreases in certain metal concentrations such as Cu, after an initial accumulation, appeared to be related to such factors as organic matter loss following remediation. Second, there was a high degree of variability in metal uptake by plants as a function of soil age. For instance, Cd was more readily taken up by oregano plants grown in freshly remediated soils compared plants grown in older aged soils at a heavy traffic location. Third, elevated concentrations of certain elements measured in plant tissues compared to soils such as Cd suggest metal uptake through atmospheric deposition in addition to soil-plant transfers. The next phases of this research will continue to explore current trends, as well as examine the role of mineralogical controls in governing the fate of metals from the solid to liquid phase.

601 Geochemistry of Chromium and Nickel in Sediment of California Embayments Suggest Natural (Ultramafic) Origins S. Clough, Haley & Aldrich, Inc, Risk Assessment, Haley & Aldrich, Inc; J. Parkin-Kullman, Haley & Aldrich, Inc., Risk Assessment. Investigations of facilities for potential impacts to sediment often call for a statistical evaluation of "Site" concentrations relative to "Background" conditions. These comparisons often result in false positives because of a lack of statistical power, which can be due either to an inadequate background dataset or a right-skewed bias in the data for the Site. Simple graphical presentation of geochemical relationships between naturally occurring metals, which allow for the visualization of potential correlations, can prove a better (and easier to understand) approach than more traditional statistical evaluation methods. The magnitude of the importance of this assessment is related to the selection of Constituents of Concern (COCs) for a Site, which typically hinges on whether concentrations found in Site sediment exceed identified

Background levels. Recent sediment chemical data obtained from a San Francisco industrial facility underlain by a serpentine (ultramafic) bedrock formation revealed that concentrations of both nickel and chromium were greatly elevated. Serpentine bedrock, however, is widely known to be naturally enriched in both of these metals, indicating it as the potential source that would be considered a Background condition. Because of the ultramafic nature of the California (CA) coastline in general, the CA Sediment Quality Objectives database was further mined to examine the potential to establish relationships between chromium, nickel, and other matrix metals. Graphs of concentrations of chromium and nickel in sediment samples from all of the major CA embayments revealed a surprisingly consistent correlation between these two metals based on the available data. Furthermore, plots of the ratios of chromium and nickel concentrations for the embayments normalized using either aluminum or iron concentrations for the associated samples, showed a remarkably "vertical" character, validating the consistency of this relationship. These observations will be compared to similar analyses conducted for datasets of sediment chemical data from East Coast harbors. The efficacy of using nickel and/or chromium concentrations as benchmarks for discerning Site-related metals contamination versus background in West Coast sediments will also be discussed.

602 Linear Free Energy Relationships for Describing Metal Binding to Nitrogen Functional Groups R.F. Carbonaro, Manhattan College, Civil and Environmental Engineering, Manhattan College, Dept of Civil and Environmental Engineering; Y.B. Atalay, Cardno Entrix, Civil and Environmental Engineering Dept; D.M. Di Toro, Univ of Delaware, Dept of Civil Engineering. Nitrogen functional groups are an important constituent of natural organic matter (NOM) and are known to be responsible for complexation of metal ions in aquatic and terrestrial environments. Their role in metal partitioning to NOM was investigated through the development of linear free energy relationships (LFERs) for small organic molecules containing nitrogen functional groups. LFERs for estimating the metal-ligand stability constants, log K_{ML}, were developed using a data set of 57 monodentate and 101 bidentate ligands for 6 metal ions: Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} and Cd^{2+}. Monodentate and bidentate log K_{ML} values were adequately described using the Irving-Rossotti LFERs previously developed for ligands containing negatively-charged oxygen functional groups. Corrections to the LFER equations were necessary to account for steric hindrances to metal complexation affected by primary, secondary, tertiary amines. Predictive capabilities of the LFERs were excellent as RMSE values for each metal were less than 0.5 log units. The resulting LFER equations can be used to estimate log K_{ML} values for monodentate and bidentate ligands containing neutral nitrogen donor groups where such values do not currently exist in the literature. Comparison of these results to our previous work with negatively-charged oxygen donor atoms reveals that nitrogen functional groups are comparable in strength to their oxygen counterparts for most metal ions.

603 Method Comparisons for Copper Speciation in Salt Water and Implications for Bioavailability Model Development S. Smith, Wilfrid Laurier Univ, Dept of Chemistry, Wilfrid Laurier Univ, Chemistry; R. Diamond, T. Tait, Wilfrid Laurier Univ, Chemistry; R. Santore, HDR|HydroQual; C. Wood, McMaster Univ, Dept of Biology. Determination of copper speciation is essential to understand and predict copper bioavailability in saltwater environments. In particular, copper speciation methods must be representative of true speciation at copper levels toxic to organisms in marine and estuarine systems. In the literature, several speciation techniques are proposed but there is a need for side-by-side method comparisons utilizing the same set of samples. Towards this end, four different marine samples were collected from a variety of locations and copper speciation was determined using four distinct methods: direct anodic stripping voltammetry (ASV), competitive ligand voltammetry, ion selective electrode (ISE) and fluorescence quenching. For ISE it was found necessary to utilize flow through apparatus to have sufficiently low detection for quantification of ambient free copper. In general, direct voltammetry overestimates the amount of free and inorganically complexed copper compared to ISE. For example, using ISE a Florida bayou sample was found to have free copper of $10^{-10.3}$ whereas ASV determined a labile copper concentration of 10^{-8} mol/L. Direct voltammetry detects any copper species labile enough to react at the mercury electrode (Cu^{2+}, $CuOH^{+}$, $CuCl^{+}$, ...) whereas the ISE only responds to free cupric ion. If the ISE free copper is assumed to be correct, chemical equilibrium calculation, with chloride, hydroxide and carbonate complexation, predict ASV-labile copper of $10^{-9.1}$ mol/L, which is still an order of magnitude lower than the measured value. Likely, weak organic complexes are also being detected by the ASV method. Fluorescence quenching titrations on these same samples predict copper speciation consistent with ISE analysis. Accurate and reliable Cu speciation estimates are critical for input to bioavailablity models and the reliability of electrochemical methods need to be established by multi-technique measurements on the same samples. Funded by NSERC, ICA and CDA to CMW and DSS

604 The Mobility, Bioavailability, and Human Bioaccessibility of Trace Metals in Urban Soils X. Luo, The Hong Kong Polytechnic Univ, Dept of Civil and Structural Engineering; S. Yu, Institute of Urban Environment, Chinese Academy of Sciences; X. Li, The Hong Kong Polytechnic Univ, Dept of Civil and Structural Engineering. Mobility, effective and potential bioavailability, and human bioaccessibility were combined in evaluating the integrated ecological and health risks of heavy metals (Cu, Pb, Zn) in contaminated urban soils of Hong Kong. Different metals and even the same metal showed different soil-specific patterns for various environmental availabilities. Anthropogenic Pb in urban soils tended to be environmentally available. The various available concentrations (mg kg-1) and availabilities (%) of heavy metals in urban soils could be estimated from their relationships with the total metal contents and major soil parameters, such as pH, organic matter, EC, and soil texture. To make use of the total concentrations of heavy metals in urban soils, multiple regression equations predicting various availabilities of metals to plants, organisms, and humans, as well as the leaching potential to groundwater were developed from the studied soils. Taking into account the role of land use in the exposure of soil pollutants to humans, the introduction of site-specific available concentrations might give more realistic estimations of the risks posed by metal contamination to human health and ecosystem. The results would facilitate producing more applicable guidelines for risk assessments and soil remediation.

605 Sources of PAH in Arctic Offshore Oil and Gas Development Areas J. Neff, Neff & Associates LLC; J.S. Brown, Exponent Inc. There has been extensive exploration for and some development of oil and gas resources in Arctic waters of Alaska, Canada, Norway, and Russia. Monitoring in these development areas in the last 10 years has shown that polycyclic aromatic hydrocarbons (PAH) are abundant in Arctic river and offshore sediments, coastal peat, and the tissues of marine animals. Total PAH concentrations in continental shelf sediments of the Chukchi and Alaskan and Canadian Beaufort Seas range from about 10 to 4,500 ng/g dry wt (parts per billion). Highest concentrations are off major rivers (e.g., the Macenzie and Colville Rivers) and at a few exploratory well sites. Concentrations in Barents Sea sediments range from about 20 to 1,500 ng/g. Fingerprinting indicates that the sediment PAH are from a mixture of petrogenic, pyrogenic, and biogenic sources. The PAH in surface sediments at former exploratory well sites are enriched in perylene, indicating the PAH are primarily from peat and kerogens from rivers draining the extensive peat bogs along the Arctic Ocean. Total PAH concentrations in bivalve mollusks and benthic crustaceans from the study areas range from 20 to 360 ng/g, suggesting that sediment PAH have a low bioavailability. There is evidence of PAH from diesel fuel in sediments at a few locations, probably from accidental discharges from commercial vessels involved in offshore oil exploration and development operations. Most of the petrogenic PAH in Arctic sediments and benthic invertebrates probably are primarily from the abundant natural seeps, oil shale, and coal deposits along the Arctic coasts.

606 Trophic Transfer of PAH Metabolites in Short Aquatic Food Webs V. Carrasco Navarro, Univ of Joensuu, Faculty of Biosciences, Univ of Eastern Finland, Dept of Biology; M.T. Leppanen, Univ of Eastern Finland, Dept of Biology; J. Honkanen, Akvaplan-niva, Environment & Petroleum Research Group; J.V. Kukkonen, Univ of Eastern Finland, Joensuu Campus, Dept of Biology. Polycyclic aromatic hydrocarbons (PAHs) are widespread contaminants in the aquatic environment. Opposite to other Persistent Organic Pollutants (POPs), the current understanding is that PAHs are not prone to biomagnification along the trophic chain. The low potency for biomagnification is suggested to be a result of the higher biotransformation and excretion capabilities at higher trophic levels. Although the biotransformation of PAHs may lead to the formation of metabolites that could be more toxic than the parent compound, there is not abundant information about the trophic transfer of biotransformation products. Using pyrene as a model PAH, the trophic transfer of its biotransformation products was

tested in aquatic laboratory exposures. *Lumbriculus variegatus* (Oligochaeta) and *Chironomus riparius* (Diptera: Chironomidae) were exposed to pyrene in water and used as prey fed to the predators brown trout (*Salmo trutta*) and the arctic seawater amphipod *Gammarus setosus*. By using high performance liquid chromatography (HPLC) it was determined that one phase II biotransformation product produced by *L. variegatus* is transferred to *S. trutta* through diet. Similar results were found in studies conducted with *G. setosus* as predator and *C. riparius* and *L. variegatus* as prey. Additionally, pyrene and total body burdens of prey and predator analyzed through HPLC and Scintillation Counting (SC) are in accordance with the transfer of metabolites, showing that there are more mols of metabolites in predators' tissues than mols of parent pyrene ingested, indicating that necessarily a transfer of at least part of the metabolites occurred. The results highlight the fact that also the PAH metabolites should be taken into account when assessing the overall risk caused by PAHs.

607 Evaluating the Toxicity of Petroleum in Arctic and Other Aquatic Environments P.M. Chapman, Golder Associates Ltd; P.M. Landrum, Southern Illinois Univ; J. Neff, Neff & Associates LLC; D.S. Page, Bowdoin College, Dept of Chemistry. Aquatic toxicology has evolved from an initial evaluation of individual chemicals to evaluations of mixtures of chemicals and complex substances. However, experimental designs for evaluating the toxicity of complex mixtures such as petroleum in aquatic environments can be highly variable and, if not appropriate, can and have produced data that are difficult or impossible to interpret accurately. We provide guidance for the proper design of laboratory and field assessments of the toxicity of mixtures of low-solubility organic chemicals such as comprise different petroleum products, based on two fundamental requirements: establishing a dose-response relationship; and, determining the causative agent(s) of any observed toxicity. These two requirements can be met only if exposure conditions and measurement endpoints are appropriate, modifying factors are considered (e.g., test conditions, test organism life stage, chemical transformations, mixture dilution, sorbing phases), and concentration/dose response relationships are correctly interpreted. Problems that occur when these two fundamental requirements are not met are illustrated using case studies from the Arctic marine environment.

608 Toxicity of Physically and Chemically Dispersed Petroleum to Arctic Species W. Gardiner, NewFields LLC; J.Q. Word, NewFields, Applied Environmental Sciences, Newfields Northwest, Applied Environmental Sciences; K. McFarlan, R. Perkins, Univ of Alaska Fairbanks. A joint industry program was formed to investigate the toxicity of chemically and physically dispersed oil to valuable ecosystem components of the Beaufort and Chukchi Seas. Sensitive life stages of the copepod *Calanus glacialis*, polar cod (*Boreogadus saida*), and sculpin (*Myoxocephalus* sp.) were collected from the Beaufort and Chukchi Seas near Barrow Alaska and tested in laboratory facilities at the Barrow Arctic Sciences Consortium. Toxicity tests were completed using methods previously established by CROSERF, with modifications to represent conditions in ice-free, Arctic waters. Three preparations of fresh Alaska North Slope (ANS) crude oil were evaluated: physically dispersed oil, chemically dispersed oil, and physically dispersed oil under increased mixing energy conditions. Tests were conducted as spiked-tests with a half-life of four hours at 2°C to simulate environmental conditions. Total petroleum hydrocarbons (TPH), alkanes, and polyaromatic hydrocarbons PAH were analyzed by gas chromatography/mass spectrometry (GC/MS) at the beginning of each test. The mean LC_{50}s for chemically-dispersed oil were 55 mg /L TPH (arctic cod); 22 mg /L TPH (early-season copepods); 62 mg /L TPH (late season copepods) and 27 mg /L TPH (larval sculpin). Under low mixing energy conditions, the physically dispersed ANS did not produce enough dissolved TPH to elicit a response from the copepods, but the TPH was sufficient to provide a mean LC_{50} for the arctic cod and sculpin of 1.6 mg/L and 2.2 mg/L TPH, respectively. Under increased energy mixing conditions, the physically dispersed oil proved to be significantly more toxic to both the arctic cod and early season copepod with mean LC_{50}s of 3.3 and 3.7 mg/L TPH, respectively. Comparison of the LC_{50}s obtained from this study with previous studies performed on temperate and non-arctic species shows that the arctic cod, copepod, and sculpin were similarly sensitive to chemically dispersed oil than their temperate and non-arctic counterparts.

609 The Arctic Copepod *Calanus glacialis* Is Less Sensitive to Acute Oil Exposure than its Boreal Sister Species *Calanus finmarchicus* B. Hansen, SINTEF Materials & Chemistry, Marine Environmental Technology; D. Altin, BioTrix; S.F. Rorvik, I.B. Overjordet, A.J. Olsen, Dept of Biology, NTNU; T. Nordtug, SINTEF Materials and Chemistry. The use of temperate species to assess the risk of chemical toxicity to Arctic species may be difficult, because different temperatures and differences in organism lipid content affect uptake/depuration kinetics and the subsequent toxic responses. There have so far only been a few attempts to determine whether temperate effect levels are in fact applicable to polar biota. In order to address these issues we conducted a comparative study using two closely related calanoid copepod species; *Calanus finmarchicus* and *Calanus glacialis*. *C. finmarchicus* is considered an Atlantic copepod, whereas the *C. glacialis* is considered an Arctic copepod, and the experiments on *C. finmarchicus* and *C. glacialis* were conducted at relevant temperatures for the two species; 8°C and 2°C, respectively. Copepods were exposed to water-soluble fraction of fresh and weathered crude oil in three differently designed acute experiments. Firstly, LC50 levels for both contaminants were determined for both species. Secondly, experiments were conducted applying sub-lethal exposures at three different concentrations to both species followed by sampling after 12, 24 and 48 hrs. Sampled copepods were analyzed for expression of stress genes (e.g., glutathione S-transferase). Finally, we conducted experiments revealing the relationship between lipid content and acute toxicity to WSF exposure. Clear differences were shown in terms of acute toxicity, and the WSF of the fresh and weathered crude oil was more toxic to the Atlantic copepod. This may be attributed to differences in temperature optimum and lipid content of the two species. A suspected lipid content-dependent alteration of acute toxicity was verified, since for both species lipid-rich copepods survived longer than lipid-poor copepods. We also observed differences between the two species and also between lipid-poor and lipid-rich copepods in the ability to express stress genes following exposure. In conclusion, in terms of effect limits to oil exposure, the boreal copepod can be used as a model species for Arctic copepods without underestimating acute oil toxicity.

610 Indigenous Microorganisms Degrade Oil in Arctic Seawater K. McFarlin, Univ of Alaska Fairbanks; M. Leigh, Univ of Alaska Fairbanks, Biology and. Wildlife; R. Perkins, Univ of Alaska Fairbanks, Civil and Environmental Engineering. A number of techniques can be used to respond to a marine oil spill such as mechanical recovery, in situ burning, the application of dispersants and natural attenuation. The success of the latter two options relies upon biodegradation by indigenous microflora. As oil exploration expands in offshore Arctic regions, it is imperative to assess the potential rate and extent of oil biodegradation in arctic marine environments by indigenous microflora under environmentally relevant conditions, including at low temperatures. A respirometry experiment validated with chemical analyses was conducted in order to determine the potential for indigenous arctic marine microorganisms to biodegrade Alaskan North Slope (ANS) crude oil in the presence or absence of a dispersant (Corexit® 9500), both in fall and late winter/early spring conditions. Sea water was collected from the Beaufort and Chukchi Seas to provide an indigenous consortium of biodegrading microorganisms. Tests were conducted at an on-site laboratory (Barrow, Alaska), at seasonal temperatures (2°C and -1°C) with minimal nutrient addition. Manometric respirometry combined with GCMS chemical analyses was used to evaluate the rate and extent of biodegradation. Biodegradation and mineralization occurred in fresh and 20% weathered ANS crude at both 2°C and -1°C with indigenous Arctic microorganisms. The presence of Corexit 9500© was not inhibitory to natural microbial degradation. The addition of Corexit 9500© enhanced the degradation of both fresh and weathered oil both in the presence and absence of low-level nutrients.

611 Microbial Metagenomics as an Environmental Monitoring Tool for Offshore Oil Exploration and Production B. Metzger, Battelle. Microbial metagenomics—the study of the genomic profile of entire microbial communities including cultured and uncultured organisms—is a powerful tool to assess widely diverse ecosystems to detect perturbations in and monitor the recovery of microbial communities. The cost of nucleic acid sequencing is rapidly decreasing, making metagenomics competitive with traditional microbial monitoring, while providing substantially more community-based and unbiased information than traditional microbial approaches. In this study, we examined the microbial metagenomic profile in three distinct environments: marine, human, and sediment. In the first case we demonstrated the application of bioinformatics data mining to identify hydrocarbon-degrading bacteria and associated functional genes in marine waters using publically available data. Examination of the Sorcerer II Expedition genetic

data revealed putative oil-degrading bacteria and related functional genes at several distinct marine locations not obviously impacted by oil-drilling operations, suggesting exposure of normal marine microflora to petroleum. The second case study focuses on the metagenomic profile of human saliva to identify microbial diversity in the normal microflora. Human saliva samples were whole-genome sequenced and after filtering out human sequences, the relative abundance of genetic sequences from prokaryotic organisms was determined using the Basic Local Alignment Sequence Tool with specified parameters. More than 20 known individual bacterial species were identified including *Streptococcus thermophilus*, a bacterium not considered part of the normal human microflora. Instead, this unique organism most likely correlated with the recent consumption of an industrially processed dairy product, illustrating the power of metagenomics to detect temporary changes in normal microflora. The third case study used novel bioinformatics processing to compare the microbial metagenomic profile in geographically identical sediments to assess impacts of Alaskan crude oil on microbial diversity and functional gene expression, resulting in a unique microbial response pattern that may be applied to future predictions or examinations of exposure to and recovery from potential hydrocarbon contamination. Further, this study sought to extend microbial environmental monitoring using transcriptomic and proteomic approaches.

612 Attu Island – Where WWII Continues to Wage War on the Environment D.D. Rudis, US Fish & Wildlife Service, Ecological Services. Most people regard National Wildlife Refuges as pristine areas reserved for wildlife and fish. However, during the World War II Aleutian campaign, Attu Island was of strategic importance and was occupied by both Japanese and American forces. Remains of buildings, tent camps, gunneries, fuel storage tanks, dumps, ammunition piles, utilities, and much ordnance are found on Attu. These lands are part of the Alaska Maritime National Wildlife Refuge. Attu is the westernmost of the Near Island group of the Aleutian Islands. It is over a thousand miles from the Alaskan mainland and 750 miles northeast of the northernmost of the Japanese Kurile Islands. Attu encompasses a variety of habitats including rolling tundra where cackling geese and rock ptarmigan nest, coastal cliffs that serve as nesting sites for thousands of seabirds, rivers where salmon spawn, and rocky shorelines where common eiders nest and feed offshore along with sea otters that are found in the coastal kelp forest. The majority of contaminant problems on Attu are from WWII activities. Leakage and spills from petroleum product tank farms and other storage areas, fuel lines, burn pits and barrel dumps are common, as are battery dumps, ammunition piles, and debris piles. Extensive soil and water sampling has been conducted at both islands by contractors for the US Army Corps of Engineers, the branch of the US Army responsible for assessing extent of contamination at former military sites. Contaminant analysis has also been done on some fish samples, soil, and sediment by USFWS. There has been no hazardous waste cleanup on Attu, with the exception of a large ordnance dump. Because some of the contaminated sites are due to long-term fuel leaks, these areas are a hazard to terrestrial birds that forage in these upland locations. There are also sites where during warm weather periods, fuel flows into nearby streams. In addition, groundwater contamination by petroleum hydrocarbons may also be a problem at tank farm sites. We are collecting and summarizing all available contaminant information on Attu for the US Fish and Wildlife Service Contaminant Assessment Process. This information will be used by the USFWS to make informed management decisions about contaminant threats and assist with site prioritization for Army Corps of Engineers cleanup actions.

613 The Modified Guideline Study: What Can We Learn? A. Samel, DuPont Crop Protection, Ecotoxicology. Standardized study designs have been developed by many organizations including the USEPA, the Organization for Economic Co-operation and Development (OECD), Environment Canada, ASTM and ISO. Standardized toxicity testing is an essential part of the regulatory process and often results in a collection of base-line data that is critical for the regulatory review of new and existing chemicals. The goal of standardized testing is to generate high quality results and reduce variability while increasing comparability across multiple data-sets. In a standardized test, the study method is defined using established protocols, regardless of the testing laboratory or the chemical tested, with similarly derived study end-points (EC/LC50, NOEC). Large data-sets of these similarly derived end-points provide a powerful tool to regulatory reviewers and investigators. The advantages of standardized testing, however, are also its biggest disadvantages. The standardized test represents a worst case scenario that is often not representative of actual field conditions. For example, the maintenance of test concentrations for the duration of a standardized test in a water-only test system is often not representative of actual exposure duration times and chemical concentration levels in the field. In standardized tests, a single surrogate test species of uniform size and age is used to represent an entire taxonomic grouping (invertebrates, fish, algae). Modifications to standardized tests can increase the understanding of the fate and effects of a chemical. These modifications can range from testing non-guideline ecologically or regionally relevant test organisms to specific study design modifications that address, for example, pulse exposures with spikes and declines in concentration levels over time. Modifications might address specific questions such as the effects of fed versus unfed test organisms, effects to multiple age classes, testing in the presence of sediment, etc. Overall, modifications to standardized tests can provide a more comprehensive understanding of the fate and effects of a chemical to specific taxa and can provide information of greater ecological relevance without the need for field testing. Case studies of modifications to the standardized acute invertebrate toxicity test will be presented as examples of the usefulness and importance of the modified standard toxicity test.

614 Control Treatment Water Selection Can Affect the Findings of Toxicity for *Selenastrum capricornutum* Toxicity Tests: A Source of False Positives? S. Clark, R. Ogle, J. Cotsifas, Pacific EcoRisk. The USEPA has well-vetted and standardized aquatic toxicity test protocols that are applied nationwide in the determination of compliance with a wide variety of regulatory programs. Although there have been and continue to be efforts to further standardize test methods and reduce variability, the freshwater algae test with the green alga *Selenastrum capricornutum* allows the testing laboratory the flexibility to select different control/dilution waters for the tests (e.g., culture medium, uncontaminated receiving water, synthetic (reconstituted) water, or some other natural water). Several split-lab studies were performed in which the testing labs used different control waters, and the test results differed significantly as to identifying the samples as toxic or not. We hypothesized that in addition to the nutrients that are added per the test protocol, there can be significant differences in nutrients (and nutrient availability) in the different control/dilution water matrices used by different labs. This has the potential to result in biostimulation in some waters that could lead to a false conclusion of toxicity when compared to algal growth in an effluent. We performed experiments using several of the standard laboratory control waters used by commercial labs, with the results being compared to algal growth in actual test samples. The samples were identified as being toxic for some of the control waters, and not toxic for others, potentially resulting in "false positives" depending upon which control water was used for the regulatory compliance reporting. Results of these comparative tests will be discussed regarding implications for regulatory compliance.

615 From Bugs in Mud to Fish in Coldwaters: Lessons Learned Adapting Standard Test Methods to Novel Conditions J. Van Geest, Univ of Guelph, School of Environmental Sciences, Intrinsik Environmental Sciences Inc; D. Moore, Univ of Guelph, School of Environmental Sciences. Why start from scratch when so much work has already gone into the development and standardization of test methods? Designed for defined and general use, standard test methods are not always best suited to answer specific research and regulatory questions but are useful a basis for the technical, quality control, and reporting aspects that are important to any study. Modifying certain aspects of standard methods is a means of rapidly moving research forward by allowing critical evaluation of emergent issues while still relying on the basic foundation of the method, giving merit to the argument that standard tests are still relevant in the changing face of environmental risk assessment. As researchers using standard methods, we discuss the lessons learned from our research adapting existing bioaccumulation test methods to develop the Ontario Ministry of the Environment's new bioaccumulation test method and assessing the impact of modifying factors on the existing Environment Canada rainbow trout standard test method. We provide an overview of the benefit and complications of adapting existing standardized test methods to answer new questions, important data gaps observed in the literature, and highlights of data obtained by modifying the standard test methods.

616 Is *Hyalella* Reproduction a Practical Endpoint to Use in Toxicity Testing? A. Bartlett, L. Brown, Environment Canada. Reproduction in *Hyalella* can be a more sensitive and environmentally relevant endpoint

than survival or growth; however, it is also much more variable, making it difficult to interpret the results and bringing into question the practicality of conducting reproduction tests on a routine basis. Previous research in our laboratory adapted standard sediment toxicity test methods for survival and growth to include a reproduction endpoint, and although reproduction appeared to be a more sensitive endpoint than survival, the data were too variable to use on a routine basis. The objective of this study was to conduct static-renewal sediment toxicity tests under control conditions (Lake Ontario culture water, Lake Erie sediment) to characterize reproduction in *Hyalella*, and then to manipulate test parameters, such as test duration, frequency of renewal, sediment:water ratio, and number and density of *Hyalella* in order to design methods to reduce variability in reproduction. The first set of experiments was conducted in 250-mL glass beakers with a 9:1 ratio of sediment:water and 10 replicates per treatment. In treatment 1, reproduction was characterized over 20 weeks by conducting static-renewal tests in which survival, growth, and reproduction were measured every 2 weeks starting at week 4. The juvenile:adult ratio was stable from 6-20 weeks, reproduction was highly variable (coefficients of variation ranged from 43-110%), and longer exposures did not reduce the variability in reproduction. Next, test duration and frequency of renewal were investigated by conducting: a static-renewal 10-week test with a renewal at week 4 (treatment 2), a static 6-week test (treatment 3), and a static 10-week test (treatment 4). When comparing the results to treatment 1: treatment 2 had a higher juvenile:adult ratio, perhaps due to reduced handling stress (one renewal versus three); treatment 3 was comparable; and treatment 4 had more variable (and lower) survival, likely related to deterioration of water quality. A second set of experiments is currently being conducted in 1-L Imhoff settling cones to stabilize overlying water quality. Test parameters, including sediment:water ratio and number and density of *Hyalella*, are being varied. The results of these tests will be presented and compared to those from 250-mL beakers. The practicality of using *Hyalella* reproduction as an endpoint in toxicity testing and directions for future research will be discussed.

617 Minefields Associated with Mining Data from Peer-reviewed Literature C. Russom, USEPA, Mid-Continent Ecology Division. The USEPA's ECOTOX database is the largest compilation of ecotoxicity study results, providing information on the adverse effects of single chemical stressors to ecologically relevant aquatic and terrestrial species. The primary source of data included in the ECOTOX database is the peer-reviewed literature, with information gathering accomplished through manual data abstraction and data entry. ECOTOX is used by all sectors of the environmental toxicology community in risk assessments, screening and prioritization exercises, data analysis projects, and species and chemical extrapolation model development. Typically an evaluation of the relevance, adequacy, and reliability of a test result is conducted prior to using it in risk assessment and modeling efforts. Therefore, critical to the usability of this data is the complete reporting of experimental design and test results by authors. The ECOTOX database is designed to capture, in discrete data fields, all aspects of test methods and associated results, but assumptions about test protocols, and interpretations of the data are not made. Therefore many data fields remain unpopulated due to lack of detail provided in the publication. This presentation will cover limitations and information gaps related to published research results; how these information gaps may affect the inclusion of a study in products of research and in risk assessments (e.g., models, Agency benchmarks, etc.); and possible solutions such as open access data repositories. The contents of this abstract neither constitute nor reflect official USEPA policy.

618 The Advantages and Application of Using a Light Dusting of Substrate for Experiments with Newly Hatched and 3rd Instar *Chironomus dilutus* T.W. Valenti, National Research Council; US Environmental Protection Agency, National Research Council; T. Highland, R. Hockett, US Environmental Protection Agency, Mid-Continent Ecology Division; T.J. Norberg-King, US Environmental Protection Agency, ORD, NHEERL, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; D.R. Mount, US Environmental Protection Agency, ORD. Ongoing research efforts are focused on identifying the relative degree of sensitivity provided by the standard 10-d sediment toxicity test initiated with 3rd instar *Chironomus dilutus* (common name: midge) compared to the modified 20-d sediment toxicity test initiated with < 1 h old newly hatched midges. The 10-d method is extensively used as an assessment tool because of its relative ease and low cost to conduct. The 20-d procedure is desirable because it is presumed to be more sensitive, but some laboratories have reported difficulties achieving consistent results with the method. Prior comparisons suggest that earlier midge instars are more sensitive; however, most of these are based on acute exposures in which only lethality was monitored and it is unclear whether these differences will persist in longer exposures when sub-lethal endpoints are also measured. The overall goals of this research are to 1) better understand the relative sensitivity of 10-d and 20-d exposure methods and 2) determine if there are procedural changes that may improve laboratory success and consistency with the 20-d method. A major challenge for comparing responses between the methods is the inability to follow early survival and development of < 1 h old midges, as once they are added to sediment, it is nearly impossible to isolate them again from substrate until late in the test. To avoid this problem, we evaluated an alternative approach in which a light dusting of substrate is used. This approach provides organisms with materials to construct cases and allows easy recovery of animals for intermediate survival and growth measures. While a dusting of substrate does not allow for evaluations of bedded sediments, it can be used for water column exposures to directly compare the sensitivity of different life stages to toxicants. By selecting substrates that minimally interact with contaminants, it is possible to maintain consistent exposure concentrations and therefore accurately quantify the relative sensitivities across life stages of *C. dilutus* and between endpoints generated by the 10-d and 20-d procedures. High rates of survival and growth are shown for both < 1 h and 3rd instar old midges in both natural and artificial substrates under control conditions. In addition, we shall compare the responses observed during water-only exposure to copper, with emphasis on the relative sensitivity of each life stage. This abstract does not necessarily reflect USEPA policy.

619 The Application of Multi-generation Tests in Aquatic Toxicology Research P. Sibley, Univ of Guelph, School of Environmental Sciences, Univ of Guelph, Dept of Environmental Biology. Benthic organisms in most contaminated freshwater environments are exposed to low concentrations of contaminants over relatively long periods of time. Realistic assessment of potential chronic effects in such cases is arguably best achieved using exposure regimes commensurate with these conditions. Most current standard test methods for long-term exposures typically encompass all or a portion of an organism's life cycle, as exemplified by the standard sediment tests for *Chironomus* spp. and *Hyalella azteca*, and the aquatic test using *Daphnia magna*. Life cycle tests can provide a wealth of information based on ecologically relevant endpoints such as growth and reproduction but are somewhat constrained in their capacity to extrapolate to populations, the protection of which is a key goal in ecological risk assessment. An extension of the life cycle test is the multi-generation test. Multi-generation tests use repeated applications of standard life cycle tests to investigate effects (e.g., enhanced tolerance/resistance, extinction, compromised immunity, etc) that are more likely to, or may only, become manifest after trans-generational exposure to contaminants. Using data generated from life cycle and multigenerational tests conducted with *C. dilutus*, *H. azteca*, and *D. magna* this paper will discuss the utility and challenges of developing and applying multigenerational tests in aquatic toxicology research. The potential value of multigenerational tests as a research tool to address questions that cannot be addressed using currently available standard life cycle tests, and the potential for developing new, or refining existing, standardized test methods will be discussed.

620 What Makes Standard Toxicity Tests Tick? R. Scroggins, Environment Canada, Ecotoxicology and Wildlife Health Division; L. Taylor, Environment Canada. Biological toxicity tests have come a long way from ten fish in a bucket. Typical standard methods contain background information, guidance and specific procedures for culturing or holding of test organisms, test conditions, setting up a test, observations during the test, test take-down, analysis of results, and reporting. As an introduction to the session, this talk will provide an overview of the existing standardized test methods available and the value of following these methods in more research-oriented environmental assessments. Attendees will benefit greatly from learning about the advantages and limitations of the existing international and national standard methods, future plans to update older methods or develop new methods and the research that supports methodological improvement, and some of the challenges for future method development. In the application of standardized toxicity tests to research-type studies, we stress the importance of quality control and assurance practices which are relevant to all aspects of the test method (e.g., organism health criteria, allowed ranges of physical conditions such as temperature or lighting,

randomization of test vessels, minimizing technician bias, proper statistical analyses, test validity criteria, and minimum reporting requirements).

621 Comparative Nanogenotoxic Study of DNA Damage Between Prokaryotes and Eukaryotes J. Lan, N. Gou, Northeastern Univ, Civil & Environmental Engineering; A. Gu, Northeastern Univ, Dept of Civil & Env Engineering, Biotechnology Initiative Program, Dept of Civil & Env Engineering, Biotechnology Initiative Program. Nanomaterials (NMs) have been reported to induce DNA damage, which can potentially lead to mutational heritable changes in organisms. However, little is known of their detailed mechanism of damage and repair pathways involved. In this study, we investigated and compared transcriptional level effect and gene expression changes associated with a number of specific DNA damage and repair pathways in both prokaryotic and eukaryotic cells, after exposure to a number of different NMs. Transcriptional effect in prokaryotic cells was evaluated by GFP-infused K12 *E. coli* library with genes of DNA damage and repair regulation system including SOS system. RT-qPCR was applied to assess the changes in specific genes indicative of certain DNA damage recognition and repair pathways for eukaryotic A549 cell line. In addition, cytotoxicity test and comet test were performed for confirmation and comparison. NMs evaluated include nTiO_2-anatase, carbon black, SWCNT (single wall carbon nanotube) and fullerene. MMC (mitomycin C), a model genotoxicant, was used as a positive control. The results showed that NMs leading to DNA damage to prokaryotic cells also caused DNA damage in eukaryotic cells, although detailed mechanism vary between species. Gene expression exhibited significant changes within 4 hours at doses lower than LD50, suggesting this method is more rapid and sensitive for sub-cytotoxic exposures. Among the NMs tested, nTiO_2_a displayed the most wide range of genotoxicity for DNA damage, including single and double strand damage, as well as oxidative damage on bases. CB seemed to lead to different type and more severe DNA damage in eukaryotice cells. SWCNT and fullerene induced altered expression in genes involved in DNA damage and repair for eukaryotic cells but not in procaryotes, suggesting that eukaryotic cells are more sensitive towards NMs genotoxicity, especially to more severe double strand break, likely due to the differences in their cell wall/membrane structure and therefore different susceptibility to DNA damages, directly or indirectly. Temporal trends of gene expression levels for A549 cells revealed details of the nature of DNA damage and repair response and, in comparison with parallel comet tests, indicated the variation in DNA damage generation, repair response and final DNA damage. The results demonstrated that gene expression may lead to a better understanding of damage mechanisms, which will help designing more benign NMs for wide applications.

623 Size, Shape, and Surface Chemistry: The Three S's of Nanoparticle-Cell Interactions T.R. Garner, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX), Clemson Univ, Institute of Environmental Toxicology; W.S. Baldwin, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX); A.M. Rao, Clemson Univ, Dept of Physics and Astronomy; S.J. Klaine, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX), Clemson Univ, Institute of Environmental Toxicology (ENTOX) There are currently over 1000 consumer products on the market that contain or utilize nanomaterials, and this number is expected to increase exponentially in the near future in the absence of detailed knowledge concerning the interactions of such materials with biological systems. While nanoparticles have been shown to cross cellular membranes, little research has examined the influence of particle characteristics on membrane transport. Furthermore, our inadequate understanding of potential human and ecological effects has resulted in uncertainties of the potential risks of this technology and impeded the advancement of quantitative risk assessments. The goal this project was to characterize the influence of particle size, shape, and surface chemistry on the movement of gold nanoparticles across mammalian cellular membranes. A549 carcinomic human alveolar cells were utilized to characterize the movements of gold nanoparticles across cellular membranes. Specifically, the absorption of three different gold nanoparticle shapes were examined at multiple sizes: spheres (4, 10, and 50 nm), cubes (50 and 75 nm) and rods (20x100 and 20x200 nm). The influence of surface chemistry on absorption was examined through surface modifications of these particles of various shapes and sizes by protonated amine, PEG, and citrate. Each of these particles were characterized by TEM, DLS, UV-vis, and zeta potential. In total, comparisons of cellular interactions were examined for 21 different modifications of gold nanomaterials. Cells were plated in 12-well plates at 100,000 cells per well and exposed to 1 mg/L gold for 0.5, 1, 1.5, and 2 hours. Bioaccumulation of nanoparticles at each time point was quantified by inductively coupled plasma-mass spectrometry (ICP-MS), and movement was visualized via confocal microscopy.

624 Detection of Morphological Changes in *Pseudokirchneriella subcapitata* Following Exposure to Quantum Dots J.L. Bouldin, Arkansas State Univ, Dept of Biological Sciences, Arkansas State Univ, Environmental Sciences Graduate Program, Environmental Sciences Graduate Program, Arkansas State Univ, Dept of Environmental Science; S. Yu, Arkansas State Univ, Arkansas Biosciences Institute. Semiconductor nanocrystals are presently used for research and diagnostic techniques in biological testing; increased applications of these nanoparticles for industrial and consumer products has increased global use with further increases predicted. An organic coating protects an inner core of cadmium and selenium in these fluorescent nanocrystals. Following Quantum dot (QD) exposure, microscopic results revealed a change in cellular shape to the single-celled alga, *Pseudokirchneriella subcapitata*. Changes in cell size were determined by polygon surface area measurements. Results reveal a statistically greater surface area in cells exposed to QDs when compared to unexposed cells. A 56% increase in cell surface was measured in algae exposed to 55 ppb Qdot suspensions. Cellular changes were further quantified using a scanning electron microscope and flow cytometry. Flow cytometry analyses reveals changes in algal cell populations with increased surface area and granularity following 72- and 96-hr exposures and fluorescein diacetate (FDA) was used to determine cell-membrane integrity. Scanning electron microscopy was used to determine changes in mean length and width of individual exposed algal cells. Although outer layers offer a protective coating from the toxic metals present in the QD core to multi-cellular organisms, toxicity to single-cell algae poses a concern for environmental protection from nanoparticle release.

625 Alteration of Biochemical Pools in Cyanobacteria Induced by Nano-titanium Dioxide Exposure C. Cherchi, Northeastern Univ, Civil and Environmental Engineering; A. GU, Northeastern Univ, Dept of Civil & Env Engineering, Biotechnology Initiative Program, Dept of Civil & Env Engineering, Biotechnology Initiative Program. Progress of nanoscience poses an urgent need for fundamental understanding of the potential environmental effects of engineered nanomaterials such as nano-titanium dioxide (nTiO_2), whose presence in wastewater effluents have already been detected and will likely impact aquatic systems (e.g., algae). In this study Fourier Transform Infrared spectroscopy (FT-IR) was used to evaluate the impact of nTiO_2 at environmentally relevant doses on the cellular reorganization of macromolecules in the cyanobacteria *A. variabilis.* The comparison of the predominant chemical markers (proteins, carbohydrates, lipids, nucleic acids) obtained showed characteristic temporal changes during the short-term (96 hrs) and long-term (21 days) exposure to nTiO_2. Most dynamic variations, as indicated by the changes in the ratios of macromolecules to proteins, were observed during the first 96 hrs and mostly showed a dose-dependent pattern; however, over longer time (21days), the cells seemed to be able to recover back to more conservative levels of macromolecule composition and, the rate and time required for the recovery as well as the final ratios of the macromolecules varied with nTiO_2 doses. For example, nTiO_2 exposure led to a sudden increase in proteins levels after the initial dose (within 3 hrs) then followed by protein reduction (following 96 hrs), and the magnitude of initial protein increase and the subsequent reduction rates were found to be dose-dependent. Changes in the amide II/amide I ratio and in the -CH_2 frequencies of lipids revealed that conformational changes in membrane protein folding and cells' structural changes are possibly induced by nTiO_2 treatment, respectively. Temporal variations in the phosphodiester stretchings suggested that changes in the relative content of nucleic acids were likely induced by nTiO_2, and might impair the biogenesis of ribosome, a significant repository of phosphorus in ecosystems. Principal component analysis of FT-IR spectra showed that specific functional groups (i.e., carbohydrates) contribute to the differences among treatments. The results clearly indicated that an array of responsive changes were caused by nTiO_2, targeting membrane components, proteins and RNA-associated functional groups, energy storage products and the depository of genetic information. In conclusion, this study provides insights into the potential larger scale impact of nTiO_2 on ecological interactions and food web dynamics in aquatic ecosystems.

626 Toxicogenomic Evaluation of the Single-Walled Carbon NanoTube (SWCNT) Electronic Structure-dependent Interactions with Microorganisms N. Gou, Northeastern Univ, Civil & Environmental Engineering; C.Z. Vecities, Harvard Univ, School of Engineering and Applied Sciences; A. Gu, Northeastern Univ, Dept of Civil & Env Engineering, Biotechnology Initiative Program, Dept of Civil & Env Engineering, Biotechnology Initiative Program. Previous SWCNT toxicity studies have primarily focused on the relative toxicity as a function of physicochemical properties including diameter, surface functionality, and their subsequent dispersion/aggregation state. Another important physicochemical property that has been shown to affect the reactivity of SWCNT is its chirality-dependent electronic structure, i.e., whether the SWCNTs are metallic or semiconducting. In this study, we applied a toxicogenimic approach towards the mechanistic assessment of three purified and well-characterized SWCNTs of similar diameter and length, but consisting of varying fractions (< 5, ~30, and >95%) of metallic SWCNTs referred as S-SWCNT, X-SWCNT, and M-SWCNT, respectively. A whole-cell-array library of recombinated *E. coli* K12 strains with promoter-reporter GFP fusions the majority of known stress response genes is utilized to examine the relative toxicogenomic affects of these three SWCNT samples. A recently developed Transcriptional Effect Level Index (TELI) is used to quantify the results. The stress library TELI results indicated that M-SWCNTs induced a higher response level than the M-SWCNT and the S-SWCNT. In all cases, SWCNT exposure significantly affected the transcription level for oxidative stress and membrane stress genes suggesting these to be the two major toxicity pathways. The metallic SWCNTs induced significantly higher transcriptional level changes in oxidative stress (6 fold) and membrane stress (2.5 fold) than the semiconducting SWCNTs. Specifically, for sub-categorized membrane stress functions, metallic SWCNTs induced higher altered gene expression of those involved in electron transfer, membrane structure related macromolecular metabolism , flagellar biosynthesis, and antibiotic resistance. These results indicated that there is clearly an electronic-structure-dependent reactivity of SWCNTs and therefore varying toxicity level, consistent with the previous report. The information obtained in this study revealed details of the celluar response to these two SWCNT and provided insights into the correlation of electronic properties of SWCNT with its toxicity. The significantly higher stress response caused by the metallic SWCNT than the semicondutig SWCNT seemed to suggest that the toxicity level and mechanism of SWCNT are related with the electronic structure and electron transfer ability of the SWCNT.

627 Influence of Nanosilver on Bacterial Diversity in Natural Waters P. Das, Trent Univ; C.J. Williams, Trent Univ, Dept of Biology; R.R. Fulthorpe, Univ of Toronto, Dept of Physical and Environmental Sciences; M.E. Hoque, C.D. Metcalfe, Trent Univ, Environmental and Resource Studies; M.A. Xenopoulos, Trent Univ, Dept of Biology. The widespread usage of nanosilver (nAg) due to their antibacterial properties possesses a potential environmental risk once they are released into aquatic environment. Many studies have investigated the effects of nAg on various aquatic organisms, but very little is known about their possible toxicological effects on bacterial community composition in natural aquatic systems. We investigated the effects of nAg on bacterial community composition collected from nearby aquatic ecosystems and exposed to several nominal concentrations of nAg (ViveNano Inc.; 10nm particle size) at a level of 0.01 - 1 mg Ag L^{-1} for 5 days. We found inhibition of bacterial growth in most nAg treatments just after 1 hour, but at low nominal concentrations of 0.05 to 0.5 mg L

628 Impact of Nanoparticles to Soil Microbial Community Under Field Conditions V. Shah, Dowling College; D. Collins, Dowling College, Dept of Biology; V. Walker, N. Kumar, Queens Univ, Dept of Biology; T. Luxton, US Environmental Protection Agency. In recent times, impact of nanoparticle on soil microbial community has been discussed in the literature and change in the community structure observed. However, all such studies have been carried out in some form of controlled environment. In the study to be presented, we will illustrate the fate of copper and zinc oxide nanoparticles in soil under field conditions and show its impact on soil microbial community. Nanoparticles were sprinkled on the surface of the soil and let to stand for six months. Transport of the particles within the soil along with speciation changes on the nanoparticles were monitored as a function of time along with the changes in microbial community. Changes in microbial community were also monitored using multiple methods such as pyrosequencing, fatty acid methyl ester extraction method, and community level physiological profiling using Biolog® ecoplates.

629 Conserved Developmental Pathways and Disease Processes: Implications from Genomics Datasets Across Species J.M. Gohlke, Univ of Alabama at Birmingham, Dept of Environmental Health Sciences. Pathway or network-based methods are commonly used in the analysis of genomics datasets to provide insight into the biological processes potentially involved in the human or ecological endpoints under study. Pathway-based methods usually refer to analysis using interactions between gene products based on multiple sources of evidence from previous research published in the literature, whereas network-based approaches may also rely on de novo interaction predictions from genomics datasets. Several lines of evidence suggest conserved developmental pathways or networks may offer a useful framework for cross-species analysis. A pathway-based method describing analysis of genomics datasets to develop an environmental factor-disease network to identify and prioritize key pathways for human health relevance will be presented. In addition, a gene regulatory network describing cell fate specification in the developing mammalian forebrain and the impacts of TCDD will be presented. The relevance of these approaches in bridging ecological and human health evaluations will be evaluated, with a particular focus on phenotypic outcomes across species. As an example, the Notch pathway is a highly conserved developmental pathway that regulates cell fate specification, and therefore cell number and differentiation status across spatially and temporally restricted gradients in invertebrate and vertebrate models. Recent analyses in zebrafish and *Drosophila* link Notch signaling to regulation of dopaminergic neuronal specification, reproduction, and pigmentation phenotypes. Several human diseases are now understood as being mediated via the Notch pathway and this has guided the development of Notch based high throughput assays, such as the quantification of pigmentation phenotypes in zebrafish embryos as a screen for gamma-secretase inhibitors. Hence, highly conserved developmental pathways may provide a useful construct for integrating genomic evidence across human and ecologically relevant species in support of human and ecological risk assessment, and co-option of conserved pathways for different functions across species is highlighted as an important area for future research.

630 Genetic Architecture of Evolved Tolerance to PCBs in the Estuarine Fish *Fundulus heteroclitus* E.R. Waits, USEPA, NERL; S. Morris, B. Rinner, USEPA; D. Proestou, US Environmental Protection Agency, Atlantic Ecology Division; D. Champlin, USEPA; D. Nacci, USEPA, ORD, NHEERL, Atlantic Ecology Division, USEPA, NHEERL, Atlantic Ecology Division. Populations of Atlantic killifish (*F. heteroclitus*) resident to coastal estuarine habitats contaminated with halogenated aromatic hydrocarbons (HAHs) exhibit heritable resistance to the early life-stage toxicity associated with these compounds. Beyond our knowledge of the aryl hydrocarbon receptor (AHR) and its role in mediating this toxicity, little else is known concerning the precise downstream targets responsible for this adaptation. In the present study, we performed a genome-wide survey for quantitative genetic variation among differentially sensitive killifish in order to elucidate the genetic basis of evolved tolerance. Following exposure to PCB126, the recombinant generation of a genetic cross between PCB-sensitive (Block Island, RI) and PCB-tolerant (New Bedford, MA) killifish were phenotyped to determine sensitivity and genotyped with a dense panel of co-dominant molecular markers distributed across the genome. Multiple loci were identified strongly associated with PCB tolerance-some acting alone and others via additive and epistatic interactions. Together, these loci account for at least 44% of the phenotypic variance observed in susceptibility following PCB126 exposure between Block Island and New Bedford killifish (LOD = 11.67, $P = 1.14 \times 10^{-5}$). These data demonstrate that PCB126-induced developmental toxicity is a complex trait influenced by gene x gene and gene x environment interactions, and provide insight to the evolutionary basis of evolved tolerance to chemical contaminants in wild populations.

631 Genetic Variation Between Clones of *Folsomia candida* (Collembola) is Associated with Differential Fitness – and Transcriptional Responses to Cadmium B. Nota, VU Univ Amsterdam, Animal Ecology; D. Roelofs, VU Univ Amsterdam. The parthenogenetic species *Folsomia candida* (springtail) is frequently used as a standard test organism for soil quality assessment. Different genotypes (clonal lines), identified with both mitochondrial and nuclear markers, showed different life history trait responses to the soil-pollutant cadmium. Animals with a certain genotype seemed more tolerant to cadmium toxicity than animals with another. Microarray gene expression analysis was used to gain insight in the biological processes and mechanisms responsible for (or effected by) the different

response to cadmium. Genotype-specific changes in the transcriptome in response to cadmium revealed that fewer genes are differentially expressed in tolerant animals when compared to sensitive ones (223 and 1025 genes, respectively). A 2×2 factorial analysis (limma) identified 97 genes that showed an interaction between genotype and cadmium treatment (BH adjusted $p < 0.05$). The expression of these genes in response to cadmium showed a much more conserved pattern (i.e., lower or no fold changes) in the tolerant animals compared to the sensitive ones. Furthermore, the expression of these genes showed much more correlation with each other in sensitive animals. Many of these genes are involved in oxidation/reduction-like processes. The array data suggest that cadmium sensitive animals, when exposed to cadmium, show a typical transcriptional signature associated with stress, while the tolerant animals maintain 'normal' expression for most of their genes. These finding will have consequences for the use of genomic tools in ecotoxicology and environmental quality assessment. This study also provides insight in molecular processes behind tolerance associated with different genotypes, and suggests new evolutionary mechanisms involved in parthenogenesis.

632 Heritability of the Reproductive Response in Adult Fathead Minnow Exposed to an Anti-androgen K.L. Thorpe, Canadian Rivers Institute, Univ of Prince Edward Island, Dept of Biology; E. Postma, Univ of Zurich-Irchel, Institute of Evolutionary Biology and Environmental Studies; M. Koelliker, Univ of Basel, Zoologisches Institute. Endocrine disrupting chemicals are a globally important group of environmental contaminants known to affect populations through skewing sex ratios and inhibiting reproduction. However, little is known about their potential to influence evolutionary processes. In part, this is because most experiments have focused primarily on determining functional responses in the average animal of the group and have failed to consider the importance of individual variation in responses to exposure. Such approaches ignore the fact that variation in phenotypic traits is an essential feature of populations as, if heritable, it provides the basis for populations to evolve and adapt through the process of selection. In this study, between-pair variation in the sensitivity of reproductively active fathead minnow exposed to the anti-androgen flutamide (400 µg/L) was quantified and heritability of the observed variation determined. As expected, flutamide exposure reduced mean reproductive success (number of viable offspring) by 56%. Furthermore, there were not only large differences in reproductive success among pairs, but also in how strongly they were affected; reproduction was completely inhibited in 27% of the exposed pairs but unaffected in 23% of pairs. Although this suggests that flutamide exposure may generate selection for lower sensitivity in natural populations, the evolutionary response to selection depends on whether there is any heritable variation. Non-exposed offspring were, therefore, collected from each FHM pair, raised until sexually mature, and males and females from the different lines crossed to assess reproduction in the absence/presence of flutamide. Quantitative genetic mixed model analyses showed a substantial heritable component to variation in mean reproductive success (i.e., between treatments) as well as some heritable variation in flutamide sensitivity, indicating that both could respond to selection. There was also a strong positive genetic correlation between the two, with pairs of high average fitness being less sensitive to flutamide, suggesting there is no trade-off between reproductive success and flutamide sensitivity. Based on these findings, the potential for exposure to anti-androgens to modify evolutionary processes in natural fish populations will be discussed.

633 Meta-analysis of Toxicogenomic Data from Multiple Species Reveals Conserved Responses Across Divergent Phylogenetic Lineages K.A. Gust, US Army, Engineer Research and Development Center, Environmental Laboratory, US Army, Engineer Research and Development Center, Us Army Engineer Research & Development Center, ERDC-EL-EP-P; N. Garcia-Reyero, Jackson State Univ; T. Habib, BTS; M. Pirooznia, The Johns Hopkins Univ, School of Medicine; P. Gong, SpecPro Inc., Enivronmental Services; C. Warner, The Keck Institute; M. Wilbanks, US Army, Engineer Research and Development Center; E.J. Perkins, US Army, Engineer Research & Development Center, Environmental Laboratory, Us Army Engineering Research & Development, Environmental Processes & Effect Division. A principle task of our research laboratory is to holistically assess the impacts of environmental contaminants, principally munitions constituents (MCs), on military ranges. A great deal of research has been conducted to describe the impacts of the MC hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX). RDX has been shown to impact the central nervous system causing seizures in humans and other higher vertebrates. Comparative toxicology and comparative genomics can be used to assess the effects of a contaminant among species. For this effort, we analyzed the effects of RDX on five species to elucidate if the compound elicits effects via common toxicological mechanisms among the species examined. Our approach included phylogenetic analysis of GABAA (the substrate to which RDX binds), gene set enrichment analysis (GSEA), and context likelihood of relatedness analysis to infer transcriptional networks to compare and contrast the neurotoxic effects of RDX among five phylogenetically disparate species: rat (Sprague Dawley), the fathead minnow (*Pimephales promelas*), earthworm (*Eisenia fetida*), Northern bobwhite (*Colinus virginianus*), and coral (*Acropora formosa*). Our results showed that RDX accumulated in coral and earthworms and into the brain of rat, Northern bobwhite and the fathead minnows. Phylogenetic comparison indicated that the molecular initiating event for RDX toxicity (GABAAR-binding) was conserved across all species. The comparison of Gene Ontology terms indicated several biological processes affected by RDX in all species, such as impacts on calcium signaling (involved in seizure response), effects on xenobiotic metabolism, electron transport, and cell signaling pathways. Metabolic pathway and transcriptional network analysis of RDX impacts across species demonstrated that responses to RDX exposure are highly conserved within closely related species. However, as evolutionary distance increased, effects related to the molecular initiating event (RDX binding to GABAAR) decreased and more general effects on metabolic functions became prevalent.

634 mRNA and microRNA Transcript Profiling in Atlantic Killfish (*Fundulus heteroclitus*) Embryos from PCB-sensitive and PCB-resistant Populations S.I. Karchner, Woods Hole Oceanographic Institution, Biology; N. Aluru, Woods Hole Oceanographic Institution; M.J. Jenny, Univ of Alabama; D.B. Mark Welch, Marine Biological Laboratory; M.E. Hahn, Woods Hole Oceanographic Institution. The Atlantic killifish is a valuable model for investigating evolutionary adaptations to chemical exposure. Killifish inhabiting the PCB-contaminated Superfund site in New Bedford Harbor, MA (NBH) have developed resistance to embryotoxicity and activation of the aryl hydrocarbon receptor (AHR) signaling pathway after exposure to PCBs and other AHR agonists. A lack of genomic information has limited efforts to understand the molecular mechanisms underlying the PCB resistance of NBH fish. The advent of high throughput sequencing has facilitated an assessment of mRNA and microRNA transcriptomes and changes associated with the evolved resistance in killifish. In this study, transcript profiling by deep sequencing was performed on PCB-exposed killifish embryos from NBH and a reference site, Scorton Creek, MA (SC). Non-normalized, 3'-anchored EST libraries yielded ~175,000 reads from each library. Shotgun sequencing on 1-15 dpf pooled samples of NBH and SC killifish embryos provided broader sequence coverage (~1,500,000 reads) and facilitated annotation of the ESTs. Results indicate several novel PCB-induced and repressed genes in both populations, with limited overlap between the populations. We also profiled microRNAs in these embryos using SOLiD sequencing. Embryos from NBH and SC were collected daily from 1 to 15 days post-fertilization (dpf) and pooled samples from each site were used for deep sequencing. SOLiD sequencing resulted in 2.5 and 2.0 million trimmed reads from the SC and NBH samples, respectively. Out of the 358 total number of known zebrafish microRNAs, 342 were identified among the killifish sequences. The unmatched reads were used in a search against the known human microRNAs, which resulted in the identification of 11 corresponding killifish sequences. Comparison of annotated microRNAs between NBH and SC is ongoing. [P42ES007381, R21ES017304]

635 Understanding How *Daphnia* Populations Vary in Their Genomic Responses to Chemicals and Binary Mixtures J.K. Colbourne, Indiana Univ, and Mount Desert Island Biological Laboratory , The Center for Genomics and Bioinformataics; J. Lopez, Indiana Univ, The Center for Genomics and Bioinformatics; S. Glaholt, Indiana Univ, School of Public and Environmental Affairs; M.E. Pfrender, Univ of Notre Dame, Dept of Biological Sciences; J.R. Shaw, Indiana Univ, and Mount Desert Island Biological Laboratory, School of Public and Environmental Affairs *Daphnia*, or the water flea, is a sentinel species of freshwater ecosystems. Their populations are defined by the boundaries of ponds and lakes, are sensitive to modern toxicants in the environment, and thus are used to assess the ecological impact of environmental change. Their short generation time, large brood sizes, and ease of laboratory and field manipulation have assured *Daphnia*'s importance for setting regulatory standards by environmental protection agencies, for testing chemical safety, for monitoring water quality,

and as a model for environmental genomics research. In this study, we take advantage of the animal's clonality and mature genomics tools to partition the sources of gene expression variation in the stress response of genetic isolates to three environmentally relevant pollutants, and their binary mixtures: Arsenic, Acetaminophen, Atrazine. One isolate originates from a natural population that has faced severe chemical challenges for over a century of industrial iron/ore smelting and thus demonstrates evolved tolerance to toxic levels of certain metals. Another isolate originates from a population that has no history of chemical stress. By interrogating differential expression of 31,000 annotated genes from 25 comparisons across conditions and between isolates, this study provides new insights into the functional interactions among genes and environment. The research was conducted during hands-on training in "Environmental Genomics" – an annual summer course offered at the Mount Desert Island Biological Laboratory. See http://www.mdibl.org/courses/Environmental_Genomics/199/.

636 Using the Model Organism *Daphnia pulex* to Delineate Molecular Pathways Responding to Environmental Stress K.A. De Schamphelaere, Ghent Univ, Environmental Toxicology and Aquatic Ecology, Ghent. Univ (UGent), Environmental Toxicology and Aquatic Ecology, Ghent Univ, Environmental Toxicology and Aquatic Ecology; J. Asselman, D. Deconinck, UGent; S. Glaholt, Indiana Univ; C. Janssen, UGent; J. Colbourne, J. Shaw, Indiana Univ. Recently, the full genome sequence of *Daphnia pulex* has been published. Along with this, a suite of molecular tools dedicated to this emerging model species is becoming available, including a high-density (12x130k) whole-genome long oligonucleotide microarray for whole-genome expression studies. In this study we have used this microarray to study whole genome expression of two isolates of *Daphnia pulex* exposed to Cd and the toxic cyanobacteria Microcystis aeruginosa. An automated pathway analysis pipeline was developed and programmed in R and this was used to delineate molecular pathways responding to these environmental stressors. For instance, this analysis revealed that exposure to M. aeruginosa invoked major changes in oxydative phosphorylation, carbohydrate metabolism and protein turnover. Moreover, a comparative analysis of responses of two isolates of *D. pulex* (one tolerant to Microcystis and one sensitive to microcystis in terms of reproductive inhibition) is beginning to shed light on the molecular mechanisms involved in the genetic basis of large tolerance differences observed among individuals of this species. This research contributes to and benefits from the Daphnia Genomics Consortium.

637 Prioritizing CECs for Aquatic Ecological Applications J. Diamond, H. Latimer, Tetra Tech, Inc.; K. Munkittrick, Univ of New Brunswick, Canadian Rivers Institute, Univ of New Brunswick, Dept of Biology; K. Kidd, Canadian Rivers Institute, Univ of New Brunswick, Biology; J. Gilliam, Tetra Tech, Inc. With improved analytical detection capabilities, a variety of organic chemicals of emerging concern (CEC) have been found in trace amounts in surface waters, sediment, and fish tissue. These CECs include pharmaceuticals, personal care products, surfactants, and other currently unregulated chemicals. Identifying or predicting ecological effects of CECs in aquatic systems requires different tools that can diagnose effects at multiple scales of ecological organization. Developing an approach to prioritize CECs having the greatest potential risk to aquatic communities is one critical step that could help address this question. We developed three approaches to prioritize CECs: (1) hazard-based, (2) chemical persistence, bioaccumulation potential, and toxicity (PBT), and (3) a hybrid based on hazard, persistence, and bioaccumulation potential. Using an occurrence database compiled from over 100 monitoring studies, the three prioritization approaches were applied to over 500 CECs that have been measured in water or effluent samples in the US over the past 10 years. Types of CECs identified as high priority differed among approaches: steroids/hormones, pharmaceuticals, and surfactants comprised most of the high priority CECs based on hazard alone while pesticides, industrial chemicals, and PAHs (including many CECs that are currently regulated) comprised most of the high priority CECs based on a PBT approach. Except for the synthetic hormones and steroids, results of all three prioritization approaches yielded only a few pharmaceuticals of high priority. Using a hazard-based prioritization approach, predicted chronic toxicity endpoints were more sensitive than endpoints based on estrogenic activity for most CECs. The process of developing the list is as important as the list itself and appropriate use of any priority list will depend on the goals of the user. The hazard-based approach appears to be a useful starting point for monitoring, particularly for sites that are influenced by wastewater.

638 Prioritizing Pharmaceuticals in Municipal Wastewater M. Kostich, USEPA, NERL, National Exposure Research Laboratory, USEPA; J. Lazorchak, A. Batt, S. Glassmeyer, R. Flick, J. Martinson, National Exposure Research Laboratory, USEPA. This talk will describe our prioritization of active pharmaceutical ingredients (APIs), based on estimates of risks posed by API residues originating from municipal wastewater. The goals of this project include prioritization of APIs for future research based on relative risks, and the estimation of absolute risks for individual APIs and their mixtures. The risk estimates were calculated as the ratio of an exposure rate estimate to an estimate of the lowest observable effect level (LOEL) for each API. The initial datasets used for exposure predictions included nationally aggregated drug sales and per capita wastewater production rates, which were combined in order to estimate wastewater influent concentrations. There are many shortcomings to these data, and no reliable estimates could be made for certain steps in the exposure model, most critically including in-plant and in-stream degradation rates. Several datasets were used to estimate the LOEL, including minimum therapeutic dose rates and plasma concentrations, both of which are typically available for this class of contaminants. The drawbacks and merits of these approaches will be discussed. For a handful of APIs, more detailed marketing data was available, allowing us to estimate site-to-site variability in exposure rates, which, in turn, provided the opportunity to evaluate our exposure predictions against actual measurement data. These results suggest our model is useful for estimating a ceiling for exposure rates for a particular API, but often underestimate typical exposure rates, likely due to overestimates of API persistence. The results of the prioritization will be briefly described, and compared to similar risk estimates we have made for endogenous human estrogens in wastewater.

639 Prioritization of Human and Veterinary Pharmaceuticals for Ecological Risk Assessment – An Experience in Korea K. Choi, Seoul National Univ, School of Public Health, Seoul National Univ, Dept of Environ. Health; Y. Kim, Seoul National Univ; J. Park, Soonchunhyuang Univ. Pharmaceutical residues may have impacts on nontarget biological organisms in aquatic ecosystems, and have therefore precipitated numerous investigations worldwide. Due to the great number of active pharmaceuticals which are available on the market, appropriate prioritization efforts are needed to identify the compounds that require environmental monitoring and ecotoxicological investigations. We prioritized both human antibiotics and veterinary pharmaceuticals in Korea by their usage, potential to enter the environment, or potential risk. For this purpose, the total amounts of active human pharmaceutical ingredients were estimated using the Korea Pharmaceutical Manufacturers Association (KPMA)'s monetary database. Expected introduction concentration (EIC) for each pharmaceutical was determined and corrected with excretion rate. Ten human antibiotic substances identified to have EICcorrected greater than 1 _/L, include amoxicillin, cefaclor, roxithromycin, cephradine, cefatrizine, cefadroxil, aztreonam, ceftazidime, ribostamycin, and ceftezole. Among veterinary pharmaceuticals, twenty compounds were identified as top priority, most of which were antibiotics. Eight veterinary pharmaceuticals were considered to deserve more immediate attention: amoxicillin, enramycin, fenbendazole, florfenicol, ivermectin, oxytetracyline, tylosin, and virginiamycin. To further narrow the list of target compounds for ecological risk assessment, available ecotoxicological information was also considered. Some of these compounds have been investigated for ecological risks in Korean waters.

640 Prioritization of Biosolids-borne Trace Organic Chemicals C. Higgins, Colorado School of Mines, Environmental Science and Engineering; D. McAvoy, Univ of Cincinnati; G. O'Connor, Univ of Florida. Trace organic chemicals (TOrCs) present in municipal biosolids in the US have recently received considerable attention by the public and scientific community. Whether the presence of TOrCs in biosolids results in significant risks to public health and the environment following land application is a question that remains at least partially unanswered. Though the US Environmental Protection Agency evaluated the risks associated with dioxins in biosolids-amended soils, this Water Environment Research Foundation (WERF)-sponsored effort sought to examine what data would be needed to conduct risk assessment for TOrCs in biosolids-amended soils as well as for which TOrCs these data would be needed. This present study included an evaluation and prioritization of TOrCs of greatest concern in the terrestrial environment. The assessment and prioritization was based on occurrence data and readily available information on basic properties such as bioaccumulation and toxicity. The most important parameters for conducting

ecological risk assessments and the techniques currently available for obtaining the parameter values were also identified through an evaluation of quantitative risk assessments approaches, the end result being the identification of a minimum data set needed for risk modeling. For the TOrCs identified as high priorities, a comprehensive literature review identified relevant data on fate, transport, biotransfer from soil to plants and animals, and toxicity in the terrestrial environment. From this review of the literature, data gaps were identified for the parameters most important for conducting terrestrial risk assessments.

641 Prioritizing Persistent and Bioaccumulative Chemicals of Emerging Concern: Starting Materials, Impurities, By-products and Degradation Products P.H. Howard, SRC, Inc.; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, Environment Canada, National Water Research Institute. The Great Lakes and other North American regions have always been in the forefront in terms of identification of new environmental contaminants, particularly persistent (P) and bioaccumulative (B) organic chemicals. However, the identification has been by detailed analytical chemistry and is focused largely on structural analogs of previously identified compounds with only limited application of "in silico" approaches. Of particular concern are those substances that are P and B as defined by screening criteria for persistent organic pollutants (POPs). Such chemicals can move off shore from urban source regions and accumulate in waters and sediments of the open lakes and rivers where they can result in exposures of top predator fish and fish-eating birds. With improved instrumental capabilities, the past 10 years has seen a large number of new chemicals identified, mainly halogenated organics. However, the chemicals identified represent only a small fraction of the organic chemical substances in commerce. In a previous study, we have identified over 600 P&B chemicals using quantitative structure-activity relationships (QSARs) and expert judgment from a database of 22,000 commercial chemicals used in North America. In this presentation, we will examine starting materials, impurities, by-products, and degradation products/metabolites of the P&B commercial chemicals. Most commercial chemicals are synthesized from starting materials and reagents and result in the desired product plus leftover starting materials and by-products. These leftover starting materials or by-products can be environmental contaminants just like the desired commercial products. By reviewing the commercial synthetic pathways, we were able to identify possible leftover starting materials, impurities, and by-products. In addition, once a commercial chemical is used, it may be released to the environment in a variety of ways. Using available software and databases, we were able to predict potential degradation products/metabolites. Examples of impurities, by-products, and degradation products as well as some prediction successes (chemicals predicted to be P and B for which measurements has subsequently shown to be present) will be presented.

642 Generation of 2D QSARs for Properties Relevant to Chemical Prioritization T.N. Brown, Helmholtz Centre for. Environmental Research UFZ, Dept of Analytical Environmental Chemistry; J.A. Arnot, F. Wania, Univ of Toronto Scarborough, Dept of Chemistry, Dept of Physical and Environmental. Sciences; K. Goss, Helmholtz Centre for. Environmental Research UFZ, Dept of Analytical Environmental Chemistry. In recent decades regulations and methods have been developed to evaluate tens of thousands of chemicals; however, there are few measured data available for the legislated assessments. In this context, mass balance and quantitative structure-activity (property) relationships (QSA(P)Rs) are needed for chemical screening and prioritization and for chemical exposure, hazard and risk assessments. Chemical partitioning properties and reaction half-lives are required for PBT assessments and for holistic multimedia models for exposure and risk assessment. The Iterative Fragment Selection (IFS) method has been developed to generate and evaluate QSA(P)Rs and to build knowledge infrastructure for chemical assessments. IFS is an integrated method of fragment generation, dataset splitting, and model selection. This QSA(P)R method does not require pre-existing expert knowledge on structural information related to a specific chemical property. 2D fragments are generated automatically from the dataset and the method iteratively selects fragments and QSARs through an automated process of fragment selection and model testing. The application of the IFS QSA(P)R development method is illustrated for properties relevant to chemical risk assessment; fish biotransformation half-lives, water solubility, and the octanol-water partition coefficient. Merits and limitations of the IFS method are discussed as are opportunities for applying the QSA(P)R development and evaluation methods to other datasets to address pressing data gaps in chemical assessment programs.

643 Experimental Design for Assessing the Potential Ecological Risk of Consumer Product Chemicals S. Dyer, The Procter & Gamble Company, Central Product Safety, The Procter & Gamble Company, Miami Valley Innovation Center; K. Kapo, Montani Run, LLC. Receiving water biology is exposed to nutrients, metals, and organic chemicals from a myriad of sources, including storm water runoff, agricultural chemicals, industry, and down-the-drain disposal of pharmaceuticals and consumer products (often referred to as contaminants of emerging concern, CECs). Due to the myriad of sources, a pragmatic approach is required to reduce the potential confounding factors that relate CEC exposure and measured biological effects. In this presentation we propose, and demonstrate via case studies, an approach that integrates the use of modeled and measured data collected from industrial, state and federal sources to provide a suite of prioritization criteria used for site selection that minimizes confounding factors and provides a mechanism by which site based study results may be extrapolated to the thousands of river reaches that receive CECs via wastewater treatment discharge. The base for our approach is the national scale model iSTREEM (publically available via the American Cleaning Institute). The model utilizes wastewater treatment characteristics found within the USEPA's Clean Water Needs Survey, such as treatment type, dilution, population served and percent industry as key factors that can be queried to form a hierarchical understanding of existing discharge conditions. USEPA's Permit Compliance System provides information on the efficacy of historical treatment. Measured chemistry (conventional pollutants, nutrients) and instream habitat quality from Ohio EPA add instream relevance to the prioritization scheme. Finally, the relationships of all the above factors with the dependent variable, biological condition (invertebrate and fish community status), provides the means to obtain an ecological reality check for potential site selection. Since all these data and prioritization analyses are housed within a geographic information system, it is possible to ascertain potential sites where CECs may be related to biological impacts and, therefore, provide design criteria for subsequent site-based monitoring efforts.

644 How to Prioritize? T. Verslycke, M. Sharma, Gradient. If "everything is everywhere", how does one focus limited resources on those compounds that are most likely to be present at levels that warrant environmental or human health concerns? Definitions for "chemicals of emerging concern" remain fluid and numerous lists of such chemicals have been developed using a variety of approaches, ranging from intrinsic hazard to perceived risk, from measured environmental concentration to production volume. A better approach for defining "chemicals of emerging concern" would be to use a risk assessment framework, a methodology that has been implemented and used for decades to support, for instance, chemical and product safety assessments and market approval, site remediation, and water quality criteria setting. This talk will present such a framework, which could serve as the technical basis for regulatory prioritization efforts regarding environmental monitoring and assessment of chemicals. The presentation will provide a concise overview of the existing risk assessment framework and its historic applications, as well as a review of more recent efforts regarding chemical prioritization for environmental monitoring and assessment – some of which will be presented by others in this session. Overall, this talk will present an initial state-of-the-science summary of existing prioritization approaches with the future goal of performing an in-depth "meta-analysis" of chemical prioritization approaches for environmental monitoring and assessment.

645 Modeling Ground Water Contamination by Soil Fumigants in Hawaii and California: Soil Loading and Fate Input are Critical for Validated Predictions S.Z. Cohen, Environmental & Turf Services, Inc.; G. Pohll, Desert Research Institute; S.W. Wheatcraft, Wheatcraft and Associates; J. Bahme, Bahme & Associates; L. Barnes, A.J. Harding, Environmental & Turf Services, Inc.; Q. Ma, Environmental & Turf Services, Inc. (currently with Exponent) Crop-destroying nematodes have been controlled with soil fumigants, including those with the active ingredient 1,2-dibromo-3-chloropropane (DBCP) and the impurity 1,2,3-trichloropropane (TCP). These products are injected into the root zone of plants prior to planting. Ground water was contaminated with DBCP and TCP following application to pineapple fields on Maui, and TCP was found in ground water in southern California following many years of application to four other crops. Two independent teams modeled the front end – pesticide

application and movement through the root zone – and the saturated zone, without review of monitoring results, in a 'double blind' approach. More than 20 yrs each of daily weather records, pesticide application histories, and irrigation practices had to be constructed for the two sites. There was good documentation at the pineapple plantation, although some estimates/interpolation about irrigation and rainfall had to be made. The forensic investigation of the southern California site was more challenging, and it integrated evaluations of historic aerial photographs, farmer interviews, site visits, sparse fumigant sales records, and research of old Extension documents. Soils at both sites were sampled and analyzed to obtain relevant modeling parameters. Site-specific environmental chemistry parameters were derived, focusing on hydrolysis and transport parameters. Root zone contaminant flux was modeled with the EPA's Pesticide Root Zone Model (PRZM), and HYDRUS-1D was used below the root zone, which fed into saturated zone modeling using MODFLOW-2000 and MT3D. Minimal model calibration was needed to obtain excellent agreement between predicted and at least 10 years of observed concentrations for both locations. This good agreement could only have happened if the decades of front-end loading parameters had been developed correctly. The models were used to predict future contamination.

646 More Accurate Forensic Investigation of Crude Oil and Coal Tar by Multidimensional GC/MS and GC/MS with Spectral Deconvolution A. Robbat, Tufts Univ, Chemistry; C. Zeigler, P. Antle, Tufts Univ. Traditional forensic investigations of fossil fuels and their by-products rely on analysis by gas chromatography using either full scan or selected ion monitoring (SIM) mass spectrometry (GC/MS). Full scan GC/MS typically produces unresolved chromatograms, which makes target compound identification difficult due to matrix masking of mass spectral patterns. In contrast, SIM detection, based on one or two ions per target compound, results in dramatic overestimation of analytes and the absence of data to identify other compounds of environmental importance. Polycyclic aromatic hydrocarbons (PAH) and their sulfur analogs (PASH) are used to delineate source, migration pathways, weathering, and threat to human health and the environment. Alkylated PAH and PASH have many common ions, which causes misidentification, errors in quantification, and erroneous weathering diagnostics. Retention indices and mass spectra for more than 200 PAH and PASH were obtained from standards, crude oil, and coal tar by automated sequential GC-GC/MS. The data were used to delineate how soil contaminated with coal tar weathered differently than coal tar protected from the environment. GCxGC/MS provided images that showed which aliphatics and aromatics degraded due to physical vs. biological processes. Measurement precision, accuracy, selectivity and sensitivity will be discussed for chromatograms produced by GCxGC/MS and GC/MS and analyzed by the Ion Signature mass spectrometry deconvolution software.

647 The Mathematical Estimation of Baseline Concentrations of Metals in Sediments Based on Univariate Distributions and Receptor Modeling M.J. Bock, T.R. Barber, ENVIRON International Corp.; A.K. Gevertz, ENVIRON International Corp., Zoology. The determination of local baseline concentrations in sediments is often central to the assessment of point sources of contamination. Baseline is typically estimated based on observations taken from a pristine "reference area." Reference areas are either sampled as part of a site-specific investigation or regional values available from the literature are utilized. These approaches require that a source of baseline observations is available and that the geochemical conditions are similar to the area of interest (e.g., grain size, total organic carbon, source, soil type, bedrock type). In highly industrialized settings, it is often difficult to identify an appropriate baseline dataset. From a geochemical and statistical viewpoint, baseline can be defined as a unique end member with an absence of positive anomalies. This operational definition allows the use of two families of mathematical techniques for the determination of baseline; univariate methods and multivariable receptor modeling. The first class of methods treats contamination as positive anomalies in the univariate distribution of chemical concentrations. Mathematical methods exist for the identification and removal of these positive anomalies. Three statistical methods were identified as having the most promise: (1) the iterative 2-standard deviation technique, (2) the calculated distribution function, and (3) the Gaussian mixture technique. The second class of methods is based on the techniques commonly associated with receptor modeling and source identification in the chemical forensics literature. If the baseline condition is considered as an end member, potential sources of contamination can be viewed as other end members. Thus, the chemical concentration in any sample is a mixture of baseline and other end members. Statistical techniques such as Polytopic Vector Analysis and Fuzzy C-Means clustering can be used to identify the baseline end member(s). These methods were applied to metals concentrations in surface sediments obtained from publicly available sediment data from the New York/New Jersey Harbor Region impacted by multiple sources of contamination. The results of these analyses show that these methods can be used to identify baseline concentrations of metals in areas impacted by historical sources of contamination.

648 The Timing of DNAPL Releases in a Complex Fractured Clay Setting S.A. Flewelling, M. Sharma, Gradient. In this presentation, we will analyze subsurface Dense Non Aqueous Phase Liquid (DNAPL) migration from an industrial facility located in a complex geological setting (fractured clay with discontinuous sand seams). At this site, DNAPL has been found in numerous soil samples and in streambed sediments. Although DNAPL has been found repeatedly, its spatial distribution is discontinuous, resulting in hit-or-miss encounters during sampling events. One of the central questions being evaluated at the site is whether these DNAPL encounters are the result of residual stagnant ganglia, i.e., historical migration, or whether they are from ongoing transport from an upgradient source area., i.e., ongoing migration. Given the complex geological setting and the dual-phase nature of DNAPL and groundwater flow, multiple lines of evidence were utilized to evaluate the timing of DNAPL releases. We will present a framework for evaluating field data within the context of this clay-dominated setting, and then develop a quantitative model that predicts DNAPL travel times through the interconnected fractures and sand seams at the site. This approach can be utilized in other similar settings to address the question of DNAPL migration rates and release timing – key environmental forensics questions in liability assessment and cost allocation disputes.

649 Tracking Sources of Polychlorinated Biphenyls (PCBs) to Newark Bay Sediments Using Positive Matrix Factorization (PMF) T. Saba, S. Su, Exponent, Inc. The United States Environmental Protection Agency (USEPA) receptor model, Positive Matrix Factorization (PMF), was used to identify the congener profiles of potential polychlorinated biphenyl (PCB) sources and to estimate their spatial extent of impacts to Newark Bay surface sediments. PCB congener data from different locations throughout the bay were obtained from sediment investigation studies spanning from 2005 to 2008. From PMF simulations, five PCB source profiles were identified as impacting the bay surface sediments. The simulations also pointed to different shoreline areas where PCB inputs are likely to have originated. The congener profile for one of the sources closely resembled a mix of Aroclors 1254 and 1260. This source profile had the highest percent presence in sediment samples collected from the mouths of the Passaic River (north of the bay) and Elizabeth River (south of the bay). The congener profile for another PCB source indicated the prominent presence of congener PCB-15. The spatial concentration distribution of this congener pointed to a shoreline area in the southern portion of the bay. The other PCB source profiles resembled a mix of two or more Aroclors with different degrees of weathering and were also tracked back to source areas along the shoreline. The PCB source profiles obtained from the PMF simulations were corroborated by the loadings obtained from Principal Component Analysis (PCA).

650 Source Apportionment of Fine Sediment Particles in Highway Stormwater Runoff in the Lake Tahoe Basin H. Hwang, Univ of California, Davis, Dept of Civil and Environmental Engineering, Univ of California, Dept of Civil and Environmental Engineering. Lake Tahoe water column clarity has declined significantly due to urban development and traffic activities. More than 50% of Lake Tahoe's clarity loss can be attributed to fine sediment particles smaller than 20 mm. To recover the lake water clarity, Lahontan Regional Water Quality Control Board recommended 34% of reduction of the fine sediment particles from urban upland. Stormwater runoff from urban roadways is the largest contributor of fine sediment particles to the lake. One of the critical prerequisites to achieve the fine sediment particle reduction goal is accurate identification of their source profiles and loadings in stormwater runoff. To quantify the loadings of fine sediment particles from major sources such as soil and vegetation debris from adjacent area, traction sand, and pavement wear, source samples and highway snowmelt runoff samples were collected and analyzed for elements and organic markers such as unresolved complex mixture, hopanes, and alkanes. Chemical mass balance model was used to quantify the contributions

of fine sediment particles from eight possible sources. The results indicate surface soil from adjacent side hills was the predominant source, accounting for more than 50% of fine sediment particles in highway stormwater runoff. Molecular markers revealed that almost all solvent extractable organic matter was originated from the wear of asphalt pavement binder, accounted for up to 20%. The contribution of traction sand was less than 5%, which is substantially less than expected. Sampling timing may partially explain this low contribution of traction sand. The results of this study can be used to develop more efficient and cost-effective fine sediment particle load reduction plans and Best Management Practice designs.

652 World Wide Pb Isotope Distribution in Partial Digestions of Coastal Surface Sediments: Indicator of Leaded Gasoline? M.M. Larsen, Roskilde Univ, Dept of Science, Systems and Models, National Environmental Research Institute, Aarhus Univ, Marine Ecology; J.S. Blusztajn, Woods Hole Oceanographic Institution. The Galathea 3 expedition circumnavigated the globe in 2006-2007 and collected marine samples from six continents. Twenty three surface sediment samples were analyzed for Pb, Th, U and Pb isotope ratios after microwave digestion with hot concentrated nitric acid, with the hypothesis that the isotope ratio is linked to the geological area and anthropogenic input, mainly from previous use of leaded fuels. Partial digestion was used to enhance the anthropogenic signal, extracting mainly the fine particles and easily soluble part of the sediments. The Pb, Th and U concentrations in the sediments were determined with ICP-Quadrupole MS, and isotope ratios with ICP-multi-collector MS. The measured concentrations were clearly divided into two groups of "background areas" less than 40 mg kg^{-1} lead and harbor areas of Sydney (Australia), Charlotte Amalia (St.Thomas, Virgin Islands) and Boston (USA) ranging from 150 to 265 mg kg^{-1} lead. The measured isotope ratios was for the most in line with marine upper crust ratios of $^{206}Pb/^{204}Pb$ vs. $^{207}Pb/^{204}Pb$, and in most cases in the range expected for lower crustal xeolithes and marine sediments. Geological distinction between volcanic and mantle signatures was evident except for samples from Accra (Africa) and Greenland, where ratios were beyond the normal ranges. Comparison of the measured Pb isotope ratios of $^{208}Pb/^{207}Pb$ vs. $^{206}Pb/^{207}Pb$ with literature distributions of ratios for different sources of Pb in gasoline and coal, and the effect of distance to the harbors of both concentration and Pb isotope ratios will be presented.

653 Photochemical Degradation of Triclosan: Mechanistic Highlights S. Kliegman, S.N. Eustis, S. Qian, ETH-Zuerich, Dept of Environmental Sciences/Institute for Biogeochemistry and Pollutant Dynamics; W.A. Arnold, Univ of Minnesota, Dept of Civil Engineering; K. McNeill, ETH-Zuerich, Dept of Environmental Sciences/Institute for Biogeochemistry and Pollutant Dynamics. Triclosan is an antimicrobial compound that is used widely in consumer products, is ubiquitous in the wastewater system, and has been frequently observed in surface waters. Sunlight irradiation of triclosan results in efficient degradation of triclosan as well as formation of small amounts of 2,8-dichlorodibenzo-*p*-dioxin and 2,4-dichlorophenol. Neither the major products, nor a detailed mechanism of these transformations are known, prompting the current study of triclosan photodegradation. The results of experimental and computational studies presented here shed light on the physical and chemical processes that occur when triclosan becomes photochemically excited.

654 Persistent Organic Pollutants in the North Atlantic Bloom Experiment L. Zhang, Univeristy of Rhode Island, Graduate School of Oceanography; R. Lohmann, Univ of Rhode Island, Graduate School of Oceanography, Univ of Rhode Island. Previous modeling studies have suggested that polychlorinated biphenyls (PCBs) are taken up by planktons and transported downward by sinking particles. These fluxes are dynamically coupled with the air-water exchange processes which may represent a key controlling process in the environmental behaviors of persistent organic pollutants (POPs) locally and globally. A research cruise conducted during the North Atlantic Bloom Experiment (NABE) presented a unique opportunity to verify this hypothesis in the field. From 4/30/2008 to 5/21/2008, air, water, and zooplankton samples were collected every 12 to 24 hrs in a relatively small area south of Iceland on board R/V *Knorr* as the blooms evolved. The partitioning of PCBs and organochlorine pesticides (OCPs) between the dissolved phase and zooplankton (copepod Calanus) were determined to assess whether the partitioning is at steady state or kinetically limited, which determines if it can be modeled as a first order loss process. Our field measurement indicated PCBs and small OCPs in the air were fairly abundant at the beginning of the cruise. The highest air PCB concentrations for seven ICES congeners were found in the Reykjavik at 71 pg m^{-3}, which is in line with the findings from passive air sampling in Iceland. As the blooms evolved, although OCPs and small PCBs were still detected in the air, heavy PCBs with more than four chlorines were not found anymore. For example, HCB and PCB-28 were detected in 93% and 68% of all samples with average concentrations of 44 pg m^{-3} and 3.6 pg m^{-3}, respectively. Whereas PCB-138 were only detected in the samples collected before the blooms evolved. The dissolved PCB concentrations were relatively constant with time, most of which were less than 1 pg L^{-1} with a few peak concentrations at several pg L^{-1}. An Eulerian two-box model was set up for atmospheric boundary layer and seawater mixed layer including several different source and sink processes of POPs. The modeling simulation results are compared with field measurements, to provide insights into the contribution of partitioning to organic particles, sinking particles export, chemical degradation, and air-water gaseous exchange of PCBs and OCPs to the environmental behavior and fate of these compounds during NABE.

655 The Fate of Organic Pollutants to Discarded Plastic in Marine Environments C.M. Rochman, San Diego State Univ and Univ of California, Davis, Marine Ecology/Environmental Health; B. Hentschel, San Diego State Univ and Univ of California, Davis, Dept of Biology; M. Oei, S. Kaye, San Diego State Univ and Univ of California, Davis; E. Hoh, San Diego State Univ, Graduate School of Public Health. Discarded plastic at sea has recently become a problem of great concern in marine environments. Alone they are considered pollution, but it has also become evident that plastics can have an effect on the fate of organic pollutants at sea. In the marine environment, Persistent Organic Pollutants (POPs) such as PCBs, organochlorine pesticides, PAHs, and PBDEs are found adsorbed to discarded plastics at concentrations orders of magnitude above that in the water column. Many marine organisms have been shown to ingest plastic debris directly, and plastics may serve as another pathway for bioaccumulation. The objective of this study is to measure the fate of POPs to marine plastic debris in the ocean. We deployed six types of mass-produced and consumed plastic resin (Polyethylene terephthalate, High-density polyethylene, Polyvinyl chloride, Low-density polyethylene, Polypropylene, Polystyrene) at six different locations in San Diego Bay, CA. These pellets were collected after 1, 3, 6, 9, and 12 months in the Bay and are being analyzed for the rate of adsorption and concentrations of PAHs, PCBs, and organochlorine pesticides. Results to date will be presented at this meeting. At this time we have analyzed data from High-density polyethylene (HDPE) and Polypropylene (PP). We found that after 12 months HDPE adsorbed significantly higher concentrations of PAHs than PP ($p < 0.001$) and PP adsorbed significantly higher concentrations of PCBs than HDPE ($p = 0.008$). We also found differences in the concentrations of plastic-associated POPs among the six sites in San Diego Bay. For example, two of the six sites in the bay concentrate relatively high concentrations of PAHs while another site concentrates relatively high concentrations of PCBs. In general PAHs were 2-3 orders of magnitude higher in concentration than PCBs and organochlorine pesticides. This trend is expected since PAHs are unintentional pollutants of transportation and industrial activity, and PCBs have been banned in the US for decades.

656 The Measurement of Nonylphenol in Aqueous Aerosols and Marine Waters in the Bermuda Costal Region and Atlantic Ocean M. McInnes, Trent Univ, Student, Trent Univ, Chemistry; A.J. Peters, Bermuda Institute of Ocean Science; D.A. Ellis, Trent Univ. Nonylphenol (NP) is an environmentally ubiquitous organic pollutant. Understanding the mechanisms by which it and other pollutants are transported in the environment is of utmost importance. NP exhibits surface active properties and may therefore be subject to transport via aqueous aerosols. Lab studies have shown that aqueous aerosols are subject to increased concentration of organic surfactants when compared with the surface waters they were generated from. This study investigated the concentrations of NP in aqueous aerosols and waters in the Atlantic Ocean and Bermuda coastal region. Aqueous aerosols were collected at heights of 10 m and 20 m from the Research Vessel Atlantic Explorer and a land based atmospheric research tower on the coast of Bermuda. NP was also determined in surface waters around Bermuda and to depths of 4000m at the Bermuda Atlantic Time Series (BATS) sampling site in the Atlantic Ocean. Results show that aqueous aerosols produced from the oceans surface are enriched in NP when compared to the surface water they were generated from. This represents a unique route to the atmosphere

and could subject this non volatile compound to long range atmospheric transportation.

657 Quaternary Ammonium Compounds as Contaminants and Biogeochemical Tracers in Estuarine Waters: A Review B.J. Brownawell, Stony Brook Univ, School of Marine and Atmospheric Sciences; X. Li, Connecticut Agricultural Experiment Station, Analytical Chemistry; A.C. Doherty, Stony Brook Univ, School of Marine and Atmospheric Sciences, Stony Brook Univ, graduate student; P.C. Fitzgerald, Stony Brook Univ. Quaternary ammonium compounds (QACs) are cationic surfactants with sewage-specific sources to urban waterways. Several are particle-reactive and stable once associated with fine grain coastal sediments. Concentrations of QACs can be remarkably high and are detected with high sensitivity in sediments far from source areas. Several are potent disinfectants leading to questions of effects on microbial communities. However, more toxic and soluble QACs can be highly degraded during sewage treatment. Further fractionation occurs prior to incorporation into sediment beds, after which there appears to be little additional degradation or desorption after extensive transport of resuspended sediments. While very low bioavailabiliy will limit toxicity, the properties of QACs lead to their ability to serve as sensitive tracers of: 1) contaminant source allocation, transport and fate; 2) processes related to the lateral transport and burial of sediments; and 3) microbial source tracking. Recent work shows that concentrations and compositions of QACs are markedly different when suspended matter originates from treated sewage, combined sewage overflows, storm waters, groundwater discharge or resuspended sediments. Illustrative examples will be presented that highlight the potential of QACs as tracers in different applications, and insights into the advantages and difficulties that are inherent in the use of tracers where inputs are not at steady-state over timescales of interest.

658 Sorption of Aromatic Amines to Soils and Soil Minerals: Implications for the Fate of Emerging Contaminants D. Vasudevan, T. Arey, Bowdoin College, Dept of Chemistry; M. Newman, T. Zhang, Bowdoin College. Numerous chemicals containing cationic amine functional groups, such as antibiotics, herbicides, and antidepressant drugs, have been detected in surface and ground waters, and some of these pose risks to humans and ecosystems. Understanding and predicting the extent of sorption under a wide range of environmental conditions is key to anticipating potential contamination of groundwater by these chemicals. Cation exchange, the primary mechanism for cationic amine sorption has been well studied. However, there is a lack of knowledge surrounding potential secondary mechanisms of sorption and the soil characteristics that may facilitate secondary, intermolecular interactions between amines sorbed to the surface and adjacent amines in solution. The presence of secondary interaction mechanism can lead to non- linearities in sorption phenomena. If the equilibrium sorption constant (Kd), a key parameter in contaminant transport models, is not constant over a wide range of solute concentrations, the sorption is considered non-linear. Transport models that assume a constant Kd and do not account for non-linearity will under or over predict contaminant transport and provide ineffective assessments. By studying the sorption of a series of model compounds that represent important sub-structures of antibiotics and pesticides, this study addresses three significant gaps in current understanding of cationic amine fate: (i) the influence of compound structural criteria on amine cation sorption, (ii) secondary interactions mechanisms that contribute to non-linearity in sorption phenomena, and (iii) effect of soil properties on sorption linearity and non-linearity.

659 The Importance of Sorption Kinetics for Modeling Fate and Transport of Contaminated Sediments: Application to the Upper Hudson River PCB Site P. Israelsson, P. Oates, J. Connolly, C. Forrest, W. Ku, P. Mugunthan, U. Kipka, J. Benaman, R. Petroni, L. Zheng, F. Chen, Anchor QEA, LLC; K. Ziegler, Anchor QEA, Dept of Chemical Engineering, PO Box. A novel framework for simulating the fate and transport of sediment-bound persistent pollutants in surface waters is proposed and applied to the Upper Hudson River (UHR) PCB Superfund Site. Over the past few decades, coupled numerical models of hydrodynamics, sediment transport, and chemical fate and transport have become common in evaluating contaminated sediment site dynamics under various management alternatives. Our work challenges a central assumption typically made within these frameworks, namely the equilibrium partitioning of contaminants between the sorbed and dissolved phases within the water column. We focus on the prediction of downstream cumulative loading of UHR PCBs as it is a primary regulatory metric. In evaluating the fate of PCBs resuspended either by high flow events or by dredging, we demonstrate that the characteristic settling times of coarser particle size classes (fine sands and larger) are shorter than the timescale for desorption for most of the sorbed PCBs, based on measured UHR PCB desorption rates. Consequently, we argue that equilibrium partitioning in the water column can often be a poor assumption, because it tends to over-predict downstream PCB load by artificially transferring mass into the dissolved phase and away from resuspended coarser particles, thereby reducing the PCB sink associated with the settling of this material. Our solution to this shortcoming of traditional models is a generic multi-rate, size-class-specific kinetic sorption model, i.e., a framework that can represent the kinetics and transport of an arbitrary number of sorbing chemical phases (e.g., labile and resistantly sorbed chemical) independently for each particle size class of the parent sediment transport model. The setting for our work, the UHR PCB Site, is one of the most studied contaminated sediment sites in the world, offering a rich database upon which to build and calibrate a site-specific model application. Of particular note is the availability of data both during baseline conditions as well as during the first phases of the ongoing dredging program, allowing us to investigate and calibrate the influence of sorption kinetics under a range of flow conditions and loadings. The potential inaccuracy caused by equilibrium partitioning can also be characterized. Lastly, we note that although our application concerns UHR PCB dynamics, similar considerations are expected to apply at other sites across a range of conditions and contaminants.

660 Dissolved Natural Organic Matter – Hydrophobic Organic Contaminant Interactions: Controlling Factors and Environmental Implications J.V. Kukkonen, J. Akkanen, Univ of Eastern Finland, Joensuu Campus, Dept of Biology. The association with dissolved natural organic matter (DNOM) has been shown to affect the environmental fate and effects of hydrophobic organic contaminants (HOCs). The main findings have indicated that DNOM for example increases the solubility and reduces the bioavailability of HOCs, both processes being very important for the transport of HOCs in the aquatic environment. Since the quality and quantity of DNOM varies greatly both spatially and temporally, site specific estimation and prediction of these effects is difficult. This presentation will challenge some of the current assumptions concerning the DNOM-HOC interactions. First assumption: DNOM quality has major implications for extent of sorption. This is true especially in the case of polycyclic aromatic hydrocarbons (PAHs), but less applicable in the case of polybrominated diphenyl ethers (BDEs). Sorption of the latter appears to be almost independent of DNOM quality. The behavior of polychlorinated biphenyls (PCBs) lies somewhere between that of PAHs and BDEs. Second assumption: sorption of HOC to DNOM is completely irreversible. Recent studies indicate that there is also desorption resistant fraction. The environmental implications of the strongly sorbed fraction are not yet studied. Third assumption: DNOM associated HOCs are not bioavailable. In water phase and non-depletive conditions this holds mostly true. However, there are also indications of increased bioavailability due to low DNOM levels. In addition, recent literature shows that in multiphase systems where solid phase serves as a source for HOCs, DNOM may enhance availability. All these aspects are highly important when considering the effects of DNOM on fate of HOCs in the environment.

661 Combination of a Stressor-Response Model with a Conditional Probability Analysis Approach to Develop Candidate Criteria from Empirical Data J. Paul, USEPA, National Health and Environmental Effects Research Laboratory, USEPA, Atlantic Ecology Division; W. munns, J. Hagy, USEPA. We show that a conditional probability analysis that utilizes a stressor-response model based on a logistic regression provides a useful approach for developing candidate water quality criteria from empirical data. The critical step in this approach is transforming the response data into a binary variable using a threshold that is a desirable management goal for the intended water bodies. A logistic regression analysis on the stressor and binary response data is conducted and the result is interpreted as the probability of missing the management goal. This approach can be viewed as transferring uncertainty in empirical data to an estimate of the probability of missing the management goal. Several examples will be presented to demonstrate the robustness of this approach. The examples involve lakes in the northeast US, wadable streams on the mid-Atlantic US, and estuaries in Florida. This approach is also able to incorporate multiple stressors into the analysis. This capability allows one to look at the interaction among stressors

that can be observed from the data. The issue of nutrient co-limitation in estuaries will be used to demonstrate this capability.

662 Field vs. Laboratory-based Approaches for Derivation of Aquatic Life Criteria: Just Because We Can, Does It Mean We Should? R.W. Gensemer, S.P. Canton, GEI Consultants, Inc., Ecological Division. The current practice for derivation of water quality criteria for protection of aquatic life is to use results from standard laboratory toxicity tests with a range of surrogate test species using defined protocols to calculate both acute and chronic criteria. Such criteria have been used for decades to develop discharge permits for a wide range of chemical pollutants under EPA's National Pollutant Discharge and Elimination System (NPDES) and for other uses, such as 303(d) impairment listings and ecological risk assessments. While derivation of these criteria are intended to provide broad levels of protection for aquatic communities exposed to pollutants, uncertainties exist in extrapolating laboratory toxicity test results to protection of natural communities. Recently, however, new approaches have been proposed to derive chemical criteria on the basis of empirical relationships between benthic macroinvertebrate community structure and pollutant concentrations in synoptic surveys. The most recent examples of this approach by EPA include derivation of numeric nutrient criteria in Florida and conductivity benchmarks in central Appalachian streams chemically dominated by sulfate and bicarbonate salts. While use of field data are attractive with regards to environmental realism, identifying causality and minimizing the influence of confounding factors makes derivation of such numeric criteria or benchmarks extremely challenging. Using the conductivity benchmark as a case study, this presentation explores the difficulties of using synoptic field survey data in deriving regulatory aquatic life criteria. Such difficulties include statistical methods used, establishing causality, and approaches for identifying or minimizing the influence of confounding environmental factors. We conclude that, in this case, increases in conductivity (or the ions measured by conductivity) have not yet been shown to be causally related to changes in benthic macroinvertebrate community composition. Furthermore, the confounding factors of benthic habitat characteristics, stream flow, and other anthropogenic influences prevent rigorous application of a numeric aquatic life benchmark based on conductivity.

663 A Critival Residue Approach Linking Accumulated Zn in Aquatic Insects to Population and Community-level Effects T.S. Schmidt, US Geological Survey, Water Resouces Div, USGS, Water Resouces Div; W.H. Clements, Colorado State Univ, Fish, Wildlife and Conservation Biology, Colorado State Univ, Colorado State Univ, Fish, Wildlife and Conservation Biology; R.E. Zuellig, US Geological Survey, Colorado Water Science Center. Whole body Zn concentrations in individuals (n = 889) from three aquatic insect taxa (mayflies *Rhithrogena* spp. and *Drunella* spp. and the caddisfly *Arctopsyche grandis*) were used to predict effects on populations and communities (n = 149 samples). Both mayflies accumulated significantly more Zn than the caddisfly. The presence/absence of *Drunella* spp. most reliably distinguished sites with low and high Zn concentrations; however, population densities of mayflies were more sensitive to increases in accumulated Zn. Critical tissue residues (752 ug/g Zn for *Drunella* spp. and 634 for *Rhithrogena* spp.) caused a 20% reduction in maximum (90th quantile) mayfly densities. These critical tissue residues were associated with exposure to 7.4 and 19.2 ug/L dissolved Zn for *Drunella* spp. and *Rhithrogena* spp., respectively. A threshold in a measure of taxonomic completeness (Observed/Expected) was observed at 5.4 ug/L dissolved Zn. Dissolved Zn concentrations associated with critical tissue residues in mayflies were also associated with adverse effects in the aquatic community as a whole. These effects on populations and communities occurred at Zn concentrations below the USEPA hardness-adjusted continuous chronic criterion.

664 Alternative Methods and Endpoints for Field-derived Exposure-response Modeling: The Case of Stream Invertebrates and Salinity G.W. Suter, US Environmental Protection Agency, National Center for Environmental Assessment, USEPA, National Center for Environmental A; S.M. Cormier, USEPA, National Center for Environmental Assessment, USEPA, NCEA-Cincinnati; L. Zheng, Tetra Tech, Inc. The time has come to move from research and ad hoc applications of field-derived exposure-response models to developing a consensus of the environmental assessment community about which methods and endpoints are most useful and defensible for standard setting, causal assessment, and risk assessment. That consensus should be based on an understanding of the implications of our choices. Alternative methods include ordinary linear regression, quantile regression, inflection and break point analysis, and species sensitivity distributions. Endpoints include occurrence or abundance of species, overall species richness and abundance, and multimetric indices. The consequences of choosing among these alternative methods and endpoints will be illustrated with alternatives to the EPA's salinity benchmark for Central Appalachia.

665 Can the Effects of Insecticide Mixtures be Predicted on Non-target Aquatic Invertebrate Communities? A.C. Alexander, Univ of New Brunswick, Dept of Biology, Univ of New Brunswick, Dept of Biology and Canadian Rivers Institute; H.M. LeBlanc, Univ of New Brunswick; J.M. Culp, Environment Canada; A.J. Cessna, National Water Research Institute, Environment Canada, Environmental Health National Program, Agriculture and Agri-Food Canada. In this study we pose two questions: (1) Can single-species, single-compound, toxicity test data on non-target aquatic insects (Ephemeroptera, Plecoptera, Trichoptera) predict patterns in stream communities composed of similar taxa that were field-collected, subsampled and exposed to the same compounds individually and jointly? and, (2) Can binary mixtures of two similar Mode-of-Action (MOA) insecticides be treated additively using a Concentration Addition by Toxic Units (TU) approach? To evaluate these questions we field-collected and exposed benthic macroinvertebrate assemblages to four TU doses of either chlorpyrifos or dimethoate individually (control, 0.2, 0.4 and 0.8 TU) and in two, 1:1 mixture doses (0.2 + 0.2 TU and 0.4 + 0.4 TU) in artificial streams. We firstly examined changes in the frequency of different members of the community with respect to actual doses of insecticides using Principle Components Analysis (PCA) and looked for shifts in macroinvertebrate community response. Secondly, we examined whether there were differences in specific taxa or guilds due to treatment with insecticide mixtures compare to control (GLM) and, finally, we compared actual responses to predicted decreases in density using a chi-square approach, where the predicted values were derived from laboratory findings in the EPA Ecotox Database. We found that responses were not uniform with different taxa and guilds responding significantly differently to treatment with either of these two similar insecticides individually or in mixture. We also intend to show when, and suggest why, additive toxicity is suitable for extrapolating from individual responses to population and community level effects for these two organophosphorus insecticides that share the same primary Mode-of-Action.

666 Causation, Confounding and Field-derived Exposure Response Relationships S.M. Cormier, USEPA, National Center for Environmental Assessment, USEPA, NCEA-Cincinnati; G.W. Suter, US Environmental Protection Agency, National Center for Environmental Assessment, USEPA, National Center for Environmental A. Field-derived exposure-response relationships have a major advantage: barring errors in measurement, they characterize the real world. Their major disadvantage is that observed relationships may not be causal. This is the opposite of relationships from laboratory tests, which are causal but may relate only to the world of the beaker. Demonstrating real world causation is a difficult problem that has generated controversy from ancient times to the present among philosophers and scientists. We take a pragmatic approach that combines criteria guided inference with an explicit weight-of-evidence process to answer two questions: 1) Does the evidence indicate that the relationship is causal? 2) Does the evidence support any alternative that may account entirely or in part for the apparent causal relationship (i.e., are there confounders)? The criteria used in our approach are six fundamental characteristics of causation: time order, co-occurrence, preceding causation, sufficiency, interaction, and alteration. Evidence is categorized by its relevant causal characteristic and is scored in terms of its strength and quality. The evidence scores are combined to obtain a final score for the putative cause or potential confounder. This approach has the advantage of incorporating all available evidence in a transparent manner.

667 Field Exposure-Response Relationships Established from (Bio) monitoring Data Provide Insight in SSD-Model Output (Toxic Pressure) Interpretation L. Posthuma, D. De Zwart, RIVM, Lab. for Ecological Risk Assessment. Strategic research into options for improved analysis of (bio) monitoring data has been triggered by multiple interests, amongst which water quality policies in Europe (the strive to Good Ecological Status) as well as interests in the 'quantitative' ecological meaning of exceedances of Water Quality Criteria. Such exceedances occur frequently, and are a trigger for policy concerns. The current presentation focuses on data collected

in the US as well as Europe, and on the nalyses of these data with various diagnostic techniques, with specific attention on locally occurring mixtures of toxic compounds. Over the last decades, emissions of toxic compounds ahve reduced and water quality has improved, and it can be therefore difficult to establish the relative role of toxic mixtures in causing deviations from Good Ecological Status. It is thereby common that the diagnosis of the role of toxic chemicals is hampered by the issue of "over-parameterisation" of the diagnostic statistics (a.k.a. the "curse of dimensionality"). Often, current analyses yield a 'no-recognized-toxic-signal' answer – be it with little statistical power. That is: such analyses yield no useful answer on the relative role of chemicals, and show neither presence or absence of ecological impacts. In diagnostic analyses of the various geographies, we applied the concept of Species Sensitivity Distributions (SSDs) and mixture modeling to generate acute or chronic toxic pressures per sampling site (PAF or msPAF, multi-substance Potentially Affected Fraction). A chronic PAF of 5% relates to the concept of HC5 (Hazardous Concentration for 5% of the species, equal to the 95% protection level), a well-known concept for deriving water quality criteria. It will be shown that this process was of help in identifying the relative probable role of mixtures in reduction of ecological status in various geographies. Moreover, it will be shown that these analyses provided insights into the meaning of the concept of toxic pressure (msPAF) itself. The presentation adresses not only diagnostics of large (bio)monitoring data sets (as collected e.g., under the Water Framework Directive), but also specifically field Exposure-Response relationships, including new insights in the ecological interpretation of (acute) toxic pressure. The SSD-model appears to help quantifying in a policy-meaningful way the impact magnitude to be expected in contaminated water systems.

668 Using Microcosm and Field-derived Exposure-Response Relationships to Validate Water Quality Criteria for Metals in Rocky Mountain Streams W.H. Clements, Colorado State Univ, Fish, Wildlife and Conservation Biology, Colorado State Univ, Colorado State Univ, Fish, Wildlife and Conservation Biology; T.S. Schmidt, US Geological Survey, Water Resources Division. The limitations of single species toxicity tests for predicting ecological effects of contaminants on aquatic communities have been described in the literature. For certain classes of stressors in which direct toxicological effects are unlikely (e.g., nutrients, sediment) or in which standard test organisms are inappropriate (total dissolved solids), field-derived exposure-response relationships have been used to establish standards. The major challenge using field-derived data is to separate effects of the specific stressor of interest from other potentially confounding factors. Our ability to establish exposure-response relationships is greatly improved when a single dominant stressor is present. Using field data from several spatially extensive surveys of over 300 Colorado streams, we established concentration-response relationships between trace metals and several measures of macroinvertebrate community structure. Results showed consistent and predictable alterations in community composition along a gradient of metal contamination. These data were supplemented by a set of 17 stream microcosm experiments that established concentration-response relationships and allowed us to estimate community-level LC20 values for metals. Additional exposure-response data were provided by a long-term (20 year) natural experiment in which we documented macroinvertebrate responses to the removal of heavy metals. Although these data showed significant improvements in water quality and macroinvertebrates over time, communities remained impaired when metal concentrations exceeded the community-level EC20 values. These investigations provided strong evidence that metals associated with historical mining operations were the primary stressors responsible for changes in macroinvertebrate communities. Although exposure-response relationships varied among endpoints, results showed that existing water quality criteria for metals were reasonably protective of benthic macroinvertebrates in Colorado streams.

669 Translating Tissue Contamination to Sediment Quality Objectives in California Bays and Estuaries S.M. Bay, Southern California Coastal Water Research Project, Toxicology Dept; B. Greenfield, San Francisco Estuary Institute. The Sediment Quality Objectives (SQOs) adopted by the California State Water Resources Control Board include a narrative objective for protection of human health related to consumption of contaminated seafood. A multiyear effort, informed by stakeholder involvement and scientific review, was used to develop a tiered sediment contamination assessment framework to implement California's human health SQO. The technical approach addresses two assessment questions: 1) do pollutant concentrations in seafood pose unacceptable health risks to human consumers? and 2) is sediment contamination at a site a significant contributor to the seafood contamination? The first question is evaluated by interpreting seafood tissue concentrations at the site, based on health risk calculations. The second question is evaluated by interpreting site-specific sediment chemistry data using a series of bioaccumulation models based on fish feeding guilds. The models were parameterized and validated for use with chlorinated hydrocarbons in California estuaries and marine embayments. The assessment framework includes three tiers (screening assessment, site assessment, and refined site assessment). Later tiers use a stochastic simulation approach, incorporating information on variability and uncertainty of key parameters, such as seafood contaminant concentrations and seafood consumption rate. Results of application of the framework to data from California embayments illustrate the impact of key regulatory study design parameters on the results, such as site area, species selection, and data quality. The proposed assessment approach would facilitate the consistent application of a risk assessment paradigm in a state sediment regulatory program.

670 Translating Tissue Levels of Selenium in Aquatic Invertebrates or Fish to Waterborne Concentrations E. Byron, CH2M Hill, Environmental Services; H. Ohlendorf, CH2M Hill. Throughout the intermountain western United States and Canada the uplift of selenium-enriched marine shales has resulted in a supply of selenium in surface runoff and groundwater that may be evaporatively concentrated or otherwise brought into surface waters at potentially toxic concentrations. Although selenium is an essential micronutrient to animals it may accumulate in diet and tissues to toxic levels in many of these environments. There is regulatory concern for potential selenium toxicity to fish, birds, and hunting or fishing humans coupled with the recognition that selenium exposure and risk occurs mainly through dietary exposure rather than water, directly. As a result, there has been an increasing emphasis in recent years to regulate selenium exposure on the basis of bioaccumulated selenium in the tissue of aquatic invertebrates and fish as well as in secondary consumers, such as in the eggs of water-dependent birds. In this talk we present examples of potentially toxic selenium concentrations in surface water at several western US locations and subsequent attempts to model and translate the measured tissue concentrations back to ambient waterborne concentrations. The modeled relationships may then be used as a tool to regulate waterborne concentrations to levels that would be protective of local fish and wildlife or to help design remediation strategies. The assumptions and causes of variability in these tissue-based models are discussed with regard to the accuracy and precision of translations for selenium between tissues and water.

671 Spatially-explicit Bioaccumulation Model to Identify Areas of Sediment Associated with Elevated Mercury Uptake by Benthic Fish J. Conder, ENVIRON International Corporation; R.J. Wenning, ENVIRON International Corporation, Ecology & Sediment Management, ENVIRON International Corporation, Marketplace Tower; F. Achour, F. Colombo, ENVIRON International Corporation. Consideration for active management of local mercury-contaminated sediment in Augusta Bay, Sicily, Italy has been prompted by the detection of mercury in local benthic fish species native to Augusta Bay, despite the fact that concentrations of total mercury in local fish are no different than concentrations observed in other Mediterranean Sea fish. Despite the lack of additional (i.e., beyond ambient) human health and ecological risk posed by local mercury-contaminated sediment via the consumption of local benthic fish, a modeling exercise was conducted to understand the relationship between concentrations in surface sediment (0-20 cm) and benthic fish. Benthic fish collected from the area of the Bay with the highest concentrations of mercury in surface sediment ("Station A"), exhibited slightly higher mean whole body concentrations (0.81 mg/kg, wet weight [ww]) compared to mean concentrations in fish collected from two other sampling areas (0.55-0.61 mg/kg, ww) 2-3 km away. Regression of whole body concentrations of mercury on body weight using data from a species found at all three Augusta Bay locations (red mullet; *Mullus barbatus*) confirmed that this observation was due to increased mercury exposure, not differences in age. Assuming that the benthic fish sampled derive sediment mercury exposure from an approximate 0.1-km^2 home range, Surface Weighted Average Concentrations (SWACs) for total mercury in surface sediment in 0.1-km^2 areas centered over the fish collection locations greater than 60 mg/kg (SWAC for Station A) were equated with the potential for similar or higher mercury exposure in fish than those caught at Station A. A "moving window" geospatial analysis was conducted by estimating the

SWACs for over 1,000 randomly-placed, 0.1-km^2 areas in Augusta Bay. Using the SWACs for each of the moving windows, a contour map showing the 0.1-km^2 SWACs was estimated to identify an area with a SWAC greater than or equal to 60 mg/kg. This analysis explicitly considers the spatial aspects of bioaccumulation of chemicals from sediment by fish, removes bias associated with spatially-unbalanced sediment sampling designs, and can be used to base management actions on both the areal extent and concentration of contaminated sediment.

672 Delineation of Areas for Sediment Management in the St. Clair River Using Invertebrate Methyl Mercury Tissue Concentrations L. Richman, Ontario Ministry of Environment; D. Milani, Environment Canada; M. Henning, ENVIRON International Corporation. The St. Clair River was identified as an Area of Concern by the IJC in 1985 because of contaminated fish, degraded benthos, beach closures, and other impairments due to poor water and sediment quality. Currently, sediment management options are under review for three Priority Areas. These areas were identified based on the risk of Hg biomagnification in fish through benthic organisms. Methyl Hg tissue data for oligochaetes collected in 2001/2004 were used to estimate maximum exposure of Hg to fish assuming fish foraged exclusively within the study area. Site specific BMFs were generated using local fish tissue concentrations (pike and redhorse suckers) and the oligochaete concentrations. These BMFs were divided into a literature derived fish tissue concentration protective of fish (Toxicity Reference Value: 0.2 mg/kg) to obtain a range of target methyl Hg concentrations in invertebrates protective of fish (0.0125 mg/kg – 0.0154 mg/kg). Using anisotropic interpolation, spatially weighted average concentration (SWAC) of methyl Hg in oligochaetes were calculated (0.020 mg/kg). To lower the SWAC below the target concentrations, locations with oligochaete tissue concentrations greater than 0.025-0.027 mg/kg require remediation. To better assess the size of the three Priority Areas requiring remediation, additional benthic tissue data was collected in 2010. Concentrations of methyl Hg in oligochaete tissue, with only a few exceptions, exceeded the target concentrations (range: 0.017 -0.050 mg/kg; median: 0.033 mg/kg). The percent methyl Hg in oligochaete tissue ranged from 4-20% (median 8%). Methyl Hg concentrations in oligochaetes were significantly correlated with methyl Hg and total Hg in sediment ($r=0.84$; $p< 0.002$ and $r=0.66$; $p< 0.04$ respectively). Total Hg in oligochaetes was also significantly correlated with total Hg in sediment ($r=0.89$; $p< 0.0001$). Overall, methyl Hg concentrations were consistent in all three Priority Areas with data from 2001/2004. The size of the Priority Areas can be refined using the new data.

673 Evaluation of One-step Versus Multi-step Partition Modeling Approaches for Relating Selenium Concentrations in Surface Water and Fish D.K. DeForest, Windward Environmental LLC; K.V. Brix, Univ of Miami, RSMAS, Marine Biology and Fisheries; W.J. Adams, Rio Tinto. For many bioaccumulative chemicals for which trophic transfer is the dominant exposure pathway, the concentration of a chemical in an organism's tissue may be a better indicator of potential toxicity than the concentration of the chemical in the external environment (e.g., surface water). However, in order to develop water quality criteria or guidelines for such chemicals, it is necessary to relate a tissue-based toxicity threshold to a water-based concentration. One example is selenium, an essential element that exists in inorganic and organic forms, with toxicity primarily manifested in aquatic systems via the transfer of organic selenium to oviparous vertebrates (e.g., fish, birds). The bioaccumulation potential of selenium is highly dependent on site-specific biogeochemistry. Mechanistic selenium bioaccumulation models have so far proven to require significant amounts of data and have not been validated for a range of sites. Rather, selenium partitioning modeling approaches based on empirical data have shown more promise. These partitioning models simply rely on coefficients that relate selenium concentrations between two media. In a one-step approach, the selenium concentration in fish or bird tissue (eggs) is related directly to co-located water selenium concentrations. In a multi-step approach, selenium partitioning coefficients are derived for each general step in the food chain: a Kd to describe selenium partitioning from water to the base of the food chain and trophic transfer factors (TTFs) to describe the transfer of selenium between trophic levels. The selenium Kd may vary by 1 to 2 orders of magnitude between sites, while TTFs are much less variable between taxa (often varying by a factor of

674 Derivation of a Tissue-based Selenium Site-specific Objective for the Newport Bay Watershed C. Claytor, GEI Consultants, Inc.; S.D. Baker, GEI Consultants, Inc., Ecotoxicologist/Wildlife Biologist; S.P. Canton, GEI Consultants, Inc., Ecological Division. Recent efforts have been made by the Santa Ana Regional Water Quality Control Board and Nitrogen and Selenium Management Program to derive a site-specific objective (SSO) for selenium (Se) in the Newport Bay Watershed in southern California in support of a Se TMDL. Using toxicity data and available fish community data, we evaluated their Se fish SSO for the study area and updated the analysis, utilizing relevant Se toxicity data for species expected to be found or which may serve as surrogate species for study area fish. These data were summarized by genus and analyzed tissue type (i.e., whole body or ovary/egg). Based on this analysis of appropriate and relevant data, it appears the bluegill is potentially the most Se-sensitive species in the study area, with a whole-body genus mean chronic value (GMCV) of 7.8 µg/g dry weight. Should a future SSO be based on ovary/egg data, it appears that again the bluegill is most sensitive, with a GMCV of 19.9 µg/g. However, data indicate that bluegill may not be commonly found in the flowing portions of the study area and it is not clear that reproducing populations are present, except in a few atypical, off-channel habitats. Rather, carp and mosquitofish appear to be the most abundant kinds of fish in these areas. In this case, an alternative SSO for those portions of the watershed not supporting reproducing populations of bluegills may be appropriate. We will also review a method for deriving a water column value by back-calculating from a tissue-based SSO, as well as recommendations for more structured site assessments to provide evidence of reproduction (or the lack thereof) through age class structure evaluations, habitat suitability evaluations, a more accurate species list for the watershed, and relative abundance of each species. It is important to note that the protectiveness of the proposed SSO in the context of the overall watershed food web, particularly as it relates to fish-eating birds, has yet to be evaluated and represents a significant uncertainty at this time. A work group comprised of fish and bird experts from private consulting, federal, state, and local agencies is being convened to address this concern.

676 Tissue Contamination and Seafood Consumption Advisories in Southern California K. Schiff, Southern California Coastal Water Research Project. Southern California has an active marine fishing community, where 8.4 million fish were landed in 2009. Southern California is also home to some widely contaminated ocean ecosystems including one of the only designated offshore marine superfund sites in the country. This level of contamination can lead to important human health risks for seafood consumers. The goal of this study was to create a southern California regionwide monitoring program for seafood safety. More than 1,700 fish were collected, including the top five-most landed recreational sportfish species. Samples of edible tissues were analyzed for mercury, PCBs and DDTs. Moderate tissue contamination was widespread, with no site exhibiting levels below advisory guidelines for all species, but only a handful of sites exceeding no consumption advisory thresholds. Mercury and PCBs were the most widespread contaminants. Despite the DDT superfund site, DDT tissue concentrations were uniformly below advisory guidelines. Embayments had greater mercury and PCB concentrations, and exceeded advisory guidelines more frequently than open coastal sites. The greater embayment concentrations compounds health risk since angler surveys illustrate these habitats are where the greatest frequency of fishing occurs.

677 A Novel QSAR Modeling Strategy: Variable Selection Method Based on Variable Interaction via Uniform Design Cross-Validation Z. YI, Nanjing Univ, Chinese Academy of Sciences, Research Center for Eco-environmental Sciences; A. Zhang, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, State Key Laboratory of Environmental Chemistry and Ecotoxicology; Y. Mu, J. Fu, Y. Sun, Chinese Academy of Sciences, Research Center for Eco-environmental Sciences. With the development of structural characterization techniques, variable selection method plays a key role in screening molecular descriptors to establish predictive and robust quantitative structure-activity relationship (QSAR) models. Random researching methods such as genetic algorithm and art colony algorithm may not ensure that the same global optimal subset is found, while it is impossible to use all-subsets regression for subset selection when there is a large variable candidate database. In order to tackle the problem, a novel QSAR modeling strategy, variable selection method based on variable interaction via uniform design cross-validation (VSMVI-UDCV), was proposed in the present study. Specifically, variable selection

method based on variable interaction (VSMVI) was developed on the basis of three techniques, forward regression, variable selection method based on prediction (VSMP), and group methods of data handling. The new method can solve the subset screening problem much faster than VSMP, exhibiting obvious advantages over VSMP when handling large set of variables. In addition, the characteristics of uniform design were adopted to modify leave-multiple-out cross-validation (LMOCV) and establish uniform design cross-validation (UDCV) to get the most possible amount of information with the minimum number of model validation. By using uniform design table, the validation strategy is achieved by setting sample number as a factor level and different factor as different LMOCV splitting way. The new strategy differs from the other variable selection procedures related to all-subsets regression by the two major features: (1)The search of various optimal subset search is controlled by the statistic q^2_{UDCV} (the correlation coefficient obtained using UDCV technique) rather than the correlation coefficient obtained in the modeling step (r^2) or q^2_{LOO} in the leave-one-out cross-validation step. (2)The searching speed of all optimal subsets is expedited by the statistic r_{int} (the interrelation coefficient between the pairs of the independent variables), together with q^2_{UDCV}. Finally, the performance of VSMVI in variable selection was assessed and verified by Selwood dataset, while the validity of UDCV was evaluated by comparison with Monte Carlo cross-validation method.

678 A QSAR-based Two-stage Prediction for Estimating Mixture Toxicity J. Kim, KIST Europe, Knowledge Research Group, Univ of Koblenz-Landau, Institute of Environmental Sciences; S. Kim, KIST Europe, Chemical Management Lab.; G.E. Schaumann, Univ of Koblenz-Landau, Institute of Environmental Sciences. Chemical risk assessment frequently focuses on single chemical substances, although most living organisms are actually exposed to chemical mixtures rather than individual substances. Much evidence on mixture toxicity shows that individual substances at levels below no-observed-effect concentrations (NOECs) may elicit toxicity due to the combined effects among substances. Hence, mixtures risk assessment covering the combined effects needs to be considered for human health and the environments. Conventionally, concentration addition (CA) and independent action (IA) models based on the concept of additive toxicity are often used to estimate the mixture toxicity of similarly- and dissimilarly acting chemicals, respectively. However, organisms and the environments are simultaneously exposed to both types of chemicals. Therefore, it practically needs to develop an integrated model to predict mixture toxicity from various chemicals. Two-Stage Prediction (TSP) model has been developed as an integrated addition model to carry out the CA and IA calculations stage by stage. But the use of the conventional TSP is limited if knowledge on the modes of toxic action on every mixture component is not readily available. The objective of this study is to develop a QSAR-based TSP model for estimating mixture toxicity in the environment risk assessment. For this purpose, the categorisation of mixture constituents using computerised analysis of chemical similarity is applied as a part of the prediction of mixture toxicity. The results show the QSAR-based TSP can overcome the limitation of the conventional TSP model, as well as the categorisation of mixture constituents based on the chemical structure can be applied to predict mixture toxicity effectively.

679 Adaptive Responses in Female Fathead Minnows Exposed to an Aromatase Inhibitor: Computational Modeling of the Hypothalamic-Pituitary-Gonadal Axis M. Breen, North Carolina State Univ, Biomathematics Graduate Program; D.L. Villeneuve, USEPA, Mid-Continent Ecology Division; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; D. Bencic, USEPA, Office of Research and Development, USEPA; M.S. Breen, USEPA, National Exposure Research Laboratory; K.H. Watanabe, Oregon Health & Science Univ, Dept of Environmental and Biomolecular Systems; A.L. Lloyd, North Carolina State Univ, Biomathematics Graduate Program; R.B. Conolly, USEPA, Integrated Systems Toxicology Division. Exposure to endocrine disrupting chemicals can affect reproduction and development in both humans and wildlife. We are developing a mechanistic computational model of the hypothalamic-pituitary-gonadal (HPG) axis in female fathead minnows to predict dose-response and time-course (DRTC) behaviors for endocrine effects of the aromatase inhibitor, fadrozole. The model includes two feedback regulatory loops within the HPG axis that mediate adaptive responses to endocrine stress. One regulatory loop controls the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the brain, and the other regulates LH and FSH receptor recycling in the ovary. Data on plasma E2 and ovarian CYP19A mRNA from two experiments with a post-exposure recovery phase were used to develop and evaluate the model. In the experiments, fathead minnows were exposed to fadrozole at 0, 3, or 30 µg/L for 8 days followed by a 8-day recovery phase (experiment 1) or to fadrozole at 0, 0.5, or 30 µg/L for 8 days followed by a 20-day recovery phase (experiment 2). Adaptive changes in plasma E2 levels occurred during exposure and overshoot occurred post-exposure. Initial efforts to identify parameter values providing good fits to the plasma E2 data were only partially successful, suggesting the possibility that additional regulatory loops in the HPG axis are needed in the model. Ongoing efforts are evaluating both this possibility and new approaches to parameter estimation for the current model structure. This study illustrates the value of computational modeling for (1) examining the possible dynamic behaviors of a given model structure and (2) exploration of modifications to model structure leading to novel hypotheses regarding the regulatory biology associated with the observed adaptive responses. This abstract does not necessarily reflect US Environmental Protection Agency policy.

680 Application of a Genome Wide Live Cell Array System in Ecotoxicity Assessment X. Zhang, Toxicology centre, Univ of Saskatchewan, State Key Laboratory of Pollution Control and Resource Reuse & School of the Environment, Nanjing Univ, School of the Environment; G. Su, Nanjing Univ, School of Environment; X. Hu, Nanjing Univ; J. Giesy, Univ of Saskatchewan; H. Yu, Nanjing Univ. Continuous real time monitoring of genome-wide responses at cellular level enables new understanding of the complex biological process modulated by exposure to environmental chemicals. We have applied a high throughput live cell reporter assay system in chemical toxicity assessment. This live cell reporter assay system contains 1820 *Escherichia coli* K12 promoter-GFP reporter strains. Over 30 different single test chemicals and mixtures have been tested to assess their cytotoxicity and genomic responses. The powerful utilities of this system have been explored in the following areas: 1) chemical classification; 2) prediction on ecotoxicity; 3) mechanistic understanding; 4) mixture toxicity prediction.

681 Baysian Process Analysis of Time-Course Microarray Expression Data to Elucidate Molecular Mechanisms for Chemical-Induced Reversible Neurotoxicity P. Gong, SpecPro Inc., Enivronmental Services. Both carbaryl (a carbamate insecticide) and cyclotrimethylenetrinitramine or RDX (an explosives compound) can cause reversible neurotoxicity in the earthworm *Eisenia fetida*. The goal of this study was to better understand its underlying mechanism using a systems biology approach. We generated a time-series gene expression dataset that captured 27 snapshots of 44K unique transcripts in the course of 6-d exposure (13 time points) and 7-d recovery (14 time points) in earthworms received carbaryl (20 ng/cm^2), RDX (2 µg/cm^2) or neither (solvent control), in addition to 4 snapshots during acclimation. A Bayesian Learning and Optimization Model (BLOM) was developed to infer gene interactions. We analyzed BLOM-inferred gene networks for three treatments and two experimental phases using different gene sets. Our results show that (1) physiological recovery measured by MGF conduction velocity was reflected in both the number and the restored expression level of altered genes; (2) physiological response also correlated with the number and connectivity strength of disrupted gene interactions; and (3) RDX and carbaryl affected different gene interactions in various KEGG pathways. Furthermore, our data support that carbaryl inhibits acetylcholinesterase while RDX binds to $GABA_A$ receptor. Networks comparison also reveals that RDX induced interactions between genes coding for $GABA_A$ receptor and that for Dlc1/2 (dynein light chain-1 and -2). These interactions disappeared during the recovery phase. Although the majority of altered gene interactions and gene expressions were restored during the recovery, some important ones involved in pathways such as neurodegenerative diseases remained aberrant, implying potential long-term adverse impacts of RDX and carbaryl.

682 ICE: Computational Toxicology Gone Wrong? P. Craig, G. Hickey, Durham Univ, Mathematical Sciences. The USEPA interspecies correlation estimation (ICE) programme is a suite of log-log linear models fitted from existing ecotoxicity databases, with the purpose of predicting the unmeasured toxicity to some species of a chemical from measurements for other so-called surrogate species. An intended use of ICE is to reduce the number

of species tested in order to fit a species sensitivity distribution (SSD) by simultaneously predicting toxicity to a large number of species from measurements of toxicity to only a few, possibly just n=1. This semi-in silico method is motivated by restrictions on the minimum sample size required for SSD based hazard assessment; for example, REACH requirements vary from 10 to 15 species. We show that the concept is statistically indefensible on three grounds. Firstly, we examine whether the underlying ICE models themselves are informative about sensitivity of individual species or, when applied, are just making noisy predictions of central tendency. Secondly, we examine whether ICE-SSDs are conceptually coherent, show how one might exploit a suite of ICE models, and quantify, by means of a residual analysis, how well ICE-SSDs predict hazardous concentrations. Thirdly, we demonstrate that the implementation of ICE in USEPA Web-ICE software, and in particular quantification of uncertainty which is necessary for adoption under REACH, is erroneous and in some cases nonsensical. We conclude that, as it stands, ICE is a tool not fit for regulatory risk assessment of chemicals and indicate more suitable models, based on Bayesian hierarchical modelling, which maximize the value of information in existing ecotoxicity databases whilst being statistically defensible. The experience with ICE shows that the advent of powerful computing is not sufficient on its own to be useful for computational toxicity. One must also use the right statistical tools in the right ways.

683 Prediction of the Aquatic Toxicity of Triazoles and Benzotriazoles by QSAR E. Papa, Univ of Insubria, QSAR Res. Unit Environ. Chem/Dep. Structural Functional Biology , Univ of Insubria, DBSF; S. Kovarich, P. Roy, S. Cassani, E. D'Onofrio, Univ of Insubria; P. Gramatica, Univ of Insubria, QSAR Res. Unit Environ. Chem. Ecotox./Dep.Structural & Functional Biology. Triazoles and benzo triazoles (TAZ/BTAZs) are synthetic molecules already included in the list of substances of very high concern (SVHC) in the European regulation of chemicals REACH. These chemicals are widely used to obtain pharmaceuticals and agricultural products, and have a wide application as anti-corrosives, cleaning agents for textiles, flame retardants, photographic emulsions, as well as they are components of liquid deicing agents for aircraft and airport runways. Experimental evidence show that TAZ/BTAZs are distributed throughout the environment and in particular in the water compartment. Despite their known toxic activity on different organisms and non-target species, and in particular on the aquatic environment, only a limited amount of data is available for a comprehensive characterization of the environmental and toxicological profile of TAZs and BTAZs. Therefore, in order to increase the level of knowledge necessary to define the actual environmental impact of these potentially hazardous emerging contaminants, they have been included among the four classes of chemicals studied in the European FP7 Project CADASTER. This study focusses on the development of multiple linear regression (OLS) QSAR models for the acute toxicity of TAZ/BTAZs on three key biological levels of an aquatic ecosystem (Alga, *Daphnia* and Fish). Moreover, Quantitative interspecies correlations were determined to extrapolate *Daphnia* toxicity to Fish. The best models were validated for their internal robustness and external predictivity. The reliability of predictions was always checked by the leverage approach in order to verify the structural applicability domain of the models. Finally, a PCA analysis of the experimental toxicity data reported for the studied species was used to rank the studied TAZ/BTAZs according to their toxicity profile in the considered acquatic scenario.

684 Quantum Chemical Prediction Models on the Environmental Photochemical Behavior of Organic Pollutants J. Chen, Dalian Univ of Technology, School of Environmental Science and Technology, Dalian Univ of Technology, Professor; S. Zhang, Q. Xie, J. Zhou, Dalian Univ of Technology. Computational prediction methods are crucial for ecological risk assessment of environmental chemicals and newly synthesized chemicals prior to commercialization. Photochemical degradation is an important transformation pathway of persistent toxic chemicals in surface waters, in atmosphere, and on plant/soil surfaces. It is impossible to experimentally evaluate the photochemical behavior for all the (potential) environmental chemicals. Thus, it is necessary to develop computational models on environmental behavior of environmental chemicals. Our studies show that it is feasible to develop predictive models on environmental photochemical behavior of chemicals. The results include: (1) Predictive models on direct photolysis quantum yields, rate constants as well as bimolecular reaction rate constants with reactive oxygen species (ROS) for aromatic compounds were developed using quantum chemical parameters [1-3]. (2) A density functional theory (DFT) based prediction model on photolytic kinetics of hydroxyl radicals (•OH) induced photooxidation was developed for semi-volatile organic pollutants in atmosphere [4]. (3) DFT based models were developed to predict and explain the different photodegradation kinetics between molecular and ionized hydroxylated polybrominated diphenyl ethers (HO-PBDEs). (4) DFT computational methods were developed to predict the photochemical transformation pathways by evaluating the energy/electron transfers between environmental chemicals and oxygen molecules/water constituents [5]. 685 Reducing Risk by Reducing Hazard: Use of Chemical Hazard Screening as the First Step in the Assessment Process C. Robertson, Hewlett-Packard; P. Mazurkiewicz, H. Holder, HP. The Green Screen for Safer Chemicals (Green Screen) tool is a comparative chemical hazard assessment tool that is used to identify safer chemical alternatives in the design process. Based on the principles of green chemistry that assert that the best way to reduce risk is to reduce hazard, the Green Screen provides a simple 1-4 benchmark score that can help identify less hazardous chemical and non-chemical alternatives. A business case for screening alternatives using the Green Screen can be made based on the cost savings realized by avoiding multiple substitutions. Substituting materials in a complex supply chain can be costly, and if the replacement chemicals face future regulation, businesses may incur that cost multiple times. Selecting inherently less hazardous alternatives as the first step in the assessment process reduces the risk that the substitutes will face future restrictions. This presentation will discuss the incorporation of hazard based screening in the selection of materials for PVC-free power cords at Hewlett-Packard. Because the transition from PVC to PVC-free materials is voluntary, the importance of ensuring that the non-PVC alternatives are truly better than PVC materials is paramount. Use of the Green Screen has led to selection of materials that are inherently less hazardous, resulting in finished products that have a lower impact on the environment and human health.

686 Improving Environmental Sustainability in the Marketplace One Step at a Time C. Kelly, AMEC Geomatrix, Inc. Successful green chemistry requires an efficient screening of a chemical's intrinsic toxicity within the context of the final product the chemical will exist in. Providing numerical rankings to our client's material choices is an integral part of the decision-making process so the client's R&D Dept can develop ways to avoid, replace, or eliminate the more toxic products. However, the potential exposure routes and typical use in the marketplace cannot be separated from the process. We will present the scoring system and decision tree developed with a client in the sportswear industry and highlight the limitations of its application in addition to the tools that have proven useful to make it robust for a variety of chemicals. We will provide example chemicals that ideally fit an automated scoring system and others that may lead to misleading scores. We will present how we avoid inadvertently including chemicals that should be removed from the product stream and inadvertently excluding other potential "green" chemicals.

687 Green Disinfectants – A Life Cycle-based Framework to Address the Hazard, Exposure, and Risk of These Products C. Baldwin, S. Cooperstein, Green Seal. Cleaning programs with disinfectants are frequently required in institutional settings including health-care facilities, child care centers, schools, hospitals, long-term care facilities, and others. Many active ingredients in disinfectants are potentially hazardous to human health and the environment. They may contain chemicals that cause cancer, reproductive disorders, respiratory ailments (including occupational asthma), and other human health effects. In addition, some of these products contain persistent bioaccumulative and toxic chemicals (PBTs), are classified as hazardous waste, and/or otherwise contribute to environmental pollution during their manufacture, transport, use, and/or disposal. Furthermore, resistance of bacterial pathogens to antibiotics has increased worldwide, leading to treatment failures in human and animal infectious diseases. As a result, effective cleaning programs minimize use of disinfectants through

targeted treatment plans. Such a targeted plan involves the identification of which surfaces require high level disinfection (high-touch surfaces with a high risk for disease transmission), those that require low-level disinfection, and those surfaces that pose no infection risk, thereby minimizing the unnecessary use of toxic, high-level disinfectants. However, to further reduce the hazards from disinfection, less hazardous products should be used for the areas identified as needing this treatment. Currently, all disinfectants are classified as antimicrobial pesticides and registered under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA). Through the implementation of this law, these products are prohibited from bearing comparative claims, including "green" claims. However, there are greener disinfectants. This presentation will discuss the attributes of preferable disinfectants and how this fits into a life-cycle based evaluation program, namely the Green Seal ecolabel program.

688 Green Chemistry Strategies: A Synthetic Chemists Perspective N. Gathergood, Dublin City Univ, Dublin City Univ, School of Chemical Sciences, Dublin City Univ, Chemical Sciences. The talk will include introducing green chemistry metrics used by research and development chemists in the design of 'safer' synthetic methods. Recent examples from our group in Dublin will showcase, how the 12 Principles of Green Chemistry can be applied. The talk will include atom economy, E factor, toxicity and biodegradation data for solvents, catalysts, and reagents. Consideration of the sustainability of raw materials, with the environmental cost due to the preparation of starting materials or reagents is also an important factor often not included. In our presentation we will give an overview of the importance of all these factors, and their careful consideration in the design of a green synthesis.

689 Evaluating Overall Degradability of Chemicals with QSARs T.N. Brown, Helmholtz Centre for. Environmental Research UFZ, Dept of Analytical Environmental Chemistry; J.A. Arnot, F. Wania, Univ of Toronto Scarborough, Dept of Chemistry, Dept of Physical and Environmental. Sciences; K. Goss, Helmholtz Centre for. Environmental Research UFZ, Dept of Analytical Environmental Chemistry. Predictive methods are required to develop and design green and sustainable chemistry to reduce potential risks as a result of chemical exposure. Overall degradability of a chemical in the environment is a key determinant of chemical exposure, and thus potential risk. Overall degradability in the environment is a function of chemical partitioning in the physical compartments of the environment (i.e., multimedia distribution in air, water, soil and sediment) and the rates of degradation in the physical compartments of the environment. Depending on the chemical usage, mode of emission to the environment, and qualities of the receiving environment, a chemical may have a different environmental fate and therefore different overall degradability. Using a combination of multimedia mass balance exposure models and quantitative structure activity relationships (QSARs) a set of structural features are identified that have a high susceptibility to degradation regardless of the their mode of emission. QSARs are developed for a number of different abiotic and biotic transformation processes using Iterative Fragment Selection (IFS). IFS is an integrated method of generating QSARs that includes dataset splitting, descriptor generation and model selection which requires no a priori knowledge (e.g., expert judgement) for the selection of chemical descriptors (fragments). A number of structural features in the form of fragments are identified that cause a contaminant to have a high potential for degradability from multiple degradation pathways.

690 Incorporating Risk(s) in Environmental Ranking and Scoring of Chemical Ingredients S. Thakali, K.R. Reid, T. Verslycke, M. Sharma, Gradient. Numerous ranking and scoring approaches for evaluating and assessing chemicals and products have been developed to help identify 'greener' alternatives. These approaches have been modified and improved such that they are now increasingly applied to chemical ingredients in consumer products. Some of these tools evaluate chemicals via qualitative, hazard-based criteria, while others are used for ranking and priority-setting; still others seek to "label" consumer products based on human health and ecological risks. However, many of these scoring and ranking frameworks generally do not explicitly consider potential risk(s) because they fail to integrate both hazard and exposure from typical product use. We have reviewed several available ranking and scoring tools and developed a risk-based approach to evaluate the relative environmental safety of surfactants widely used in personal care products (PCPs), in household laundry products, in domestic and industrial cleaners, and in a variety of industrial applications. In our application of various approaches for scoring and ranking these widely used surfactants, we used readily-available environmental fate/exposure and hazards data. We will present a review of several chemical/product ranking and scoring frameworks, and compare and contrast the results of the applications of various approaches--including our proposed risk-based approach--to score and rank environmental safety of these widely used surfactants.

691 Green Organocatalysis N. Gathergood, Dublin City Univ, Dublin City Univ, School of Chemical Sciences, Dublin City Univ, Chemical Sciences; T. Hayes, Dublin City Univ, School of Chemical Sciences and National Institute for Cellular Biotechnology. Enantiopure compounds are of great importance to the chemical industry especially as pharmaceuticals. One strategy in synthesizing enantiopure compounds involves the use of asymmetric catalysts such as organocatalysts. These catalysts are small chiral organic molecules used in substoichiometric amounts to promote organic reactions. However, for organocatalysts to be classified as green reagents, their toxicity and biodegradation needs to be assessed. For instance, polycyclic aromatic hydrocarbons, known pollutants, are to be found in the structure of chiral phosphoric acids and may be a cause for concern. Our efforts are to determine which chiral BINOLs or proline derived organocatalysts are biodegradable and exhibit low toxicity in microbial assays. Herein, we present results from our anti-microbial study of TADDOLs, BINOLs and proline derived organocatalysts. Minimium inhibitory concentration values (MIC) are determined using the microtiter broth dilution assay. The synthesis of a series of polysubstituted BINOLs is also reported.

692 Toxicity of Green Household Product Formulations to Larvae of the Grass Shrimp, *Palaemonetes pugio* J. Miller, E. Dillihay, The Citadel; W. Boyd, Benedict College; J. Weinstein, The Citadel, Dept of Biology. Although it is generally assumed that green products contain individual ingredients that are less toxic to both humans and the environment, little research has been conducted to examine whether or not the overall end product formulations are less toxic to aquatic organisms. This study examined the toxicity of several household green products relative to their conventional counterparts. Using the larvae of the daggerblade grass shrimp (*Palaemonetes pugio*), the toxicity of seven green product formulations (Seventh Generation Dishwashing Gel, Green Works All-purpose Cleaner, Green Works Dish Detergent, Earth Options Insect Killer, Tom's Mouthwash, Martha Stewart Bathroom Cleaner, and Seventh Generation Laundry Detergent) were determined and compared to that of categorically equivalent conventional product formulations. All of the products were assessed using 48-hour toxicity tests; the results of these tests were statistically analyzed in order to determine median lethal concentrations (LC50s), and then compared to one another using an LC50 ratio test. Of the seven categories of household products tested, in only two cases was the green product formulation less toxic than both tested conventional product formulations. In four cases, the green product was equally toxic compared to at least one tested conventional product. And, in one case, the tested green product was more toxic than both tested conventional products. Research examining the relative toxicity of these same product formulations following biodegradation will also be discussed. This research demonstrates that green consumer product formulations are not necessarily less toxic than their conventional counterparts. These results also suggest that the toxicity of end product formulations should be considered in the overall green product evaluation framework.

693 Effects of the Massachusetts Bay Sewage Outfall on Soft-bottom Benthos Assessed Using Canonical Ordination and an Evaluation of Pollutant Indices E. Gallagher, A. Evgenidou, Univ Of Massachusetts Boston, Environmental, Earth & Ocean Sciences; K. Keay, Massachusetts Water Resources Authority; J. Blake, N. Maciolek, AECOM; D. Dahlen, Battelle New England. We assessed the effects of the MA Bay sewage effluent outfall on MA Bay infaunal benthos using canonical ordination of chord-normalized expected species shared (CNESS) faunal dissimilarities. This ordination, called CPCA-H, is based on transforming species abundances to hypergeometric probabilities and offers an ecologically meaningful alternative to CANOCO's ordination of chi-square distances. Triplots indicate that depth, total organic carbon and % fines are the major determinants of benthic community structure and that the outfall had little effect on benthic community structure. The outfall's discharge increased the concentrations of

Clostridium perfringens spores, a sewage tracer, in depositional areas near the outfall, and our CPCA-H found a positive association of these spores and the abundances of three polychaete species: *Mediomastus californiensis*, *Tharyx acutus*, and *Aricidea catherinae*. Our MA Bay canonical ordination allows us to evaluate several widely used pollution indices based on the pollution sensitivity of infaunal species. Canonical ordination and inverse analysis using ter Braak & Juggins' C2 program allow us to determine the association between infaunal species abundance and pollutant gradients and to assign pollutant scores and tolerances for individual species. As a related measure of pollutant impacts using hypergeometric probabilities, we've found Fisher's alpha and Hubbell's theta provide strong indicators of long-term changes in community structure and departures from the expected evenness based on these species abundance distributions can be an effective tool for identifying impacted benthic communities using Sanders-Hurlbert rarefaction.

694 Effects of Sewage-impacted Sediments on Growth and Reproduction in the Benthic Crustacean *Leptocheirus plumulosus* A. McElroy, Stony Brook Univ, School of Marine and Atmospheric Sciences; A. Zulkosky; L. Ferguson, Duke Univ, Civil and Environmental Engineering; B. Brownawell, Stony Brook Univ, School of Marine and Atmospheric Sciences. Sediments serve as a major source and sink for hydrophobic chemicals in aquatic ecosystems, and in urban areas as a repository for a suite of sewage derived contaminants. This study was undertaken to assess the toxicity of sediments from two heavily sewage impacted urban sites, Boston Harbor, MA and Jamaica Bay, NY. As the detergent breakdown product nonylphenol (NP) and its ethoxylated precursors (NPEOs) have been found to be present at extremely high concentrations in Jamaica Bay, we measured levels of these contaminants as well as another sewage marker, *Clostridium perfringens* spores in sediments from both sites, and also compared the toxicity of sediments from these sites to those from a reference site dosed with NP. Growth, reproduction, and survival endpoints in the benthic amphipod, *Leptocherius plumulosus*, exposed to field collected or NP dosed sediments were used for toxicity assessment. Sediments from Jamaica Bay had higher levels of NP and NPEOs than sediments from Boston Harbor, but had more similar levels of *C. perfringens* spores. Boston Harbor sediments were not significantly toxic in any endpoint measured (10-day adult mortality, or 28-day reproductive output or average growth), while one of the Jamaica Bay sites, Bergin Basin, was acutely toxic in 10 day adult tests, and the other, Grassy Bay, led to significant reductions in reproductive output after 28 days. Experiments with NP dosed sediments determined the 10-day LC50 to be 150 µg/gdw with no reproductive or growth effects quantified as sediment concentrations as high as 60 µg/gdw). Sediments examined in this study were collected in 2000, almost a year after the sewage outfall in Boston Harbor was relocated to Massachusetts Bay. The reduced levels of NP and NPEOs and sediment toxicity observed, indicate levels and impacts of sewage-derived contaminants may already have been decreasing at that time, and demonstrate sediment toxicity in Boston Harbor at that time was less than that observed in another urban estuary with continuing sewage inputs, Jamaica Bay. This study was supported by the Massachusetts Environmental Trust.

695 The Relationship Between Improved Sediment Quality and Indicators of Flounder Health in Boston Harbor C.D. Hunt, Battelle; M. Moore, Woods Hole Oceanographic Institute; D. Dahlen, Battelle; M. Hall, Massachussetts Water Resourcce Authority. Loading of contaminants to Boston Harbor has been reduced through harbor cleanup initiatives implemented over the past thirty years. The 1972 Clean Water Act and other factors such as the recession in the 1980's reduced the effects from inefficient industrial treatment and discharge practices. The Massachusetts Water Resources Authority Harbor Cleanup project with its excellent and aggressive source reduction program, removal of sewage sludge discharge, commissioning of primary and secondary sewage treatment, and offshore discharge continued the improvements through the 1990's and early twenty-first century. These reductions have demonstrably improved the quality of surface sediments in the harbor. The improved quality of Boston Harbor is also evident in the recovery of the health of a major living resources (e.g., winter flounder) of the Harbor and a general reduction in contaminant levels in fish and shellfish resources in the system. Moreover, the high prevalence of liver neoplasm (tumor) in winter flounder (*Pseudopleuronectes americanus*) collected from Boston Harbor in since 1984 show a steady decrease as do concentrations of organic contaminants. The prevalence of Centrotubular Hydropic Vacuolation (CHV), a precursor to liver tumors has also declined in the harbor and is presently half of what they were during the early 1990s. This paper explores the relationship among the improved sediment quality and the decreasing CHV trend.

696 Estimating Narcosis Potential in Boston Harbor Sediments Using Passive Samplers and Two-dimensional Gas Chromatography A. Tcaciuc, Massachusetts Institute of Technology, Civil and Environmental Engineering; J.K. MacFarlane, Massachusetts Institute of Technology, Dept of Civil and Environmental Engineering; M. Nipper, Texas A&M Univ-Corpus Christi, Center for Coastal Studies; R.K. Nelson, Woods Hole Oceanographic Institution, Dept of Marine Chemistry and Geochemistry; R. Carr, USGS CERC, Marine Ecotoxicology Research Station; J. Biedenbach, USGS/BRD, Marine Ecotoxicology Research Station; C.M. Reddy, Woods Hole Oceanographic Institution; P.M. Gschwend, Massachusetts Institute of Technology, Dept of Civil and Environmental Engineering. Sediments from around Boston Harbor always exhibit contamination with polycyclic aromatic hydrocarbons (PAHs) and many other hydrophobic organic chemicals (HOCs) as a result of commercial shipping, urbanization, and/or industrial activity. While individual contaminants may exhibit specific toxic modes of action, all HOCs contribute to toxicity through a common baseline narcosis mechanism. HOCs are usually present in the environment as complex mixtures; but toxicity assessments so far, tend to focus on a certain subset of identifiable chemicals with known toxic effect concentrations. Here we propose a method to determine the integrated narcosis toxicity due to all the HOCs present in contaminated sediments. For that we make use of the fact that narcosis is nonspecific, additive, and thought to occur beyond critical body burdens of approximately 0.01 g HOCs/g of lipid. By using polyethylene samplers and two dimensional gas chromatography, coupled with flame ionization detector (GCxGC-FID), we have developed a methodology to estimate the total load of HOCs in the lipids of organisms living in a contaminated sediment. Previous research has shown that GCxGC retention times can be used to predict chemical properties such as aqueous solubility and K_{ow}. With appropriate training set, we have extended this capability to the prediction of the partition constants between the polyethylene sampler and water (K_{PEW}) and phospholipids and water (K_{PLW}). We then use these partition constants and the relatively constant response factor of the FID, to calculate the corresponding membrane lipid concentration for each compound detected in the GCxGC analysis of a polyethylene sampler equilibrated with the sediment of interest. The total lipid load is then calculated by summing the contributions from individual compounds. We have applied this narcosis calculation to polyethylene sampler extracts from five sites around Boston Harbor. The estimated integral HOCs lipid loads were lower than the proposed narcosis threshold of 0.01g/g of lipid, which was in general agreement with toxicity results from fertilization and embryo development tests. Overall, this analyses of the sediments does not indicate that narcosis toxicities would be expected.

697 Nutrient Input and Competition of Phaeocystis and Diatoms in Massachusetts Bay Spring Bloom M. Jiang, Univ Of Massachusetts Boston, EEOS; D. Borkman, Univ of Rhodes Island; S. Libby, Battelle Memorial Institute; D. Townsend, Univ of Maine; M. Zhou, Univ Of Massachusetts Boston. The phytoplankton community in Massachusetts Bay has displayed dramatic long-term changes and inter-annual variability in the last two decades, with increasing strong *Phaeocystis* (*Phaeocystis pouchetti*) blooms and generally opposite fluctuations in diatom abundances. A new ecosystem model has been developed for Massachusetts Bay to explicitly simulate the *Phaeocystis* dynamics. Model results and an analysis of data collected during the same period suggest that the changes of nutrient conditions play a critical role in controlling the competition between diatoms and *Phaeocystis*. A series of idealized simulations of the model also show long-term trends and inter-annual variability of *Phaeocystis* and diatom biomass that are highly correlated with the observed phytoplankton abundances. These results are further interpreted with the resource competition theory. Using long-term environmental data, we also explore the key drivers for these phytoplankton changes in Massachusetts Bay spring bloom.

698 The Mechanisms Behind the Decreasing Metal Concentrations in the Surface Sediments of Boston Harbor L.H. Kalnejais, Univ of New Hampshire, Earth Science Dept; W.R. Martin, Woods Hole Oceanographic Institution, Marine Chemistry and Geochemistry; M.H. Bothner, US Geological Survey, Woods Hole Field Center. The concentrations of silver, lead and copper in the sediments of Boston Harbor have decreased by about

50% between 1978 and 2010. This observation motivated a comprehensive study to understand how geochemical environment, seasonal cycles and sediment resuspension influence the exchange of metals between contaminated sediments, porewater, and overlying bottom water. High-resolution (3 mm) profiles of metals in porewater and sediments were collected at two contrasting sites. The first site, in Boston Harbor, received inputs of contaminants from Boston's sewage outfalls until 2000. The second site, in Massachusetts Bay, is less impacted. At both sites there is a diffusive flux of copper to the water column throughout the year, while silver is released only in winter and lead is never released diffusively. This distinct seasonal pattern is controlled by the competition between processes releasing and removing metals in the shallow porewaters. Metals are released to the porewaters when rapid reactions break down the phases that carry the metals to the sediments and when authigenic sulfides are mixed into the oxic layer and oxidized. On the other hand, dissolved metals are removed from solution by scavenging by iron oxyhydroxides. Deeper in the sediments, dissolved metals are removed by the formation of sulfide minerals. The relative importance of each of these processes differs at each site and between seasons, and determines if there is a diffusive release of metals from the sediments. The release of metals due to sediment resuspension was determined with erosion chamber experiments coupled to hydrodynamic model results. The annual quantity of solid-phase metals resuspended is greater than the river inputs of metals to the Harbor. The dissolved metal release from sediments, due to both sediment resuspension and diffusion is more than 10% of the total (dissolved plus particulate) metal input from rivers. These results indicate that contaminated sediments remain as a continuing and significant source of metals to the water column of the Harbor. We are applying our quantification of metal release mechanisms with data on changing inputs to the Harbor to understand the decreasing metal concentration in the sediments with time. Furthermore, we are continuing to develop models of the long-term behavior of sediment metals and the influence of the sediments on the water quality of Boston Harbor.

699 Three-dimensional Modeling of Cu and Pb Distributions in Boston Harbor and Massachusetts Bay L. Li, First Institute of Oceanography, State Oceanic Administration; M. Jiang, Univ of Masschusetts Boston; F. Pala, Battelle; G. Wallace, Univ Of Massachusetts Boston. The transport and distribution of dissolved Cu (Cudiss) and Pb (Pbdiss) in Boston Harbor (BH), Massachusetts Bay (MB) and Cape Cod Bay (CCB) were simulated by integrating trace elements into an existing 3-D hydrodynamic model. Despite cessation of discharge from a major treatment plant in 2000 and concurrent reduction in metal loading, Cudiss and Pbdiss concentrations in the Harbor remained relatively unchanged since the early 1990s. In contrast, the original modeled results in BH only recovered ~ 10% of the observed current standing stock of Cudiss and ~ 20% of Pbdiss in 2002. It is proposed that the previously contaminated sediment of the Harbor may be currently the major source of these metals to the Harbor. Based on the comparison between modeled results and observational data in the Bays, Cudiss can be simulated as a conservatively transported tracer, while a first-order scavenging process needs to be incorporated in the Pb model. Particulate organic carbon (POC) extracted from a water quality model was employed as the sorption and scavenging matrix for particulate Pb. Sensitivity analyses were also conducted to evaluate the importance of each source and sink for Cudiss and Pbdiss in the Harbor and Bays.

700 Validation and Application of a Chemical Equilibrium Model for the Prediction of Free Copper Ion Activity in Boston Harbor and Massachusetts Bay F. Pala, Battelle; L. Li, First Institute of Oceanography, State Oceanic Administration; G. Wallace, Univ Of Massachusetts Boston, EEOS. The prediction of metal bioavailability in aquatic systems is strictly related with the ability to accurately measure and model free metal ion activity ({Me(n+)}) and metal speciation in aquatic systems. A Sediment Chemical Equilibrium Model (SCEM) was proposed by Wallace G. to describe the interdependence among ambient {Me(n+)}, surface sediment organic carbon (OCsed), and non-crustal metal sediment (Me_nc) concentrations in Boston Harbor and Massachusetts and Cape Cod Bays for a variety of metals (Cu, Zn, Pb, Cd, Ag, Hg, Ni). The SCEM interprets the sequestration of metal ions by oxic marine sediment by a surface complexation equilibrium process where sediment OCsed serves as a surrogate for binding ligand concentration, and {Me(n+)}, is linked to OCsed-normalized Me_nc by an apparent adsorption equilibrium constant (β*CuSed). The SCEM was validated for the case of Cu by isotherm adsorption titration of slurries of surface (0-1 cm) sediment, collected from various geographic locations and characterized by a range of OCsed and metal concentrations. Interpretation of the isotherm adsorption curves by the SCEM provided an average log β*CuSed of 8.9 ± 0.2 (95% CL) and showed no statistical evidence that β*CuSed changes with sample location or sedimentary organic carbon concentration. The application of the SCEM to Boston Harbor and Massachusetts Bay sediment composition data collected during the past two decades allows for the reconstruction of free copper ion activity, and therefore bioavailability of copper, in the study region.

701 Analysis of Oral Lead 1, 2, and 3 Pellet Exposure in Northern Bobwhite Quail: A 56 Day Study R. Gogal, Univ of Georgia, College of Vet Med, Anatomy and Radiology; R. Kerr, J. Holladay, Univ of Georgia, Anatomy and Radiology; L. Tannenbaum, US Army Public Health Command, Environmental Health Risk Assessment Program, US Army institute of Public Health; B. Meldrum, Virginia Tech, Biomedical Sciences and Pathobiology; S. Williams, Univ of Georgia, Poultry Diagnostics and Research Center; S. Holladay, Univ of Georgia, Anatomy and Radiology. We recently reported in a 28 day study that acute oral lead (Pb) pellet (#9 shot) exposure in Northern Bobwhite quail resulted in significant toxicity in birds ingesting 5 Pb pellets or greater. Birds that received a single lead pellet showed no overt clinical signs of toxicity, but had sustained depressed plasma δ-aminolevulinic acid dehydratase (d-ALAD) activity. In the present study, bobwhite quail, fed the same seed-based diet, were orally gavaged once with Pb spent shot (0, 1, 2 and 3 pellets/bird) and evaluated for 56 days for changes in feed consumption, weight gain, peripheral blood Pb levels and physiology, renal, immune and gastrointestinal parameters. Birds in the 3-pellet group showed a significant decrease in weight gain that did not correlate with feed consumption. Mean blood Pb levels increased proportionately to the number of pellets ingested at 7 days post exposure. Similar to the previous study, male blood lead levels were significantly higher compared to the females up to 14 days post exposure. These Pb blood levels declined weekly but remained elevated throughout the study according to baseline data. Similar to the previous study, the δ-aminolevulinic acid dehydratase (d-ALAD) activity decreased significantly in all Pb pellet-treated birds, began to recover in the males but remained lower than controls. Blood hematology, immune cytology and the other endpoints were not remarkable. The results of this study support our previous findings with regards to the 1 pellet birds and extend it by showing that birds exposed to 2 and 3 pellets, although becoming transiently moribund, began to show clinical signs of recovery 2 months post exposure.

702 Arsenic Speciation in Snowshoe Hare (*Lepus americanus*) from Yellowknife, Northwest Territories, Canada J. Dee, Royal Military College of Canada; I. Koch, K. Reimer, Royal Military. College of Canada, Environmental Sciences Group. Yellowknife, Northwest Territories, is an excellent study site for arsenic speciation in terrestrial mammals because of naturally elevated levels of arsenic in soil as well as local contamination from gold mines in the city. The objective of the present study was to determine arsenic uptake and metabolism in terrestrial animals that are exposed to mostly toxic inorganic arsenic species in their diets. Snowshoe hare (*Lepus americanus*) was targeted because it is a commonly studied ecological receptor, and it is also a potential source of country food to local residents. Hares were collected from contaminated and uncontaminated sites, dissected on site, and their tissues were analysed for arsenic speciation and total arsenic via high-performance liquid chromatography-inductively coupled plasma-mass spectrometry and also using x-ray absorption near edge structure analysis at the Canadian Light Source in Saskatoon, Saskatchewan. Hares collected from contaminated areas had substantially higher arsenic body burdens than hares collected from background areas. Dimethylarsinic acid was the main arsenic species found in tissues from hares collected during spring and early summer periods and arsenite (a toxic form of arsenic) was present in a minor amounts. The formation of DMA in hares is not unexpected and is a metabolite in other mammals, including humans. However we also identified arsenobetaine, a non-toxic arsenic compound with a more complex chemical structure [(CH3)3As+CH2COOH], as the major species in one hare (collected in the fall) and as a minor species in two others (one of which was collected in the spring while the other was collected in the fall). Arsenocholine (also non-toxic, [(CH3)3As+CH2CH2OH]) was also identified as a minor constituent in some of the tissues from hares collected during the spring. The arsenobetaine found in the fall-collected hare may have been ingested in mushrooms, which would have been an available food source

during the collection period. Arsenic species in the stomach contents were similar to those in tissues, reinforcing the hypothesis that hare are ingesting the arsenobetaine rather than producing it. Arsenocholine was not identified in the stomach contents but it may be a metabolite of arsenobetaine. Both compounds are excreted readily from mammals in laboratory studies and thus their retention in the hare tissues is unexpected and warrants further research.

703 Direct Uptake and Trophic Transfer of Tungsten into a Gastropod and Plant A.J. Kennedy, US Army Engineer Research and Development Center; J. Lindsay, US Army Engineer Research and Development Center, Environmental Laboratory; A.J. Bednar, US Army Engineer Reseach and Development Center; D.R. Johnson, US Army Engineer Research and Development Center, Environmental Laboratory; J. Seiter, US Army Corps of Engineers, Research Physical Scientist; R. Boyd, P. Allison, T. Rushing, US Army Engineer Research and Development Center. Tungsten (W) was purported to be a green alternative to lead for munitions, kinetic energy penetrators and canister rounds. However, incidents in Nevada and Massachusetts have led to greater scrutiny on the lack of knowledge-based regulations for W. Previous studies have indicated tungsten in soil bioaccumulates in plant tissue. In the current study, we employed cabbage (*Brassica oleracae*) and a terrestrial snail (*Otala lactea*) to determine the toxicity, bioavailability and food chain mobility of W via direct exposures to contaminated substrate and trophic exposures. Dermal exposure to the more bioavailable tungstate species (WO4) indicated more W bioaccumulated in the snail hepatopancreas (152 W/kg) relative to the foot (20 mg W/kg), resulting in a lethal median residue (LR50) of 80 (52 – 123) mg W/kg. A more environmentally realistic exposure to soil spiked with W powder that was aged for four years to allow polymerization (tungstate, polytungstates) was also conducted applying both a concentration gradient of W (range: 0 to >7000 mg/kg) and a single concentration (550 mg W/kg) involving temporal tissue sampling. Results indicated dose-dependent toxicity and bioaccumulation for both cabbage and snails. Kinetic models indicated steady state concentrations of 287 and 34 mg/kg for the cabbage and snail, respectively. Bioaccumulation factors (BAFs) indicated cabbage (BAF = 0.55) bioaccumulated W more efficiently than the snail (BAF = 0.06) through the dermal exposure route. However, snail bioaccumulation efficiency greatly increased (86 mg/kg; BAF = 0.36) when consuming contaminated cabbage. Synchrotron mapping revealed W bioaccumulation in both cabbage veins and leaf tissue and within snail hepatopancreas, mantle and shell nacre. Metal incorporation into the calcium carbonate gastropod shell may advance metals biomonitoring at contaminated sites.

704 Effects of Zinc on Survival and Zinc Uptake in Florida Apple Snails (*Pomacea paludosa*) in an Outdoor Microcosm Study T.C. Hoang, Florida International Univ, Southeast Environmental Research Center/Dept of Environ Study, Loyola Univ Chicago, Center for Urban Environmental Research and Policy; G. Rand, Florida International Univ, Ecotoxicology & Risk Assessment. Zinc (Zn) is an essential element for aquatic organisms. However, depending on water quality, zinc may become toxic at elevated concentrations. Although research has been conducted to characterize Zn uptake and potential transfer through the food chain in aquatic ecosystems, most studies have been conducted with standard test organisms. Florida apple snails (*Pomacea paludosa*) are a key species in the Everglades Ecosystem and the main food source of many higher trophic organisms. To our knowledge, research on Zn uptake in apple snails has not been conducted. Earlier studies in our laboratory concluded that *P. paludosa* accumulated Cu in tissues up to 2800 mg/kg, which may pose a risk to snail predators. The present study characterized Zn uptake in *P. paludosa* in an outdoor microcosm system. In a 100 exposure day study, snails were exposed to five Zn treatment concentrations in 800 L polypropylene tanks that contained 600 L water and 40 L of sediment. Water was spiked with Zn one or two times per week to maintain Zn concentrations. Snails and water samples were collected every two weeks for tissue and water chemistry analyses. Results of this study indicated that Zn affected apple snail survival. After two weeks of exposure, 100% mortality occurred in the highest Zn treatment concentrations (750 µg/L dissolved Zn). The LOEC following 100 days of exposure was 160 µg/L dissolved Zn. Apple snails accumulated high Zn concentrations, especially in the snail viscera. Zn concentrations in the snail foot and viscera increased with exposed time and followed first order kinetics. Zn concentrations in the snail foot and viscera were 858 mg/kg and 23,816 mg/kg dw, respectively. Zn concentrations in the snail shell were less than 200 mg/kg dw. For snail foot, there was a strong positive correlation for Zn concentrations in water and tissue. However, snail foot tissue Ca and Mg concentrations were negatively correlated with water Zn concentrations. Snail foot tissue Zn concentration was also negatively correlated with snail foot tissue Ca and Mg concentrations. These results indicate that Zn inhibited Ca and Mg uptake in the snail foot tissue. This is in agreement with the literature that Zn inhibits Ca uptake in aquatic organisms. However, inhibition of Zn on Mg uptake has not been demonstrated in the literature. Our earlier study also found that Cu inhibits Mg uptake in apple snails

705 Human Contamination Status and Health Effects of Pb in Lead Battery-Recycle Area, Vietnam S.H. Hirata, Tottori Univ, Dept pf Regopnal Environment; K. Komori, F. Horiuchi, Ehime Univ Graduate School for Medicine, Dept of Neuropsychiatry, Neuroscience; T. Noguchi, T. Itai, S. Takahashi, Ehime Univ, Center for Marine Environmental Studies (CMES); P.H. Viet, Hanoi Univ of Science, Vietnam National Univ; L. Khanh, Central Military Hospital 108, Clinical Research Institute 108 for Medical and Pharmaceutical Sciences; S. Tanabe, Ehime Univ, Center for Marine Environmental Studies (CMES). In recent several years, we have monitored Pb contamination in human and environmental samples from a lead battery-recycle area, Dong Mai, Vietnam. In the blood samples of a study in 2007, mean Pb level in Dong Mai people was found to be 31.1ug dL-1 (normal range: < 10 ug dL-1). Blood Pb levels in more than 95% of the donors exceeded 10 ug dL-1, which can cause mild toxic symptoms such as decline of heme-synthase activity. In addition, Pb levels in about 50% of the donors exceeded 40 ug dL-1, which can manifest neurobehavioral disorders. These results suggest that serious Pb pollution exists in Dong Mai. In 2010 sampling, to evaluate health effects on adults in Dong Mai, we executed Mini-Mental State Examination (MMSE), a neurobehavioral test, and found that orientation, long-term memory, attention and concentration in Dong Mai people were defective than in other areas. Moreover, we took MRI images of two adult men whose blood Pb levels were 107 ug dL-1and 75 ug dL-1. In these MRI findings, encephalopathy due to Pb poisoning was noticed in the donor with 107 ug Pb dL-1 level. In order to assess health effects on children in Dong Mai, we took hair, blood and urine samples from them, and executed psychopathological test (Strength and Difficulties Questionnaire: SDQ) in the survey conducted in 2011. Total SDQ score in Dong Mai children was higher than in the general trend in Vietnam and other countries. This result indicates that disorders in behavior are more serious in Dong Mai children than in others. The present study clearly revealed that pollution related diseases by Pb do exist in Dong Mai, and health effects by Pb poisoning on people, particularly children are apprehensive. Continuous monitoring and risk assessment of the people, epidemiological research, and measures to improve the labor environment for the workers and people are necessary in Dong Mai.

706 Including Metal Speciation in LCA: Choosing the Appropriate Regionalization Scale G. Plouffe, Ecole Polytechnique de Montreal, CIRAIG; C. Bulle, CIRAIG, Ecole Polytechnique de Montreal, Chemical engineering Dept; L. Deschenes, CIRAIG, Chemical Engineering. Ecotoxicological impacts are sometimes difficult to consider in life cycle assessment (LCA) because they affect local environments surrounding emission sources and thus require data not always available. This is particularly true for metals, because their toxicity depends largely on speciation, which in turn, is closely related to physico-chemical properties of the environment. Recently, the use of freshwater archetypes has been suggested to account for the influence of freshwater physico-chemical properties on metal speciation in LCA. Although really interesting, this approach is not necessarily applicable to soils because soils heterogeneity is much greater than for freshwater environments. The most influent soil physico-chemical characteristics often covary and are not easily definable. The main goal of this project is thus to determine a regionalization scale for soils that encompass the local parameters influencing metal speciation and large enough to be applicable to a global method like LCA. The Harmonized World Soil Database version 1.1 (Nachtergaele et al., 2009) was used to define soil archetypes according to five influent soil physico-chemical parameters on metal speciation, chosen on the basis of a literature review. The selected parameters are: soil pH, soil texture (clay and sand content), organic and inorganic carbon contents. Intervals for each soil parameter were created and each archetype was attributed a combination of these intervals. For example, archetype 1 includes all soils with low pH, low clay, low sand, low inorganic and low organic carbon contents. The definition of soil archetypes is validated

using at first commercially available speciation models (WHAM 6.0 and MINEQL+) and will be confirmed with a new speciation model developed specifically for soils in this project. Using the new regionalization scale here defined, new characterization factors with quantified spatial variability will be obtained for Zn, Ni and Cu for terrestrial ecotoxicity. Preliminary results show that it is possible to group soils of the world in forty-two archetypes and account for five soil physico-chemical parameters (pH, clay and sand content, organic and inorganic carbon), a scale that could be adequate for its implementation in LCA.

707 Metallomics of Wildlife: An Approach to Understand the Mechanism of Mercury Detoxification T. Agusa, Dept of Legal Medicine, Shimane Univ Faculty of Medicine, Shimane Univ, Center for Marine Environmental Studies (CMES), Ehime Univ, Ehime Univ; T. Ikemoto, Center for Marine Environmental Studies (CMES), Ehime Univ; T. Kunito, Shinshu Univ; S. Yasugi, S. Tanabe, H. Iwata, Center for Marine Environmental Studies (CMES), Ehime Univ. Metallomics is developing as an interdisciplinary science to understand the roles and functions of biomolecules that bind to trace elements in biological systems. This field covers chemical speciation, dynamics, and kinetics of trace elements, and is expected to unveil the physiological and pathological mechanisms related to trace elements in animal health and disease. We have investigated Hg accumulation and its detoxification mechanism in marine mammals and seabirds by the approach of metallomics. A significant positive correlation between Hg and Se was observed in the liver of these animals. Concentrations of Hg and Se in the hepatic nuclear/lysosomal/mitochondrial fraction were higher than those in the microsomal and cytosol fractions. With an increase in the concentration of Hg in the nuclear/lysosomal/mitochondrial fraction, extraction efficiencies of both elements by protein extraction agents were decreased and the molar ratio of Hg/Se was close to 1.0, suggesting the formation of Hg-Se complex in a Hg concentration-dependent manner. In the cytosol, a large portion of Hg and Se was detected in the high molecular weight fraction. The equimolar of Hg and Se was observed in the high molecular weight fraction of the liver cytosol that showed high Hg levels, implying that the Hg-Se complex may bind to high molecular weight substances. Further metallomics approach may provide an insight into the mechanism of Hg detoxification.

708 Predicting Exposure of Bat to Soil-associated Heavy Metals B. Hernout, Univ of York, Environment; K. Somerwill, FERA; K. Arnold, C. McClean, Univ of York; V. Grimm, Helmholtz Center for Environmental Research; A. Boxall, Univ of York. Wildlife may be exposed to heavy metals in soils via uptake through the food chain. The accumulated metals may then affect the health of the wildlife species. In this study, we developed a modeling framework to predict the exposure of 14 bat species in the UK to soil-associated heavy metals (Pb, Cu, Zn, Cd) and to determine the potential risks of exposures to bat health. The modeling framework considered exposure to single metals as well as metal mixtures. Our results show that highest exposure occurs around industrial areas, where predicted exposures for several bat species were at a level at which toxicological effects might be expected. Lead was found to be the biggest contributor to risk. A sensitivity analysis of the modeling framework is currently underway and the exposure component of the modeling framework is currently being evaluated using analysis of bat carcasses obtained from a large number of sites distributed across England and Wales. The presentation will explain the model, the results of simulations to date and the findings of the sensitivity analysis. Initial validation data will also be presented.

709 Study of Biodegradable Solvents for the Biorefinery N. Gathergood, Dublin City Univ, Dublin City Univ, School of Chemical Sciences, Dublin City Univ, Chemical Sciences. A wide range of approaches have been investigated for manipulation and conversion of biomass. Of paramount importance in all these methods is the choice of a suitable solvent, (including scCO2, water, or ionic liquids). Due to the large volumes of solvent required in a commercially viable biorefinery, release into the environment is inevitable, whether from vented gasses, water waste, solvent leaching or accidental spills. Our research investigates the development of biodegradable ionic liquids for the biorefinery. Results towards the synthesis of low antimicrobial toxicity and ecotoxicity ionic liquids is presented. While all efforts to recycle solvents are made within the biorefinery, a 'fail-safe' where the ionic liquid on release biodegrades is a worthwhile goal.

710 The Effect of Different Lignocellulosic Pretreatment Methods on Diverse Microbial Consortiums in a Bioprocess Step to Generate Fuel Precursors L.T. Angenent, M.T. Agler, J.J. Werner, Cornell Univ, Biological and Environmental Engineering; S. Heger, Institute for Environmental Research, RWTH Aachen Univ, Institute for Environmental Research, RWTH Aachen Univ, Dept of Ecosystem Analysis; H. Hollert, RWTH Aachen Univ, Institute for Environmental Research, Dept of Ecosystem Analysis, Institute for Environmental Research, RWTH Aachen Univ, Deptartment of Ecosystem Analysis, RWTH Aachen Univ, Inst. for Envrionmental Research; B.S. Dien, L.B. Iten, M.A. Cotta, NCAUR-ARS-USDA, Bioenergy Research Unit. We used diverse microbial consortiums to convert lignocellulosic biomass into short-chain or medium-chain carboxylates, which are important future platform chemicals for bioenergy production. We derived our consortiums from natural sources, and then evolved them via applied environmental conditions to either produce C4 (n-butyrate), C6 (n-caproate), and C8 (n-caprylate) carboxylates. The lignocellulosic feedstocks that are used as substrates must be pretreated to destroy the lignocellulosic matrix with the goal to speed up hydrolysis by the microbes. Within an experimental design that entailed four 5-L bioreactors we tested the effect of three different chemical/physical pretreatment methods (and no pretreatment as the control) on the biological conversion of corn fiber (i.e., a waste product from the corn kernel-to-ethanol industry) into n-butyrate. The three pretreatments were performed in fluidized sand bed reactors at 36% corn fiber w/v in water at 160°C for 20 min with the variations: 1. 0.5 % w/v H_2SO_4 (acid); 2. 1:10 CaO to biomass ratio (base); or 3. hot water only. We performed massively parallel pyrosequencing to examine microbial community dynamics and to link environmental conditions with community changes over the entire 450-day operating period in intervals of < 3 weeks. In addition, we performed an ecotoxicological evaluation by different acute and mechanism specific in vitro biotests. We found differences between the pretreatment methods in regards to their ecotoxicity levels for the resulting biomass solution, which is the substrate for our bioreactors. The pretreatment methods also had a profound effect on the community composition of the microbial consortia in the bioreactors.

711 What's Up Inside the Reactor – Biotests for Risk Assessment of Biofuel Fermentation S. Heger, Institute for Environmental Research, RWTH Aachen Univ, Institute for Environmental Research, RWTH Aachen Univ, Dept of Ecosystem Analysis; K. Bluhm, M. Brinkmann, K. Winkens, A. Schneider, M. Wollenweber, S. Maletz, Institute for Environmental Research, RWTH Aachen Univ; M.T. Agler, Dept of Biological and Environmental Engineering, Cornell Univ; T. Seiler, Institute for Environmental Research, RWTH Aachen Univ; L.T. Angenent, Dept of Biological and Environmental Engineering, Cornell Univ; H. Hollert, Institute for Environmental Research, RWTH Aachen Univ. As a consequence of the increasing use of biofuels and bioenergy as alternative energy sources to replace fossil fuels, there is an urgent need for ecotoxicological evaluation, in particular within processes that are used to gain these alternative energies. Although research in the field of energy sciences was steadily growing during the last years, ecotoxicological data on the intermediates in the fermentation processes have not yet been sufficiently investigated. Thus, a project was initiated to assess the pollutant development by microbial conversion from substrate to end product in cooperation between Cornell Univ and RWTH Aachen Univ. Cornell Univ works on the conversion of lignocellulosic wastes into n-butyrate, which can be further converted to the liquid biofuel n-butanol in a subsequent fermentation step. To ensure sufficient biological breakdown, lignocellulosic materials are pretreated with several different techniques, such as hot water acid and hot water base treatment. This process, however, has a known disadvantage of generating toxic compounds, which can inhibit microbial cultures that are grown in down-stream bioprocesses. Undefined mixed cultures may destroy the toxic compounds, which would prevent inhibition of these microbial cultures. However, if intermediates are not degraded they are assumed to be of ecotoxicological relevance due to possible release into the environment. In this approach, we want to meet this hypothesis applying a battery of acute and mechanism specific in vitro biotests. Biological analysis will focus on different pretreated and untreated substrate samples, as well as on complementary effluent samples. In detail, cytotoxicity will be assessed using the neutral red retention assay, and Ah receptor agonist activity will be detected with the EROD assay, both using RTL-W1 cells. In addition endocrine activity will be determined in the yeast endocrine screen (YES) assay and embryotoxicity by means of the fish embryotoxicity test (FET). Further biotests are considered.

Finally, toxic impacts of effluents resulting from the production process will be assessed.

712 Chemical and Ecotoxicological Analyses of the Water-soluble Fractions of Neat Biodiesel, Diesel and Biodiesel/Diesel Blends S.A. Pereira, Federal Univ of Bahia, Dept of Biology; V.Q. Araujo, Federal Univ of Bahia; M. Reboucas, F. Vieira, M. Almeida, Braskem; F. Chinalia, Cranfield Univ; I.A. Nascimento, Federal Univ of Bahia, Dept of Biology. Biodiesel is considered less toxic than diesel, but the comparison is mostly based on gaseous emissions. Little information is available regarding the potential toxic effects of different biodiesel/diesel blends when reach water bodies and/or groundwater. The aim of this study is to evaluate and compare the toxic properties of the water-soluble-fraction (WSF) obtained from diesel, biodiesel and biodiesel/diesel blends. The hypothesis is that biodiesel is less toxic than diesel, imposing, therefore, less impact in the case of environmental contamination after leaks and/or spills. Aromatics are present in the diesel-WSF. This study showed that their concentration correlated positively with increasing ratios of diesel. On the other hand, biodiesel can interact with any aqueous matrix and generate methanol, which is toxic. Highest methanol concentration was observed in biodiesel-WSF, but little concentrations were also found in blends. WSF toxicity tests were carried out using marine and freshwater microalgae. Diesel alone showed to be more toxic than all the tested blends and biodiesel. Depending on the tested blends and microalgae species, the WSF concentrations inhibiting culture growth in 50% (IC50), varied from 6.6 to 81.4%. Methanol showed to be toxic, but seemed to not synergistically increase the toxic effect of aromatics in the WSF. The results support the hypothesis that blending biodiesel with diesel is an effective strategy for reducing environmental impact caused by accidental spills or leakages.

713 Two Potential Biofuels in an Ecotoxicological Investigation K. Bluhm, Institute for Environmental Research, RWTH Aachen Univ, Deptartment of Ecosystem Analysis, Instit.for Environm.Research, RWTH Aachen Univ., Dept of Ecosystem Analysis; S. Heger, Institute for Environmental Research, RWTH Aachen Univ; J. Loerks, T. Seiler, Institute for Environmental Research, RWTH Aachen Univ, Dept of Ecosystem Analysis; A. Schaeffer, Institute for Environmental Research, RWTH Aachen Univ, Chair of Environmental Biology and Chemodynamics; H. Hollert, Institute for Environmental Research, RWTH Aachen Univ, Deptartment of Ecosystem Analysis. The interest in biofuels for the transport sector increased within the last years. Biofuels are considered renewable alternatives with the benefits of reduced dependence on fossil fuels and a potential to slow down the effect of global climate change due to decreased greenhouse gas (GHG) emissions. Consequently, biofuel production increased dramatically in recent years. Growing production capacities and the associated rise in biofuel consumption also increased the risk of a release into the environment. However, comparatively little knowledge on (eco)toxicological effects of biofuels are available. In this study we investigated the potential risks of selected substances derived from biomass and with promising properties for the use in combustion engines (ethyl levulinate and 2-MTHF). The substances were compared to water accommodated fractions of a fossil diesel fuel using assays on the acute aquatic toxicity and biotests to reveal mechanism-specific effects. First results revealed practical problems with the investigation of these materials (e.g., due to their low pH-value and rapid corrosion of pipette tips and microplates) as well as indications for adverse impacts on the organisms or cell cultures tested. 2-MTHF revealed a lower toxic potential in the fish embryo toxicity (FET) test with zebrafish and the cytotoxicity test using RTL-W1 cells than ethyl levulinate. In addition, a statistically significant effect on the development of the head length in zebrafish embryos was observed for ethyl levulinate even at 40 mg/L, the lowest test concentration. The Ames fluctuation assay gave no mutagenic potential for both 2-MTHF and ethyl levulinate. In conclusion, the results reveal a potential hazard of these substances and further investigations of potential biofuels or biofuel components are essential to provide a basis for identifying alternative fuels with low environmental impact. Acknowledgement: This work was performed as part of the Cluster of Excellence "Tailor-Made Fuels from Biomass", which is funded by the Excellence Initiative by the German federal and state governments to promote science and research at German universities.

714 Understanding Resilience in Coupled Industrial-Ecological Systems T. Seager, Arizona State Univ, School of Sustainable Engineering & Built Environm; J. Park, P.C. Rao, Purdue Univ; D. Mu, U Minnesota, Twin Cities. The recent investment boom and collapse of the corn ethanol industry calls into question the long-term sustainability of traditional approaches to biofuel technologies. Compared with petroleum based transportation fuels, biofuels production systems are more closely connected to complex and variable natural systems. Especially as biofeedstock production itself becomes more independent of fossil fuel-based supports, stochasticity will become an increasingly important inherent feature of biorefinery systems. Accordingly, a fundamental change in design philosophy is necessary to ensure the long-term viability of the biorefinery industry. To respond effectively to unexpected disruptions, the new approach will require systems to be designed for resilience, as well as for risk. However, quantitative tools for understanding the resilence of alternative fuel technologies are poorly developed, if available at all. This presentation describes the distinction between risk management and resilience approaches, especially as applied in the context of the biorefinery supply chain, and proposes a novel approach to assessing the resilience of biorefinery systems in terms of their stability to exogenous shocks.

715 Fitness for Purpose in Dioxin Testing Y. Tondeur, B. Vining, J. Hart, Analytical Perspectives. Achieving a reasonable balance between the cost of making incorrect decisions and testing is an outgrowth of the performance-based measurement system (PBMS) introduced by EPA to provide more flexibility, and to facilitate the incorporation of new technologies, as well as the latest knowledge and improvements for analytical protocols. The latter were promulgated decades ago under a command and control environment. Over time, it became evident that changes were necessary to dislodge the performance status quo. An analytical result is deemed fit for purpose when its uncertainty maximizes its expected utility. In essence, achieving a smaller uncertainty in a measurement lowers the chance of making an incorrect decision or incorrectly assessing compliance. Existing analytical protocols, as well as the current ways of doing business, are not serving the end user well – because fitness for purpose is not central and none seem to be aware that the data quality objectives associated with analytical measurements are constantly in flux. Our solution to EPA's direction was to develop a novel protocol which, when used in conjunction with existing methods, transforms the infrastructures of current methodologies by aligning them with PBMS. The innovative approach ensures quality improvements, the generation of effective data, and the removal of delays associated with the promulgation of revised methods. The new protocol is the product of 10 years of work, and is supported by extensive validation. The approach does the following: 1) fundamentally renders PBMS tangible, 2) allows a comprehensive and accurate assessment of performance, 3) acts as a gate keeper for performance and data quality before the data reaches the end user, 4) offers uncertainty measurements for each toxic target analyte and for the TEQ on a per sample basis (i.e., when & where needed!), 5) provides a context for assessing data quality and for making intelligent and rational decisions, 6) captures information for traditional lab data flags by quantifying their impact on data reliability, and 7) is a tool for planning future testing events such that the data generated are fit for purpose (i.e., meet the end user's data quality objectives and are found to lie within the tolerable error range necessary for decision making). Such an approach is particularly important at this point in time since action limits have been set low and treacherously close to actual detection limits.

716 Analysis of Dioxins, Furans, and Polychlorobiphenyls in Fish and Clams for the Houston Shipping Channel, TX B. Subedi, Baylor Univ, Dept of Chemistry and Biochemistry, Baylor Univ, Dept of Biology, Baylor Univ, Dept of C; L. Aguilar Lazaro, Baylor Univ, Environmental Science; S. Usenko, Baylor Univ, Dept of Environmental Science, Baylor Univ, Assistant Professor. Fish and clams were collected from the San Jacinto River waste pits, a superfund site in Houston, TX and analyzed for polychlorodibenzo-*p*-dioxins, polychlorodibenzofurans (PCDD/Fs) and dioxin like polychlorobiphenyls (dl-PCBs). Sample preparations comprised of tissue homogenization, simultaneous pressurized liquid extraction and cleanup, and concentration. Isotopically labeled surrogates were spiked prior to extraction and were used to correct for target analytes loss during sample preparation. Samples were analyzed employing gas chromatography negative chemical ionization mass spectrometry. The method detection limits ranged from 2.0 to 10 pg/g ww in fish tissues. Ten out of twelve high priority dl-PCBs (Identified by World Health Organization, 2005) were measured with concentrations ranged from 2.0 to 948 pg/g ww. Concentrations of three most abundant dl-PCBs (PCB 105, 118, and 123) were an order of

magnitude higher in fish than in clam tissue. The toxicity equivalent calculated using toxicity equivalency factor ranged from 0.46 to 0.80. PCDD/Fs were not detected in fish tissues; however, 2,3,7,8-TCDF was measured up to 30 pg/g ww in clam tissues.

717 Semi-continuous Determination of PCDDs/PCDFs and dl-PCBs in Stack Emissions: Policy Development and Laboratory Strategies J. Rivera-Austrui, CSIC, Dioxin Laboratory – Environmental Chemistry Dept; K. Martinez, CSIC; E. Abad, M. Abalos, CSIC, Dioxin Laboratory – Environmental Chemistry Dept; M. Adrados, J. Rivera, J. Saulo, CSIC. At present, dioxin stack emission determinations in Europe are set according to the European Standard EN1948:1(2007) based on manual short-time samplings of 6 hours. European Directive 2000/76/CE on waste incineration sets the dioxin emission limit for stacks (0,1 ng I-TEQ/Nm^3) and refers to this standard to verify the conformity of plant emissions twice a year. A part from manual method spot measurements, automatic sampling systems, which have been used since several years, are capable of permanently sampling the stack and allow semi-continuous determination (four weeks sampling and analytical determination in the laboratory). Continuous sampling systems allow the measurement of total plant emissions for longer periods, providing reliable data that is a useful tool for the improvement of plant operation protocols and to obtain accurate results that can considerably improve the current emission inventories. This has led to their generalized use due to the interest of plant administrators, or because of local or national legal requirements (e.g., Belgium, France, Italy). At the same time, tests have been conducted to certify sampling systems (EPA, TUV, MCert) or in some cases, to validate these methods by intercomparison measurements with manual sampling methods. However, little information has been published on the analytical treatment in the laboratory of these samples which are mainly characterized by a far higher amount of sampled volume resulting in higher amounts of analytes of interest but also interfering compounds. In this study are presented the results of several tests developed in order to extend the scope of validation of the methodology for the analysis of samples provided by continuous sampling systems. These tests were carried out with samples collected with automatic isokinetic sampling system in a monthly basis from 4 different industrial processes (cement plant with and without waste combustion, municipal and hazardous waste combustor). Special attention is paid to parameters that differ from the well-established methodology described in EN1948 or EPA23, such as levels of native and labelled analytes when using an aliquot, sampling recoveries related to longer periods, etc. From these experiences, a scheme of aliquot and standard addition protocol is suggested. The presented experiences and results can help to set the basis for analysis methodology to include in future standards concerning long-term sampling determinations.

718 Are Dioxins Dechlorinated in Sewers? L. Rodenburg, Rutgers, the State Univ of New Jersey, Dept of Environmental Sciences; J. Guo, Rutgers, the State Univ of New Jersey, Dept of Environmental Science; S. Du, N.U. Oseagulu, RUTGERS Univ; D. Fennell, RUTGERS Univ, Dept of Environmental Sciences. Recently we published evidence that polychlorinated biphenyls (PCBs) undergo extensive microbial dechlorination in sewers, especially combined sewers. Since PCBs and polychlorinated dibenzo-*p*-dioxins and –furans (PCDD/Fs) are structurally similar, we hypothesized that PCDD/Fs might also be dechlorinated in sewers. To test this hypothesis, we used Positive Matrix Factorization to analyze several databases on concentrations of PCBs and PCDD/Fs in the influents and effluents of more than 70 wastewater treatment plants in New Jersey, New York, Pennsylvania, and Delaware. Most of the samples of both influents and effluents contain evidence of dechlorination of PCBs via either a partial dechlorination regime that produces primarily PCBs 47 and 51, or an advanced dechlorination regime that produces primarily PCB 4. Furthermore, analysis of a data set containing information on both PCBs and the 17 2,3,7,8-substituted PCDD/Fs indicates that the advanced dechlorination signal that is dominated by PCB 4 is also characterized by high proportions of 1,2,3,4,6,7,8- heptachlorodibenzo-*p*-dioxin (HpCDD), a documented dechlorination product of octachlorodibenzo-*p*-dioxin (OCDD). OCDD was absent in this advanced dechlorination factor, suggesting that OCDD is dechlorinated to 1,2,3,4,6,7,8-HpCDD in sewers, raising the possibility that PCDD/Fs may undergo dechlorination via a number of pathways in sewers.

719 Sequence and In Vitro Function of Chicken, Ring-necked Pheasant and Japanese Quail AHR1 Predict In Vivo Sensitivity to Dioxins R. Farmahin, Univ of Ottawa, Dept of Biology, Environment Canada, National Wildlife Research Centre; D. Wu, D. Crump, Environment Canada, National Wildlife Research Centre; J.C. Herve, Univ of Ottawa, Dept of Biology, Environment Canada, National Wildlife Research Centre; S.P. Jones, Environment Canada, National Wildlife Research Centre; M.E. Hahn, Woods Hole Oceanographic Institution; S.I. Karchner, Woods Hole Oceanographic Institution, Biology; J.P. Giesy, Univ of Saskatchewan, Biomedical Veterinary Sciences & Toxicology Centre, Michigan State Univ, Dept of Animal Science; S.J. Bursian, M.J. Zwiernik, Michigan State Univ, Dept of Animal Science; S.W. Kennedy, Univ of Ottawa, Dept of Biology, Environment Canada, National Wildlife Research Centre. There are large differences in sensitivity to the toxic and biochemical effects of dioxins and dioxin-like compounds (DLCs) among vertebrates. Some of the largest differences in sensitivity to aryl hydrocarbon receptor-mediated effects of DLCs occur among species of birds. Avian toxic equivalency factors (TEFs) have been established by the World Health Organization and are applied in the risk assessment of mixtures of DLCs including polychlorinated dibenzo-*p*-dioxins (PCDDs), dibenzofurans (PCDFs) and some polychlorinated biphenyls (PCBs). However, TEFs do not account for differences in species sensitivity to DLCs, and may not accurately predict DLC toxicity in all avian species. Previously, we demonstrated that differences in sensitivity between domestic chicken (*Gallus gallus domesticus*) and common tern (*Sterna hirundo*) to aryl hydrocarbon receptor 1 (AHR1)-dependent changes in gene expression following 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) exposure is based upon the identities of the amino acids at two sites within the ligand binding domain of AHR1 (chicken: Ile324_Ser380, highly sensitive vs. common tern: Val325_Ala381, less sensitive). Here, we tested the hypotheses that (a) the sensitivity of other avian species to TCDD, 2,3,4,7,8-pentachlorodibenzofuran (PeCDF) and tetrachlorodibenzofuran (TCDF) is determined by the amino acids at sites corresponding to 324 and 380 and (b) Ile324_Ala380 and Val324_Ser380 genotypes confer intermediate sensitivity to DLCs in birds. We compared ligand-induced transactivation function of full-length AHR1s from chicken, common tern, ring-necked pheasant (*Phasianus colchicus*; Ile324_Ala380) and Japanese quail (*Coturnix japonica*; Val324_Ala380) and three Japanese quail AHR1 mutants. The results suggest that avian species can be grouped into three general classes of sensitivity to DLCs. Both AHR1 genotype and in vitro transactivation assays predict in vivo sensitivity. Contrary to the assumption that TCDD is the most potent DLC, PeCDF was more potent than TCDD at activating ring-necked pheasant (5-fold), Japanese quail (23-fold) and common tern (31-fold) AHR1. Our results are consistent with previous in vitro and in vivo work that demonstrated ligand-dependent species differences in AHR affinity. The findings and methods will be of use for dioxin and DLC risk assessments.

720 Unintentionally Produced Persistent Organic Pollutants (POPs) from Solvent Production R. Weber, POPs Environmental Consulting; F. Oliaei, Cambridge Environmental, LLC. The Stockholm Convention currently list five Persistent Organic Pollutants (POPs) as unintentionally produced POPs (UPOPs): polychlorinated dibenzo-*p*-dioxins (PCDD) polychlorinated dibenzofurans (PCDF), polychlorinated biphenyls (PCB), hexachlorobenzene (HCB) and pentachlorobenzene (PeCB). These UPOPs are commonly formed as by-products during the production of chlorinated organics; in processes where elemental chlorine is present; and in thermal processes in the presence of all forms of chlorine. For certain solvent productions (e.g., tetrachloroethene, trichloroethene, tetrachloromethane, dichloroethene) it is known that large amounts of hexachlorobenzene (HCB) waste was and is produced. In some cases these wastes have been deposited and have generated POPs contaminated sites. Recently it has been discovered that some of these wastes also contain relevant levels of POPs PeCB. Furthermore also hexachlorobutadiene (HCBD) – nominated in May 2011 by the EU for assessment as POPs under the Stockholm Convention – is included in such wastes. This contribution gives an insight in some contemporary case studies and related contaminated sites or stockpile management challenges. Such historic deposits are probably now the major stocks of HCB, PeCB and HCBD. The likely contamination of the wastes with other UPOPs is also discussed. As a consequence of the formation chemistry it is likely that chlorinated styrene (octachlorostyrene), chlorinated naphthalene and chlorinated biphenyls and depending on the oxygen and water content possibly also PCDF/PCDD can be expected in some or

all such deposits and contaminated sites. The case studies demonstrate that production of key chlorinated solvents in factories without adequate waste destruction capacity generated thousands of tonnes of hazardous waste containing high levels of the UPOPs HCB and PeCB. The study highlights the importance of a more detailed assessment of these deposited wastes from chlorinated solvents productions and the need of developing inventories of current productions and existing stockpiles and thus support future assessment and clean-up of these sites.

721 Policy Implications from Observations of PCBs and PCDD/Fs Fate, Transport, and Inter-media Distributions N.L. Howell, H.S. Rifai, Univ of Houston, Civil & Environmental Engineering. Polychlorinated dibenzo-*p*-dioxins and dibenzofurans (PCDD/Fs) and polychlorinated biphenyls (PCBs) are highly chlorinated, lipophilic, persistent pollutants composed of hundreds of chemical variants. Only 29 are considered to be toxicologically relevant as they relate to what is often touted as "the most toxic man-made chemical" (2,3,7,8-TCDD). In this research, a comparative analysis was undertaken of geographic distributions, observed bioaccumulative ability, medium-to-medium transfer, and potential sources of PCDD/Fs and PCBs for 1041 samples of bed sediment, suspended sediment, water, catfish, and blue crab in the Houston Ship Channel (HSC) in Texas over a three-year period. Important findings include that current and historical sources in the HSC have created different trends in the contaminants that seem to correlate to known Superfund site locations, that water-phase partitioning between the contaminants are different (not always found primarily on suspended sediments), and that bioaccumulation was more effective in PCBs over PCDD/Fs making PCBs more toxicologically relevant than what toxic potency alone would suggest. A characterization of bioaccumulation factors (BAFs) using various water column contaminant partition models and estimates of the highly hydrophobic sorbent, black carbon, was undertaken. The observed variation in BAFs and the partial explanation of that variation using abiotic contaminant concentration and ancillary measurements (e.g., mass suspended solids, particulate organic carbon, etc.) reduced the total observed variation in biotic concentrations and allowed better prediction of what concentrations will be. A key finding is that more of the congeners than the 29 "TCDD-like" are useful for understanding the source and fate-and-transport issues related to actualized toxicity. For example, the use of chemical fingerprinting may aid in locating sources and tracking their effects. Safe concentrations in fish and crab are the goals for the eventual lifting of consumption advisories, but the biota may not be an adequate target for the prediction of future human health risk. Complex geographic distributions and nuanced fractionation amongst abiotic phases in the water help determine the biotic endpoint and thus must be used to explain known aquatic biota contamination and predict what will occur if a water body is left on its own or if remediation is attempted.

722 Soil Cleanup Levels for Dioxins: Contrasting a Site-specific Analysis with the Draft EPA PRG L. Yost, Exponent; C. Kirman, Summit Toxicology; R. Budinsky, J. Zabik, The Dow Chemical Company. The 2010 draft EPA preliminary remediation goal (PRG) for chlorinated dibenzo-*p*-dioxins and furans (PCDD/Fs as toxicity equivalence TEQD/F) in residential soil is13-fold lower than the prior value of 1 ppb used nationwide. PRGs, while not cleanup standards, are often applied as such or require substantial resources to characterize potential exposure and risk in efforts to establish alternative values. This presentation will provide an overview of the use of problem formulation as described in the National Academy of Sciences (NAS) report titled Science and Decisions: Advancing Risk Assessment, (i.e., the Silver Book) as a critical first step to derive a range of site-specific soil cleanup levels for PCDD/Fs. Estimates were derived through deterministic and probabilistic methods and integrated considerable site-specific data on influential exposure terms (residence duration, bioavailability, and exposure frequency), and applied soil ingestion rate data for children and adults from recent studies. The problem formulation approach then allows for incorporation of site-specific biomonitoring data to further refine risk estimates and to improve risk management. Derivation of toxicity values for TEQD/F representative of human health risk is still underway with EPA responding to extensive comments from the EPA Science Advisory Boards and the NAS on the proposed EPA Draft Dioxin Risk Assessment. Analyses here applied toxicity values derived from NTP (2006) assay with the intent to address NAS recommendations regarding cancer risk assessment. Deterministic soil cleanup level estimates ranged from 19 to 250 ppb through application of linear and nonlinear cancer toxicity values, and a cleanup level of 5.3 ppb was estimated based on the World Health Organization toxicity value for noncancer and cancer endpoints. A wide range of cleanup level estimates were calculated using probabilistic methods, with the prior EPA 1 ppb clean-up value falling below the first percentile of estimates, suggesting that the 1 ppb value is health protective. Supporting these estimates are the extensive biomonitoring studies that show little relationship between human contact with dioxin in soil and dioxin in human serum (i.e., the Univ of Michigan Dioxin Exposure Study, and studies in Japan, and West Virginia). The problem formulation approach provided a multiple-lines-of-evidence basis supporting informed risk management decisions that are health protective and practical.

723 Chemistry and Toxicity of Urban Stormwater: Overview G.S. Toor, Univ of Florida, Gulf Coast Research & Education Center, Gulf Coast Research & Education Center, Univ of Florida, Soil & Water Science Dept; N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology. Urbanization of our planet has been an ongoing phenomenon and a necessary evil to accommodate increasing populations. Urban growth alters the natural processes and pathways of water and pollutant transport in human-dominated watersheds. The foremost impact of urbanization is increase in impervious surfaces (building rooftops, parking lots, paved streets) that reduce water percolation in soil and increase the amount and intensity of stormwater runoff. As stormwater flows over the impervious surfaces, it carries pollutants such as sediment, pesticides, hydrocarbons, and trace metals from land and rapidly transport them to nearby water bodies. The goal of this presentation is to provide (1) an overview of common sources of pollutants found in urban stormwater runoff and their fate and transport to water bodies and (2) discuss the toxicity, bioaccumulation, and trophic transfer potential of stormwater pollutants to aquatic organisms.

724 Recent and Ongoing Developments in the Transport, Occurrence, Fate and Ecotoxicology of Pyrethroids in Urban Settings A.C. Barefoot, E.I. Du Pont De Nemours And Co., Inc., Crop Protection Products; P. Hendley, Syngenta Crop Protection, LLC., Senior Syngenta Fellow; M. Dobbs, Bayer Crop Science; K. Henry, Syngenta Crop Protection, LLC, Ecological Sciences; R. Jones, Bayer Crop Science; G. Hancock, Waterborne Environmental, Inc., Ecotoxicology. Over the last few years, considerable interest has developed in the occurrence and potential impacts of pyrethroid insecticide residues found in sediment and water samples from urban streams. A great deal of related monitoring has taken place in California where the Dept of Pesticide Regulations instituted a re-evaluation program to ensure development of data on pyrethroids to help refine related risk assessments and identify the most likely residue sources and, where necessary, potential mitigation alternatives. The Pyrethroid Working Group (PWG) has been developing data to address the re-evaluation requests in addition to conducting a wide range of related studies to better understand the science underlying the transport, occurrence and impact of the pyrethroids arising from residential uses. This presentation will use the conceptual model that has been developed for pyrethroid occurrence and transport data from a CA-wide use survey to provide a context to help explain how the studies already completed or underway are refining our knowledge. Some of the studies are "real world" monitoring programs in several stream systems matched with bioassessment studies and sediment deposition area mapping in the same streams. Laboratory-based studies include sediment fate studies, acute ecotoxicology studies on *Hyalella azteca* and *Chironomus tentans*, as well as ongoing improvements in analytical methods. In addition, indoor studies have been conducted to examine the washoff potential of commercial pyrethroid products from various building surfaces. A field site has also been established for conducting replicated studies to identify the transport pathways which make the most significant contributions to residential pyrethroid transport (e.g., driveways vs. vertical walls vs. turf). Preliminary results and future plans for these studies will be discussed.

725 Pyrethroid Product Washoff from Driveway Concrete Under Simulated Rainfall Conditions P. Hendley, Syngenta Crop Protection, LLC., Senior Syngenta Fellow; R. Jones, Bayer Crop Science; G. Hancock, Waterborne Environmental, Inc., Ecotoxicology; C. Harbourt, Waterborne Environmental Inc. A study has been conducted to determine the potential for washoff of a series of commercial pyrethroid insecticides following application to residential concrete surfaces such as driveways. Small concrete slabs (24 inch by 9 inch) were poured and brushed to simulate a driveway

concrete surface. After the slabs had been aged for several weeks, individual slabs were each treated with one of 17 different commercial pyrethroid insecticides. The products were applied using a track sprayer at use rates and spray volumes reflecting label specifications. After drying for approximately 24 hours indoors, groups of slabs were subjected to simulated rainfall events of 1 inch/hour for 1 hour using an indoor rainfall simulator designed to generate droplets of realistic sizes and energy and to provide uniform rainfall intensity across an area of around 8 by 15 ft. The slabs were held at an angle of 5 degrees to ensure the washoff flowed off the slab surface into collectors and ultimately into bottles that collected all the washoff. Three replicate slabs were inundated for each product; thus, along with control slabs, this generated fifty-seven individual washoff samples. Chemical analyses quantified the mass of the active ingredients found in the washoff and the data were compared in terms of the percentage of applied chemical that was removed by the simulated rainstorm. There was generally close agreement between the washoff percentages for replicate slabs for a given product indicating that this experimental design was suitable for conducting a comparative study of this type. Results will be compared and contrasted in the context of the behavior of general formulation categories and options for additional related research will be discussed.

726 Surface Water Contamination Associated with Fipronil Use in Residential Landscapes J. Wu, UF/IFAS-IRREC; J. Lu, Y. Lin, Univ of Florida/IFAS-IRREC, Soil and Water Science; P. Wilson, Univ of Florida, IFAS, IRREC- Soil & Water Science. The phenylpyrazole pesticide fipronil has been increasingly used for pest control in residential landscapes. The presence of fipronil and some of its' degradates in surface water has attracted public attention due to their potential risks to ecosystem and human health. A monitoring study was carried out from September 2008 to July 2010 to investigate the occurrence of fipronil and two of its metabolites in surface water associated with residential land-uses. Five canals and three stormwater retention ponds collecting surface water from residential land-uses were sampled and analyzed by GC-ECD weekly. Fipronil and fipronil sulfone were detected at five of eight sampling sites, with concentrations ranging from 0.5-210.6 and 0.5-77.1 ng L-1, respectively. The same respective compounds were detected in 3.1% and 1.0-5.2% of the samples collected from three of the canals, and in 33-45% and 78-81% of samples collected in two of the ponds. Except for the two retention ponds, fipronil and its metabolites were detected in less than 5% (most below 3%) of the samples collected. Fipronil sulfide was detected in 16-46% of the samples from the two ponds and in 1-2% from the other sites, at concentrations ranging from 0.4-26.9 ng/L. Contamination appears to be significantly influenced by irrigation management, as well as by rainfall/stormwater runoff events.

727 Evaluating the Potential Ecological Impact of Perfluorinated Chemicals (PFCs) in Minnesota Lakes Using cDNA Microarrays R.A. Lehr, Northland College, Natural Resources; R. Colli-Dula, Univ of Florida; C.J. Martyniuk, Univ of New Brunswick, Dept of Biology/Canadian Rivers Institute, Univ of New Brunswick, Biology; N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology. Perfluorinated chemicals (PFCs) stem from a wide range of sources and have been detected in stormwater runoff and aquatic ecosystems around the world. Laboratory research suggests that PFC exposure can result in a number of adverse health outcomes for aquatic organisms, but relatively little research has been conducted to assess whether PFCs are impacting the health of lakes and streams. To assess the potential impact of PFCs in aquatic ecosystems, gene expression patterns in largemouth bass were quantified across a PFC exposure gradient in lakes throughout the Twin Cities Metro Area (TCMA) in Minnesota using a 15,000 gene cDNA microarray. Gene expression patterns in largemouth bass corresponded closely with PFC concentration across the TCMA lakes, where fish from lakes with the highest PFC exposure were observed to have 5437 and 5936 differentially expressed genes in liver and gonad tissues, relative to reference sites. Similarly, largemouth bass with high PFC tissue concentrations consistently exhibited changes in the expression of genes related to lipid metabolism, energy production, RNA processing, protein production/degradation and contaminant detoxification—all of which are consistent with biomarker and bioindicator responses observed in previous laboratory studies with PFCs. Interestingly, although the biological process that are differentially regulated in largemouth bass with high PFC tissue concentrations are consistent with laboratory observations, the mechanisms of action associated with these changes are variable across studies. Taken together, these results suggest that PFCs are potentially influencing the physiological condition of largemouth bass in several lakes throughout the TCMA. However, given the wide range of genes that are differentially expressed across the lakes and the variability observed in the mechanisms through which different biological processes have been affected, it is unlikely that PFCs are the only stressors affecting largemouth bass in TCMA lakes.

728 Impact of CSO and Stormwater Runoff on Water Quality in Urban Streams J. Bushey, Univ of Connecticut, Asst Professor; A. Aragon-Jose, Univ of Connecticut; C. Perkins, Univ of Connecticut, Center for Environmental Sciences and Engineering; M. Mendes, Univ of Connecticut; G. Ulatowski, Univ of Connecticut, Center for Environmental Sciences and Engineering. Combined sewer systems (CSSs) impact water quality of receiving water bodies, especially during high discharge events, in many urban systems. Such urban systems not only receive contaminant loading from stormwater, but also as a result of sewage contributions from combined sewer overflows (CSOs). A wide range of contaminants have been detected including nitrogen, phosphorous, trace metals, coliforms and anthropogenic organics. However, the chemical composition of stormwater and CSOs varies within an event, representing contributions from multiple sources. Management of contaminant loading often ignores these temporal shifts in speciation as well as fate within the receiving water body, further compounding the difficult and challenging problem that many municipalities face of assessing ecological impacts. To assess potential changes in loading and chemical speciation we have collected stream water samples in the Park River sewershed (Hartford, CT) during base flow and events to assess potential for contaminant loading and mobilization. Three events have been collected to date. Trace metal, TSS and DOC concentrations increased with discharge. However, trace metal concentrations and flux values reflected the degree of urbanization and industry present in the watersheds. All samples contained low DOC with the majority of the flux occurring in the particulate phase. Dissolved transport with DOC, particularly for Hg, decreased with urbanization. The degree of urbanization also increased TN flux as well as the distribution among N chemical species, with urbanized systems increasing in the NOx fraction.

729 Urban Stormwater-associated Prespawn Mortality of Coho in the Greater Seattle Region: Could Simple Dissolved Organic Carbon Quality Explain It All? J.A. Colton, King County Dept of Natural Resources, Water and Land Resources Division, King Cty. Dept of Nat. Resources, Water and Land Resources Division; R. Jack, King County, Dept of Natural Resources and Parks; D. Lester, King County Dept of Natural Resources, Water and Land Resources Division. Prespawn mortality of coho salmon is an acute mortality phenomenon associated with urban stormwater runoff. Substantial prespawn mortality rates (up to 90% of females) have been observed in many urban streams in the Seattle metropolitan area. The exact cause of the acute mortality is unknown but has been posited as one or more metals, pesticides, or some other organic chemical or group. This presentation discusses the potential for an alternative causal factor: dissolved organic carbon (DOC) quality. King County conducted a study in 2009 designed to compare water chemistry changes at baseline flow and throughout a storm event, and metals gill tissue levels in prespawn and successful-spawned coho between two streams: Longfellow Creek, a well-studied, high prespawn stream, and Lund's Gulch Creek, a reference stream. This study demonstrated dramatic changes in water chemistry (e.g., calcium, sodium, magnesium, copper, zinc) during storm events within a stream, the most extreme of which occurred in Longfellow Creek. Although metals concentrations in water peaked during a storm event, levels did not go above Washington State Water Quality Standards. However, lead accumulation in gill tissues tested as the only metal statistically higher in Longfellow Creek prespawn coho than Lund's Gulch coho. Although a hypothesis of hypocalcemia is entertained due to the combination of calcium drops, metals spikes, and weak calcium pumps in transitionary coho, the potential for large differences in DOC quality became a strong option as well. King County conducted a second study in 2010 which measured UV absorbance as an index for DOC quality during baseline and storm flow in the same streams (as well as metals and cations). Published evidence is mounting for the importance of DOC quality in ameliorating metals toxicity and its role appears to be more diverse than previously thought (e.g., affecting gill physiology and metals bioavailability). The habitat conditions at each study stream are congruent with humic acids providing higher DOC quality and, thus, greater amelioration, at the reference stream. The 2010 UV absorbance results and water

chemistry data from both King County studies will be discussed in regard to their support for the DOC quality hypothesis.

730 Stormwater Toxicity Challenges and Innovative Solutions – Case Study at UCSD's Scripps Institution of Oceanography C. Stransky, AMEC Earth and Environmental, AMEC Earth & Environmental, Aquatic Sciences; A. Cibor, Nautilus Environmental, 4132 Avati Dr; G. Rosen, SPAWAR Systems Center Pacific, Environmental, SPAWAR Systems Center Pacific, Scientist; M. Colvin, AMEC Earth & Environmental, 4132 Avati Dr; K. O'Connell, Univ of California San Diego, EH&S Environmental Affairs, 4132 Avati Dr. The variable nature of stormwater runoff presents unique challenges with regard to accurately characterizing water quality and potential receiving water impacts. Assessment of stormwater toxicity is one of many measurements required in a variety of National Pollution Discharge Elimination System (NPDES) Permits. Toxicity testing provides a valuable measure of stormwater quality as it is a direct measure of potential effects on local biota. Toxicity also integrates effects due to multiple contaminants and site-specific water quality characteristics. Results of toxicity tests, however, are dependent on a number of factors that need to be carefully considered (i.e., species chosen, organism source and quality, biological endpoints measured, exposure duration, natural confounding factors, and test methods). Standard EPA whole effluent toxicity (WET) test methods were developed for continuous point source wastewater discharges and were not designed to assess the extremely dynamic and transient nature of non-point source stormwater runoff. The consequence for current stormwater monitoring programs is a reliance on unrealistic and disjointed lines of evidence, potentially resulting in inappropriate management decisions. For more realistic exposure methods to gain acceptance, there is a need to improve and standardize quality controls, and to simplify field application. Several methods will be highlighted including both modified sampling techniques and in situ testing. Results from a pilot study using new technology (the SEA-Ring) during dry and wet weather off the Univ of California's Scripps Institution of Oceanography in 2010 and 2011 will be presented alongside concurrent routine NPDES monitoring data required for their discharges to an Area of Special Biological Significance. The prototype SEA-Ring consists of a circular carousel capable of housing an array of toxicity chambers and passive sampling devices that can be used to assess potential impacts due to a variety of contaminants and exposure pathways in situ.

731 Defining Nano: An Investigation of the Size-dependent Effects of Nanoparticles K. Sellers, ARCADIS, Principal Environmental Engineer; M. Bartee, C. Hassinger, ARCADIS. Efforts to characterize the toxicity of nanomaterials implicitly incorporate a definition of what it means to be "nano". Members of the scientific community and regulators around the world commonly use a definition of 1 to 100 nanometers (nm) in size. But uncertainties about this definition persist, with some defining nanoparticles as sizes up to 2000 nm and others proposing definitions that incorporate size ranges or surface area metrics. A preliminary examination of the literature presented in a poster at SETAC 2010 found that many tests did show a size-dependent effect. Most tests showed that decreasing particle size increased the effects of exposure to the test substance. However, the results suggested that – logically enough – decreasing the particle size and thereby increasing the surface area to volume ratio may not markedly increase the bioavailability of very poorly soluble materials. In this presentation, the authors will discuss the results of a meta-study of the ecotoxicology literature that examines the size-related behavior of particulates. The objective of this work is to determine whether the data show one or more "bright lines" that suggest specific relationships between certain particle sizes or other particle characteristics and the potential for specific behaviors or effects. The research will focus on a nanoparticle that is well-studied and has relatively poor water solubility, thus eliminating the ion toxicity variable (i.e., dissolved concentrations versus nanoparticle toxicity). This meta-study will provide an ecotoxicology view of the ongoing debates about how to define nanomaterials for the purpose of regulatory toxicology.

732 Dynamic Measurement of Size and Fractal Structure of Single-Walled Carbon Nanotubes: Role of Chirality N.B. Saleh, I.A. Khan, Univ of South Carolina, Civil and Environmental Engineering; P.L. Ferguson, Duke Univ; T. Sabo-Attwood, Univ of Florida, Dept of Environmental & Global Health. Single-walled carbon nanotubes (SWNTs) have widespread application due to their unique physicochemical properties. To-date, there has been no studies addressing the effects of SWNT electronic structure, i.e., chirality/helicity, on its aggregation behavior in biological and natural systems. This study is the first of its kind to address aggregation kinetics and fractal dimension of chirally separated SWNTs in chemistries relevant to natural aqueous systems and biologically relevant conditions. SWNTs have been chirally separated using density gradient ultracentrifugation and analyzed using near-IR fluorescence spectroscopy. Kataura plots show a narrow distribution of chirally separated SWNTs. Detailed physicochemical and electrokinetic characterization are performed using Raman Spectroscopy, thermal gravimetric analysis, electron microscopy, and electrophoretic mobility measurements. Fundamental aggregation kinetics study with specific, i.e., (6,5) and (7,6), and mixed chiralities is performed using time-resolved dynamic light scattering. Angle-dependent static light scattering (SLS) technique is employed to measure D_f of carboxylated SWNTs of the aforementioned chiralities under natural and biologically relevant conditions. Aggregation of SWNTs followed typical DLVO type behavior. Kinetics of SWNTs varied significantly with the change in chirality and dominated by va der Waals interaction as a function of chirality. The SLS-intensity data are collected for the entire scattering range (Guinier through Fractal to Porod regimes, i.e., 12-150°) and results demonstrate strong effect of chirality and weak dependence of biological media conditions on D_f. Aggregation kinetics data and D_f values thus obtained can provide with unique insight on a more realistic SWNT exposure and fate in biological and natural environments.

733 Assessing the Environmental Risks of Nanomaterials: Critical Review of Risk Analysis Frameworks K. Grieger, Technical Univ of Denmark, Dept of Management Engineering; I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center; S. Hansen, Technical Univ of Denmark; A. Baun, Technical Univ of Denmark, Dept of Environmental Engineering. Risk assessment frameworks and strategies for engineered nanomaterials (NM) are currently being reviewed and adapted in many cases. Thus far, this has proved to be a challenging task, as well as likely extremely time- and resource-consuming. In response to these grand challenges for NM, a number of alternative or complimentary frameworks have been proposed in recent years to standard risk assessment. However, further information on these alternative approaches such as their potential strengths and limitations is currently unavailable. This analysis therefore evaluates these different risk analysis frameworks which have been proposed for NM based on a number of select criteria and specifically focusing on environmental risk analysis for NM. The following criteria were used for this evaluation: flexible for a variety of NM, suitable for multiple decision contexts, incorporate uncertainty analysis, include life cycle perspectives, iterative or adaptive, enable more timely decision making, transparent, integrate various stakeholder perspectives, integrate precaution, and include qualitative or quantitative data. Results showed that most of the investigated frameworks were i) flexible for multiple NM, ii) suitable for multiple decision contexts, iii) included life cycle perspectives, iv) transparent, v) included precautionary aspects, and vi) able to include qualitative and quantitative data. It was also found that many of the frameworks may be adapted for iterative or adaptive elements and timely decision making if needed, although these were not inherently embedded in many of the frameworks based on their current formats. In addition, most frameworks were mainly applicable to occupational settings with minor applications for the environment, and many if not most of the frameworks had not been thoroughly tested on a wide range of NM or nano-applications. Given these results, we recommend using a multi-faceted approach to assess the environmental risks of NM in which different frameworks may be used together and/or combined for a particular risk context. We also recommend additional testing of these frameworks on concrete NM applications which are specifically relevant for environmental risk contexts.

734 Using Value of Information to Prioritize Nanomaterial Research M. Barber, MIT & Army Corp of Engineers; M.E. Bates, US Army Corps of Engineers, Environmental Lab, Engineer Research and Development Center; J. Kiesler, Univ of Massachusetts; J.A. Steevens, US Army Engineer Research & Development Center, Waterways Experiment Station; M.A. Chappell, US Army Corps of Engineers, Environmental Laboratory, US Army Corps of Engineers; I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center. Even though, in recent years, much research has been done on nanomaterials and their properties, there are still large gaps in our knowledge of nanomaterial risk. While there are many uncertainties in nanomaterial risk, particularly when it comes to the human health and

environmental toxicology, having more information about certain risks may be more valuable than having more information about other risks. As more and more nanomaterials are developed each year, researchers must continually prioritize on which nanomaterials to focus their research. Multi-Criteria Decision Analysis can be used to frame the decision problem and to quantify uncertainty in risk effects, yielding an initial prioritized list of research agendas. Value of Information (VoI) analysis can then be used to determine how, if given some additional information on the risk effects of a particular nanomaterial, that prioritized list would change. The combined MCDA/VoI framework can help scientists and decision-makers select more complete and more accurate lists of prioritized research agendas to investigate nanomaterial risks.

735 Dissolution of Retained Silver Nanoparticles in Water-saturated Porous Media Y. Wang, A. Taghavy, A. Mittelman, M.D. Becker, L.M. Abriola, Tufts Univ, Civil & Environmental Engineering; K. Pennell, Tufts Univ, Dept of Civil & Environmental Engineering. Concerns over potential health and environmental impacts of silver nanoparticles (nAg), which are widely used as biocidal agents, call for a thorough understanding of their fate in the environment. Coupled experimental and mathematical modeling studies were conducted to investigate mechanisms governing the transport, retention and dissolution of nAg in a water-saturated quartz sand as a function of pH and oxygen content (DO). For each experiment, a 3 pore volume (PV) pulse of 3 mg/L nanosilver suspension (stabilized with citrate, conditioned with 10 mM sodium nitrate or sodium acetate, and pH of 4 or 7) was introduced into a olumn (10cm length x2.5cm dia.) packed with 40-50 mesh Ottawa sand (dH = 355 μm) at a pore-water velocity of ca. 7.6 m/d. At neutral pH concentrations of dissolved Ag+ in the column effluent were low (<0.03 mg/L) and approximately 25% of the injected nAg mass was retained within the column. During the subsequent elution period (30 PVs of pH 4 particle-free solution), Ag+ concentrations achieved a maximum value of 0.12 mg/L and no nAg were observed in the effluent for the entire period, indicating that retained nAg were slowly dissolving. Effluent Ag+ concentrations increased slightly (up to 0.15 mg/L) at the higher DO (8.9 ppm), but decreased markedly (< 0.01 mg/L) when pH was increased to 7.0. A hybrid Eulerian-Lagrangian simulator was developed to describe the coupled reactive transport of nanoparticles and dissolved constituents. Implementation of an empirical expression for the nAg dissolution coefficient facilitated an accurate representation of the observed nanoparticle dissolution behavior. Simulation results demonstrate the relative insensitivity of nAg dissolution to DO. Model sensitivity analyses revealed that pH, residence time and nanoparticle specific surface area were the primary factors controlling nAg dissolution.

736 A Case Study for the Release of Nano Particulate Aluminum from the Use of a Nanotechnology J.A. Steevens, US Army Engineer Research & Development Center, Waterways Experiment Station; V. Boddu, A. Bednar, M. Chappell, C. Griggs, A. Kennedy, A. Poda, C. Weiss, US Army ERDC; V. Korampally, S. Gangopadhyay, Univ of Missouri; K. Gangopadhyay, NEMS/MEMS LLC; R. Thiruvengadathan, Univ of Missouri. Currently there are very few studies that have examined the release of particulates associated with a nano-based technology. Most studies examining the potential environmental risks of nanoparticles have focused on raw "as produced" nanoparticles that have not yet been incorporated into a technology such as a composite, coating, or other matrix. In this study, we examine the residue of nanometal-based energetics following ignition; the most likely release of nanoparticles from a specific nanotechnology. Metals such as aluminum and copper offer great potential for use as energetic such as explosives propellants, and primers. In this study, green primers were ignited to collect residual material. Aluminum particles of average particle size (APS) of 80 nm having active metal content of 80 percent by weight, and 2.2 nm oxide shell layer were used as fuel in the preparation of energetic mixtures. These materials were composed of a mixture of CuO nanorods and Al nanoparticles or CuO nanorods and Al micron flakes (75% by wt) combined with nitrocellulose (25% by wt). These materials represent residues expected after ignition as part of an energetic. Materials were examined pre and post ignition. Ignition resulted in a low production of residue for characterization (10-15 %). Broad analysis by SEM shows formation of a wide range of particulate sizes (0.01 to > 100 um) for the nano based energetic while the micron sized energetic is composed primarily of large (>10 um) aggregates. It is expected the smaller size of the nano energetic residue, when combined with the acidic conditions of an ignition will result in a higher dissolution rate for aluminum and copper from the primer. Results of this study represent one of the first documented releases of a nano-sized particulate from a nano-enabled technology.

737 Risk Quantification of Engineered Nanomaterials in Water Based on Probabilistic Species Sensitivity Distribution Modeling B. Nowack, EMPA, Empa-Materials Science and Technology; E. Kost, F. Gottschalk, Empa-Materials Science and Technology. In this study we present a quantification of the risks of five engineered nanomaterials (ENM), TiO_2, ZnO, Ag, CNT, fullerenes, to aquatic organisms by linking probability distributions of modeled environmental concentrations to species sensitivity data. We evaluated published ecotoxicity tests with aquatic organisms and derived for each species and study no effect concentrations (NEC) according to the ECHA guideline [1], using assessment factors to transform acute to chronic, $L(E)C_{50}$ to chronic NOEC and NEC, and to account for laboratory-field variability. We then combined all data to derive probabilistic species sensitivity distributions (PSSD) that account for the large differences in effects of one ENM to the same organisms in different studies. Using this approach we therefore consider different forms, aggregation states, coatings, etc. of the ENM into the species sensitivity distribution. The modeled PSSD were then compared to modeled predicted environmental concentration (PEC), also in the form of probability distributions[2]. The results show that there is a 4.6% chance for a risk to organisms in surface water to nano-Ag and 0.008% for nano-ZnO. For the other three ENM no risk was predicted. In undiluted effluent from wastewater treatment plants (representing a worst-case scenario), the risks are 45% for nano-Ag, 35% for nano-ZnO and 62% for nano-TiO_2. The risks for fullerenes and CNT are negligible. These results show that using realistic ranges of environmental concentrations, slight risks to aquatic organisms might be present for nano-Ag, nano-ZnO and nano-TiO_2. These ENM should therefore be investigated further, especially with regards to their chronic toxicity and their actual form in the environment. Literature 1. ECHA, Guidance on information requirements and chemical safety assessment Chapter R.16: Environmental Exposure Estimation, European Chemicals Agency. 2010. 2. Gottschalk, F.; Sonderer, T.; Scholz, R. W.; Nowack, B., Modeled environmental concentrations of engineered nanomaterials (TiO_2, ZnO, Ag, CNT, fullerenes) for different regions. *Environ. Sci. Technol.* 2009, *43*, 9216-9222.

738 Differential Uptake Between Ionic Cadmium and Quantum Dot Released Cadmium B.C. Seda, Clemson Univ, Graduate Program of Environmental Toxicology, Clemson Univ; A.S. Mount, Clemson Univ, Biological Sciences; A. Roberts, Univ of North Texas; S.J. Klaine, Clemson Univ, Institute of Environmental Toxicology (CU-ENTOX), Clemson Univ, Institute of Environmental Toxicology (ENTOX) Much of the toxicity of semiconductor quantum dots is attributed to the release of heavy metal ions, such as cadmium in the case of CdSe/ZnS quantum dots. Because of the unique optical properties of quantum dots, their uptake in small transparent organisms such as *Daphnia magna* can be observed by fluorescence microscopy techniques. In *D. magna* that have been exposed to surface modified CdSe/ZnS quantum dots, fluorescence indicates the quantum dots accumulate in the gut tract, where they can remain for more than 24 hours, providing for circumstances allowing the gradual release of Cd. However, the amount of Cd retained in the whole organism after this time varies with particle surface chemistry. In this study, *D. magna* were exposed to CdSe/ZnS quantum dots and the equivalent concentration of Cd. Confocal fluorescence laser scanning microscopy (LSM) and laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) techniques were used to detect uptake of intact quantum dots and cadmium, respectively. Because polyethylene glycol coated CdSe/ZnS quantum dots were previously observed to not cross gut epithelium, they were not expected to do so in this study. LA-ICP-MS was used to detect metals concentrations in tissues not associated with the gut tract or external tissues. Our hypothesis is that Cd released from the quantum dots will be observed to have been absorbed by the *D. magna*. Because evidence suggests that the quantum dots are associated with the gut tract, even after depuration, tissue specific Cd concentrations were expected to similar between ionic Cd and quantum dot exposures.

739 Applying Ecosystem Services to the Ambient Air Quality Setting Process A.W. Rea, US Environmental Protection Agency, Office of Research and Development. The US Environmental Protection Agency (EPA) currently is conducting a joint review of the existing secondary

(welfare-based) National Ambient Air Quality Standards (NAAQS) for oxides of nitrogen (NOx) and sulfur (SOx). EPA has decided to assess jointly the science, risks, and policies relevant to protecting public welfare associated with oxides of nitrogen and sulfur due to both their atmospheric interactions and ecological effects. As stated in the Clean Air Act (CAA), the purpose of a secondary NAAQS is to "protect the public welfare from any known or anticipated adverse effects associated with the presence of such air pollutants in the ambient air." Assessments of adverse public welfare effects are based on how ecologically adverse impacts translate into adverse impacts on public welfare via changes in ecosystem service delivery. While adversity is not explicitly defined in the CAA, it can be inferred that adverse ecological impacts have some corresponding impact on the well-being of human populations, through reductions in ecosystem services that might include direct (e.g., recreational fishing) or indirect (e.g., provision of habitat for endangered species) services to humans. These ecosystem service linkages are being used to inform the standard setting process. The ecological risk assessment focused on several case studies in sensitive ecosystems. Ecosystem services were used to characterize adversity to public welfare of ecological effects associated with current levels of nitrogen and sulfur deposition. For aquatic acidification, ambient concentrations of NOx and SOx were linked to deposition using a critical loads approach, projecting changes in an ecological indicator (acid neutralizing capacity, ANC) correlated with changes in fish species richness and its influence on recreational fishing. For terrestrial acidification, a critical loads approach was used to link base cation:aluminum ratios to tree health and associated provision of wood products (sugar maple production and timber production). For nitrogen enrichment in estuaries, a eutrophication index was linked to degradation, hypoxia, and diversity loss associated with changes in recreational fishing and shifts in plant species composition, and with nitrogen cycling to benefits received from hunting, fishing, and wildlife viewing. An update on the current status of the review and a summary of the proposed rulemaking (July 2011) will be provided.

740 Communicating Ecosystem Services: Tools for Scientists to Engage the Public C.S. Duke, Ecological Society of America. The Ecological Society of America (ESA), in partnership with the Union of Coincerned Scientists, developed the Communicating Ecosystem Services project with the goal to increase the public's awareness of the importance of ecosystem services. The project provides series of Tool Kits for scientists, educators, and other professionals to help them address your local media, community groups, state legislators or other audiences. The Tool Kits provide background information on specific ecosystem services, as well as general tips and suggestions for developing presentations or writing articles for a non-scientific audience. Tool Kits have been completed for pollination, water purification, and marine nurseries ecosystem services. Each consists of the following elements: basic fact sheet, what you can do to preserve the service, key points, science summary, resources and references, case studies, policy overview, and presentation aids. All the information is available without charge at www.esa.org/ecoservices. This presentation will describe the tool kits and summarize their contents.

741 Ecosystem Services as Assessment Endpoints in Ecological Risk Assessment W.R. Munns, US. EPA, Atlantic Ecology Division; A.W. Rea, USEPA, National Exposure Research Laboratory; M.G. Barron, USEPA, Gulf Ecology Division; S. Jordan, USEPA. The focus of ecological risk assessment (ERA) is on assessment endpoints, explicit expressions of environmental values to be protected. Traditionally, the ecological entities identified in assessment endpoints have been components of ecosystems deemed by risk assessors to be important to ecosystem structure and function – the benthic community, for example. Yet, there is growing awareness that improved environmental management can be achieved by considering more explicitly how decisions affect the well being of people and society. Ecosystem services, the outputs of ecological functions or processes that contribute to social welfare, can complement traditional assessment endpoints by clarifying to the public the benefits and costs a decision will have to society. Ecosystem service assessment endpoints can improve the transparency of decision making by focusing ERAs on components of nature that nonscientists understand and value. By enabling a more complete evaluation of the tradeoffs involved with the alternative solutions being considered, decision makers can be more fully informed about the intended and possible unintended consequences of their choices. This presentation will describe efforts currently underway by the USEPA's Risk Assessment Forum to establish the technical foundation needed to incorporate ecosystem services in ERA, and to identify generic ecosystem service assessment endpoints that can be considered during problem formulation. Several candidate generic ecosystem service assessment endpoints are considered, including catchable fish, clean water and air, climate regulation, water supply and flood protection, arable land and agricultural productivity, and aesthetic values. General guidance is being developed for selecting ecosystem service assessment endpoints, and for translating risk to traditional assessment endpoints to risk to ecosystem services. Several case studies are being conducted to highlight how use of ecosystem service assessment endpoints can enhance decision making that span several spatial scales and types of decisions. These include case studies covering local issues involving hazardous waste sites and conductivity in Appalachian streams, to broader issues encompassing threatened and endangered species and national scale assessments for setting air quality standards.

742 Examples of Ecological Services Accounting Using Habitat Equivalency Analysis in Support of Environmental Decision Making R. Gouguet, Windward Environmental LLC. Habitat equivalency analysis (HEA) was originally developed by the National Oceanic and Atmospheric Administration as a natural resource damage assessment tool for quantifying natural resource service losses and calculating the scale of compensatory restoration required to offset those service losses. HEA can also be used to calculate and track service flow changes in areas such as mitigation requirements development, quantitative dredge material management alternative analysis, remedial alternative analysis, and ecological compensation calculation in lieu of active cleanup. The general approach includes estimating baseline conditions and gains or losses in ecological services associated with various actions based on the judgment of professionals with knowledge of the local ecosystem. Estimated changes in ecosystem service levels under projected post-action conditions are summed over time, allowing a comparison of the net present ecological service value under each scenario and the selection of the "most appropriate" alternative. This presentation will describe how ecological services accounting was used as a planning tool at five sites: (1) Craney Island, Virginia; (2) Matagorda Bay, Texas; (3) Swan Lake, Texas; (4) Port Arthur, Texas; and (5) Woodard Bay Natural Resources Conservation Area, Washington.

743 The Role of Ecosystem Services as a Management Tool for Protecting Marine Preserves in Southern California S. Gruber, Weston Solutions, Inc., Weston Solutions; M. Wartian, Weston Solutions, Inc, Water Resource Services; D.W. Moore, Weston Solutions, Inc, Director Natural Resource Management; B.J. Mastin, Weston Solutions, Inc., Natural Resources. Along the southern California coast, marine preserves known as Areas of Special Biological Significance (ASBS) have been established through the California Ocean Plan to protect the beneficial uses of these extremely valuable coastal resources. Due to their close proximity to urbanized watersheds in the coastal zone, compliance monitoring programs known as the ASBS Special Protections have been established by the California State Water Resources Control Board (State Board) to protect the beneficial uses from urban runoff and assure that water quality in the ASBS does not differ from natural water quality found at un-urbanized reference sites. Although there are some monitoring elements in the Special Protections that assess toxicological and biological endpoints, the primary focus of the Special Protections is on water quality during storm events. However, recent studies conducted by Weston Solutions at several ASBS in southern California suggest that impacts from storm water runoff may be ephemeral and have limited impacts to the resources in the ASBS receiving waters relative to other perturbations, such as long-shore transport of contaminants from nearby harbors and trampling of intertidal biota by anglers, tide pool visitors, and school groups. In order to truly protect and enhance the beneficial uses of the ASBS, the ecosystem services concept is being applied in implementing a monitoring and restoration strategy for several ASBSs in the region. The program focuses on a comprehensive approach to understanding all the potential impacts to ASBS resources, minimizing those impacts through a suite of prioritized best management practices, while enhancing the recreational services provided by the ASBS for anglers, tide pool visitors, and educators. This comprehensive approach using the ecosystem services concept has important implications for future management of these extremely valuable coastal preserves.

744 The Use of Ecosystem Services Information by the National Estuary Program L. Martin, US Environmental Protection Agency, Risk Assessment Forum; I. Purdy, US Environmental Protection Agency, Region 2

Watershed Management Branch. Ecosystem Services concepts and data are rapidly evolving through their use and application. This development is in part motivated by the belief that incorporation ecosystem services information (monetary or non-monetary valuation) will improve environmental decision-making and outcomes in those projects whose management decisions are informed by risk assessment and some form of a cost-benefit analysis. This presentation will report on a three-year exploration of the National Estuary Programs (NEP) use of ecosystem services concepts, and outcomes in meeting management objectives. The study examined attitudes toward and experience with incorporation of ecosystem services in environmental management programs for a self-selecting subset of the 28 member NEP. The study included use of targeted questions, workshop presentations and scheduled conference call dialogs between EPA and the NEP staff and managers. Results indicate that the willingness to focus on ecosystem service concepts by the NEP programs' environmental managers correlate well with the ability to use them within the existing management and accountability paradigm.

745 Economic Valuation Tools and Their Application to Ecosystem Services M. Mazzotta, EcoBenefits Research. Many of the ecosystem services that people value are not normally bought and sold; yet, this does not mean they have no measurable economic value. Economists have developed a set of approaches and tools for valuing the full range of both market and "non-market" ecosystem goods and services. These approaches and tools offer a way to understand and evaluate the many tradeoffs involved in managing natural resources and environmental risks, to answer questions such as: How can we allocate scarce resources to provide the greatest benefits to society?; or How much additional risk are people willing to accept in exchange for other valued goods and services? While value is inherently subjective, economic valuation methods aim to quantify it by looking at the tradeoffs people are willing to make, which can reveal their values for different states of the world. An overview of economic valuation tools for ecosystem services, focusing on non-market valuation, will be presented, along with some basic economic concepts that are important to economic valuation. These concepts include: the difference between economic impacts and social benefits; marginal versus total value; and dollar values versus non-monetary values and when each is most appropriate. While economic valuation tools can be tremendously useful, there are often practical limitations to their application, and they provide only one form of information to be used in conjunction with other tools and approaches to inform decisions. Thus, some caveats will be presented, and economic valuation approaches will be discussed in the context of the frameworks where they are typically applied.

746 Ecosystem Services in Soil Policy: An Example J. Van Wensem, Soil Protection Technical Committee (TCB), TCB. In many countries the issue of chemical contamination of soils is traditionally an important part of the policy. This has resulted in a strong focus on standard setting -, risk assessment- and remediation methods, thereby often neglecting other aspects of good soil quality. In the past ten years biological, physical, and ecological aspects, land use, fitness for use and ecosystem services have gained more attention from policy makers. The recognition that good soil quality is not only determined by the chemical composition of the soil is the driver behind this development. The concept of ecosystem services is slowly infiltrating in Dutch soil policy. First it was recognized that soil quality, besides chemical, has also physical and biological aspects. More focus was given to land use and the necessary soil quality to support specific types of land use. Next, a method was developed to measure biological qualities given the land use, also allowing to express these qualities in terms of the performance of – mostly – supporting ecosystem services. Recently, pilot projects have started to help municipalities to look at the soil in terms of ecosystem services and tradeoffs, thereby connecting local soil policy with spatial planning and societal demands. Early 2011 the Dutch Soil Protection Committee has been asked to prepare a recommendation for the government on how to facilitate optimal use of ecosystem services by land users and local authorities. These developments are paralleled by the European soil strategy. It is too early to predict the final result of these processes, but promising steps have been made. The presentation will focus on the steps that have lead to the introduction of more integrated approaches, based on the ecosystem services concept.

747 What are Forensic Approaches to Ecotoxicology? J.E. Elliott, Environment Canada, Pacific Wildlife Research Centre, Science and Technology Branch, Environment Canada, Pacific Wildlife Research Centre, Environment Canada, Canadian Wildlife Service. This introductory talk provides an overview of the session, and therefore of the book, and some discussion of the background and of emergent themes. The nature of forensic ecotoxicology is considered, and a definition proposed. I reflect on the experiences of some authors in trying to establish cause-effect, and the challenges of translating scientific evidence of toxicant effects into regulatory or non-regulatory action. I further examine the problem of bias and some ethical aspects in data interpretation, and consider some of the common dispute resolution processes encountered and discussed by the various authors.

748 Toxic Trees: Arsenic Pesticides, Woodpeckers and the Mountain Pine Beetle C. Morrissey, Univ of Saskatchewan, Biology; J.E. Elliott, Environment Canada, Pacific Wildlife Research Centre, Science and Technology Branch, Environment Canada, Pacific Wildlife Research Centre, Environment Canada, Canadian Wildlife Service. During the mid-1990s, an unprecedented outbreak of the Mountain Pine Beetle (*Dendroctonus ponderosae*) in the economically valuable pine forests of British Columbia triggered a major campaign by forest managers to try and control the beetle damage. The result was a major change in the landscape from harvesting and prescribed burns in addition to the wide scale application of a systemic insecticide known as monosodium methanearsonate (MSMA). Since MSMA contains arsenic, is highly stable, and was being applied in increasingly large quantities, our study evaluated the potential impacts to forest birds, particularly woodpeckers. From 2002-2006, we investigated the exposure of breeding woodpeckers to MSMA ingested via contaminated bark beetles. We measured high levels of arsenic in beetles from treated trees, and found significant amounts of debarking on many MSMA-treated trees indicating woodpeckers were feeding on them. Radio-telemetry confirmed that woodpeckers breeding near MSMA treatments regularly used those stands. Blood samples of woodpeckers and other forest birds revealed elevated arsenic concentrations. Through a concurrent laboratory dosing study of Zebra finches (*Taeniopygia guttata*), we estimated woodpeckers were receiving enough MSMA through ingestion of contaminated beetles to cause poorer growth and mortality of young birds and mass loss in adults. We concluded that the combination of extensive harvesting in the region in combination with the large numbers of treated MSMA trees was potentially detrimental to forest bird populations. By the end of our study, MSMA approval for use in Canada was revoked and the Ministry of Forests did not pursue re-registration of MSMA. We clearly demonstrated that large scale MSMA use had the potential to cause serious harm to forest birds, while appearing to have limited efficacy in beetle control. This was a landmark study in the field of wildlife ecotoxicology – a first to evaluate the exposure and effects of a toxic chemical to woodpeckers in forest ecosystems.

749 Selenium, Salty Water, and Deformed Birds H. Ohlendorf, CH2M Hill. Selenium was identified in the 1930s as the cause of embryo mortality and severe embryo deformities when chickens were fed grains grown on seleniferous soils in South Dakota. There had been no documented occurrences of such effects in wild birds before 1983, when we studied the effects of agricultural irrigation drainage water contaminants on birds feeding and nesting at Kesterson Reservoir, located within the Kesterson National Wildlife Refuge in the San Joaquin Valley of California. The Reservoir was used for disposal of subsurface saline drainage waters from agricultural fields and was intended to provide beneficial habitat for wildlife, particularly waterfowl and other aquatic birds. Analyses of food-chain biota (plants, aquatic invertebrates, and fish) and bird tissues or eggs showed that selenium was the only chemical found at concentrations high enough to cause the observed adverse effects on bird health or reproduction. Results of the studies at Kesterson Reservoir stimulated interest and concern about the effects of selenium in agricultural drainage throughout the western USA where similar scenarios might exist (as well as in industrial settings such as mining and power generation). Those studies showed that selenium-related problems with agricultural drainage were widespread and locally significant. Problems of managing selenium in agricultural drainwater are difficult to solve or mitigate, despite intensive efforts to do so. This presentation briefly describes the field and laboratory studies that documented the effects of selenium in birds using wetlands receiving seleniferous agricultural drainage, the linkages between those studies and subsequent efforts to address the issue of selenium contamination in agricultural drainage water, and the consequent conservation gains.

750 Rocky Mountain Arsenal: Chemical Weapons, Cyclodiene Pesticides, and the Making of an Urban Wildlife Refuge J.T. Edson, Edson Ecosystems LLC; J.V. Holmes, Stratus Consulting Inc.; J.E. Elliott, Environment Canada, Pacific Wildlife Research Centre, Science and Technology Branch, Environment Canada, Pacific Wildlife Research Centre, Environment Canada, Canadian Wildlife Service; C. Bishop, Environment Canada, Science And Technology Branch, Environment Canada, Canadian Wildlife Service. In 1942, the US Army purchased 70 km^2 near Denver, Colorado, to construct the Rocky Mountain Arsenal, where they manufactured chemical and incendiary weapons (mustard, lewisite, napalm) in support of the war effort. After World War II, Shell Oil and its predecessors manufactured pesticides, insecticides, and herbicides at the Arsenal, and the Army manufactured and then decommissioned Sarin (GB) nerve agent. The industrial manufacturing was concentrated near the center of the site, with many square kilometers of undeveloped land providing a buffer from urban Denver. Millions of liters of liquid wastes, including cyclodiene pesticides such as dieldrin, aldrin, and endrin, were disposed of in open basins, pits, and trenches on the site. Cyclodiene pesticides impact the central nervous system of exposed biota, causing disorientation, emaciation, and eventually death. Thousands of wildlife mortalities were documented at the site, including an estimate of 20,000 duck deaths over a 10-year period in the 1950s, and over 1,800 waterfowl deaths in one basin alone between 1981 and 1987. After manufacturing ceased in the 1980s, the Army, Shell, the US Environmental Protection Agency, and the State of Colorado endeavored to address the contamination and the Arsenal's future land use. In 1992, the USA passed the Rocky Mountain Arsenal National Wildlife Refuge Act to create wildlife habitat from uncontaminated and remediated areas and reduce risk of exposure to humans. Many aspects of the cleanup were based on pesticide risks to wildlife; however, the parties rarely reached agreement on appropriate cleanup thresholds and the size of the area requiring cleanup. Ultimately, in 2010, after nearly 30 years of investigation and cleanup efforts costing over $2 billion, "significant environmental cleanup" was completed. Millions of tons of toxic sludges and soils had been placed in hazardous waste landfills, and millions of tons more were buried in place and capped. The refuge now comprises approximately 6,000 ha, roughly the size of Manhattan. The cleanup process was contentious, resulting in multiple lawsuits, which is not a model that the authors recommend. Although contamination in some parts of the Arsenal likely is still present and should continue to be evaluated, the refuge will be an important protected oasis of wildlife habitat in the midst of the Denver urban sprawl.

751 Restoration of Lake Apopka's North Shore Marsh: High Hopes, Tough Times, and Persistent Progress R.H. Rauschenberger, US Fish and Wildlife Service; R. Conrow, E.F. Lowe, M.F. Coveney, St. Johns River Water Management District; G. Masson, US Fish & Wildlife Service. The story of Lake Apopka is a familiar one to many Floridians and has gained international notoriety. The 12,500 ha lake was once a world-class bass fishery. Then, a century-long decline occurred, traced to the loss of over 8,000 ha of wetlands to farming operations, agricultural discharges laden with phosphorus to the lake, treated wastewater discharges, and input from citrus processing plants. The state of Florida and the Federal Government purchased the 8,000 ha property with the goal of restoring wetland habitat to drastically reduce nutrient-loading and thereby restore the lake. Shortly after flooding the property in the winter of 1998-1999, a bird mortality event occurred, resulting in the deaths of 676 birds, primarily American white pelicans (Pelecanus erythrorhynchos), but also including 43 endangered wood storks (Mycteria americana), 58 great blue herons (Ardea herodias), and 34 great egrets (Casmerodius albus). The deaths of the birds, attributed to pesticide toxicosis, was followed by years of research and remediation to ensure the future safety of wildlife on the property. Presently, about 3,000 ha of wetlands have been rehydrated since resuming restoration activities, with no adverse effects to wildlife. We present and discuss the history of Lake Apopka, the efforts to restore it, and what we have learned along the way.

752 Abnormal Alligators and Organochlorine Pesticides in Lake Apopka, Florida R.H. Rauschenberger, US Fish and Wildlife Service; A.R. Woodward, Florida Fish and Wildlife Conservation Commission; H.F. Percival, US Geological Survey, Florida Cooperative Fish and Wildlife Research Unit; T. Gross, Environmental Resource Consulting, Dr. Timothy S. Gross, Univ of Florida; K.G. Rice, US Geological Survey, Southeast Ecologicial Science Center; R. Conrow, St. Johns River Water Management District. Lake Apopka is a 12,400-ha hypereutrophic lake in central Florida that was the recipient of nutrient and pesticide pollution from adjacent agricultural operations and treated wastewater for 50 years. The abnormal American alligators (Alligator mississippiensis) in Lake Apopka have been the object of a number of studies including investigations of a population crash, the epidemiology of egg failure, and anomalous endocrine function. Several hypotheses of the causes of these abnormalities have been proposed and examined by multiple research organizations over the past three decades. Initially, organochlorine pesticide (OCP) contamination was considered the factor most likely contributing to poor reproductive success. Concentrations of DDE in alligator eggs sampled in 1984-85 were approximately 4 mg/kg and those of toxaphene were approximately 2.5 mg/kg. These levels were known to cause reproductive failure in certain birds. However, transmissible diseases, population age and density, cyanotoxins, nutritional deficiencies, and combinations thereof, were also investigated for their contribution to poor alligator reproductive success. Investigations of an alligator mortality and reproductive failure event on Lake Griffin, a lake similar to Lake Apopka but with lower OCP levels, revealed analogous reproductive abnormalities that were associated with a dietary thiamine deficiency. Thiamine deficiency appeared to be associated with a diet of almost exclusively gizzard shad, which contain thiaminase, an enzyme that breaks down thiamine. OCP contaminants may contribute to these maladies, perhaps through endocrine disruption and increased stress. We present and discuss the findings of the past 30 years of work at Lake Apopka and their influence on local management decisions as well as policy at the national level.

753 South Asian Vultures in Crisis: Environmental Contamination with a Pharmaceutical L. Oaks, Washington State Univ, College of Veterinary Medicine; R.T. Watson, Peregrine Fund. In the late 1990s an unprecedented decline in the population of two of the world's most abundant raptors, the Oriental White-backed vulture (Gyps bengalensis) and the Long-billed vulture (Gyps indicus), was noticed in India. By the early 2000s, similar catastrophic declines followed in neighboring Pakistan. Ecological and forensic studies ultimately found that a non-steroidal anti-inflammatory pharmaceutical, diclofenac, was responsible. Diclofenac, long used in human medicine, had found its way into the veterinary market as a safe, inexpensive, and very popular drug for livestock in Southern Asia. Unfortunately, diclofenac residues caused kidney failure in Gyps vultures that fed on treated carcasses. And the loss of breeding adult vultures had a profound impact on the population, leading to declines on the order of 30% per year. In 2004, a series of meetings were held with government officials to inform them of this discovery. The extensive lobbying efforts that followed successfully led in 2006 to a ban on the manufacture of veterinary diclofenac in India, Pakistan, and Nepal. Sadly, in 2010, diclofenac still appears to be readily available and widely used in veterinary medicine, leaving the fate of wild Gyps vultures in doubt.

754 Bad for the Gonad: Atrazine is a Gonadotoxin With Consistent Effects Across Vertebrate Classes T. Hayes, Univ of California – Berkeley, Dept of Integrative Biology. The induction of aromatase and estrogen synthesis in the gonads of alligators was the first finding to suggest that atrazine was an endocrine disruptor in wildlife. This study was followed by field studies that suggested that atrazine is associated with feminized frogs in the wild. Thereafter, multiple laboratories showed that atrazine demasculinizes and feminizes male amphibians, but these findings and/or their significance have been challenged repeatedly by industry-funded scientists over the last ten years. Recently, however, 43 independently funded scientists representing 13 countries reviewed the effects of atrazine across vertebrate classes. Consistent effects in fish, amphibians, reptiles, birds, and mammals were revealed. In particular, the demasculinization and feminization of male gonads via multiple endocrine disrupting mechanisms have been documented and meet all of the so-called "Hill criteria" for establishing cause-effect. As should be expected, the effective doses vary across vertebrate classes with amphibian and fish being the most sensitive to the herbicide (low ppb range), and mammals and especially birds being the least sensitive. In addition, our analysis revealed multiple endocrine disrupting mechanisms including increases in stress hormones, decreases in androgens and increases in estrogens. The effects are produced via interactions at multiple sites along the stress and reproductive axes. New data in amphibians demonstrate that the morphological effects are accompanied by behavioral and functional impairments on reproductive function. Similarly, mammals showed impaired reproductive function as well. The morphological effects have also been associated with amphibians in the wild in multiple studies, suggesting that atrazine may play

a significant role in amphibian declines, but effects on other taxa have not been examined in the wild. To date, regulatory agencies have failed to comprehensively examine the totality of evidence demonstrating atrazine's effects in the laboratory and potential impact on environmental and human health.

755 Use of Passive Sampling to Measure the Sorption of PCDDs, PCDFs, and PAHs to Black Carbon in Passaic River and Newark Bay Sediments M.K. Lambert, Univ of Rhode Island. Graduate School of Oceanography, USEPA, OSRTI, Environmental Scientist; R. Lohmann, Univ of Rhode Island, Graduate School of Oceanography, Univ of Rhode Island. The partitioning of polychlorinated dibenzo-*p*-dioxins and dibenzofurans (PCDD/Fs) onto black carbon (BC) strongly controls the fate of PCDD/Fs in the environment and yet few studies have calculated equilibrium partitioning coefficients (K_{BC}) for PCDD/Fs using measurements of in situ contaminated sediments. Laboratory measurements of sorption to BC often differ from field observations due to the effect of different types of BC and of competition with other organic molecules. K_{BC} values were derived from measurements of sediments in the Passaic River and Newark Bay, NJ for PCDD/Fs and polycyclic aromatic hydrocarbons (PAHs). An OC partitioning model and a BC-inclusive, Freundlich partitioning model were used to interpret the measured sediment concentrations of OC, BC, PCDD/Fs, and PAHs, and the freely dissolved concentrations of PCDD/Fs and PAHs. A non-depletive, polyethylene passive sampling method was used to measure freely dissolved concentrations at equilibrium, circumventing the need to correct for sorption to dissolved organic carbon. Such corrections introduce uncertainty to the measured porewater concentrations. A time-series, equilibrium experiment indicated the variability for the passive sampling method used in this study was < 15%. The Freundlich model predicted the partitioning of PAHs to within a factor of 2-3 of the observed partitioning, using a Freundlich coefficient n=0.7 and literature K_{BC} values. Literature K_{BC} values for PCDD/Fs, with a n=0.7, produced predicted PCDD/F partitioning that differed by as much as 2 orders of magnitude from the observed partitioning. Site-specific K_{BC} values were calculated for PCDD/Fs at n=0.6, 0.7, and 0.8. K_{BC} values calculated at n=0.8 were 10-100 times larger than those calculated at n=0.6. Based on the close fit of the PAH partitioning using n=0.7, it was judged that this is most appropriate Freundlich coefficient for PCDD/Fs as well. The calculated K_{BC} values range up to 2 orders of magnitude larger than those derived from a study of HOC partitioning in Boston Harbor, but are 2 to 4 orders of magnitude smaller than those observed in the more pristine environment of Baltic Sea sediments. Unexpectedly, PCDDs displayed stronger sorption than PCDFs or PAHs relative to their aqueous solubilities. Although the presence of BC in the sediments reduced the overall bioavailability of PCDD/Fs by > 90%, the sediments at 2 m depth in the Passaic River display high porewater activities of PCDD/Fs.

756 Measurement and Estimation of PCB Porewater Concentrations and Release of PCBs from Sediment to Water in Indiana Harbor and Ship Canal A. Martinez, Univ of Iowa, Dept of Civil & Environmental Engineering,and IIHR-Hydroscience and Engineering; D. Reible, Univ of Texas, Environmental and Water Resources; K.C. Hornbuckle, Univ of Iowa, Dept of Civil & Environmental Engineering. Sediments contaminated with persistent, bioaccumulating and toxic compounds (PBTs) are an important source of these chemicals to the environment. PBT release from sediments is caused by both episodic resuspension and continuous soluble release from the bed sediment. The latter is a predictable function of the sediment porewater concentration, although this is a measurement that is difficult for PBTs because of their relatively low water solubilities. Measurements of PCBs freely dissolved porewater concentrations from Indiana Harbor sediment ranged from 100 to 500 ng L-1 using a novel passive sampler technique (SPME PDMS-fiber). It was possible to determine ~ 80 individual or coeluting congeners in the porewater. Isotherm experiments showed that less than 10 days were enough to achieve equilibrium between the PDMS-fiber and the sediment porewater concentration. Total organic carbon, organic carbon and black carbon were measured. High levels of black carbon as a fraction of total organic carbon were found (median ~30%), which reflect the long history of local combustion sources. Dissolved organic carbon (DOC) was also measured in the core sample and ranged from 30 to 300 mg L-1, and it is strong correlated with core depth. A partitioning approach between PCBs and organic and black carbons yielded the best approach to calculate PCB porewater concentration in the sediment from bulk PCB concentrations. A release PCB concentration was calculated from the PCB porewater (measured and calculated) and the DOC values, and was used to estimate the release of PCBs from the sediment into the overlying water. Black carbon was also incorporated in the calculation of the mass transfer coefficient.

757 Procedures for Derivation of Site-specific Equilibrium Partitioning Sediment Benchmarks for the Protection of Benthic Organisms: Nonionic Organics S. Kane Driscoll, Exponent Inc.; S. Ahn, Exponent Inc., Postdoctoral scholar; J. Pietari, Exponent Inc.; R. Burgess, USEPA, ORD/NHEERL Atlantic Ecology Division. This presentation provides an overview of draft guidance being developed by USEPA (EPA) on procedures that can be used to modify standard equilibrium partitioning sediment benchmarks (ESBs) for nonionic organic chemicals to reflect site-specific conditions. The procedures used to develop site-specific ESBs are intended to supplement the procedures described for standard ESBs based on the equilibrium partitioning (EqP) theory. EqP theory holds that nonionic chemical, such as PAHs, partition between sediment organic carbon, interstitial (pore) water, and benthic organisms. EPA currently recognizes that the standard ESBs may be under- or overprotective if the bioavailability of a chemical differs in site sediments because of additional partitioning phases (e.g., soot or black carbon). The site-specific procedures described in the guidance document assume that the concentration of bioavailable chemical can be reasonably measured or estimated from the concentration of freely dissolved chemical in interstitial water. The guidance includes examples that demonstrate the calculation of site-specific ESBs using various approaches including: a "two-carbon" model that estimates the concentrations of chemicals in interstitial water by taking into account the influence of black carbon, direct measurement of chemicals in isolated samples of interstitial water, and concentrations of chemicals in interstitial water measured using passive samplers. Consistent with the recommendations of EPA's Science Advisory Board, the guidance does not imply that ESBs should be used as stand-alone, pass-fail criteria for all applications; rather, ESB exceedances can be used to trigger the collection of additional assessment data. A potential tiered approach for implementing site-specific ESBs while balancing environmental protection and cost is presented. The first tier uses the standard EqP-based ESBs to assess the likelihood of toxicity to the benthos. In the second tier, passive samplers can be used to generate site-specific ESBs. If the site-specific ESB is exceeded, there is the option to conduct sediment toxicity testing to verify the findings of the first two tiers. Site-specific ESBs may be useful as a complement to existing sediment assessment tools, to help evaluate the extent of sediment contamination, to identify chemicals causing toxicity, and to serve as targets for pollutant loading control measures.

758 Contrasting PCDD/F and PBDE Activities in Biota, Sediment, and the Water Column of Newark Bay, New Jersey (USA) C. Friedman, MIT, Center for Global Change Science; R. Lohmann, Univ of Rhode Island, Graduate School of Oceanography, Univ of Rhode Island. The bioavailiability of polychlorinated dibenzo-*p*-dioxins and dibenzofurans (PCDD/Fs) and polybrominated diphenyl ethers (PBDEs) was determined at five sampling sites in Newark Bay, New Jersery (USA). Deposit- and filter-feeding organisms were collected from the sites and their tissues were analyzed for PCDD/F and PBDEs. Freely dissolved PCDD/F and PBDE porewater concentrations were determined in the laboratory using polyethylene (PE) passive samplers. Freely dissolved porewater PCDD/F and PBDE concentrations were also back-calculated based on their partitioning to sedimentary organic carbon (OC), and black carbon (BC) assuming equilibrium partitioning. Lastly, PE samplers were also deployed in situ to measure freely dissolved deep water PCDD/F and PBDE concentrations. All freely dissolved concentrations were compared to those based on lipid uptake. For PCDD/Fs, PE-derived porewater and/or deep water concentrations were generally closest to those estimated from lipid. For PBDEs, porewater, deep water, and sediment OC alternated in most closely predicting tissue exposures to PBDEs. Considering BC sorption of PBDEs caused underestimation of organism exposures by at least an order of magnitude. Lower molecular weight (MW) PCDD/Fs were approximately at equilibrium between porewater and deep water, whereas higher MW congeners demonstrated a gradient from the porewater to the water column. Low MW PBDEs generally had activity gradients in the direction of the water column. The direction of high MW PBDE gradients depended on the congener and site. Results indicated that PE has potential to measure bioavailability accurately for deposit-feeding organisms in the field, and that BC sorption

may play a less important role in determining PBDE bioavailbility than for PCDD/Fs.

759 Biodynamic Modeling of Remedial Success of In Situ Activated Carbon Amendment to Sediment and Possible Secondary Effects on Benthic Invertebrates E.M. Janssen, Stanford Univ, graduate student, Stanford Univ; R.G. Luthy, Stanford Univ, Civil and Environmental Engineering. The primary goal of sediment remediation is to reduce risk to ecosystems and humans by reducing contaminant release to overlying water and exposure to biota. A secondary goal is that the remedial approach should allow ecosystem recovery, e.g., the restoration of the benthic community. Our previous work showed that at full-scale, in situ sorbent amendment with activated carbon (AC) may reduce bioaccumulation of polychlorinated biphenyls from sediment by up to 85 to 90% under favorable field and treatment conditions. We demonstrate a biodynamic modeling framework for benthic organisms with different feeding strategies to assess how the remedial success of a sorbent amendment that lowers the contaminant availability can be compared to reference conditions and traditional cleanup goals, which are commonly based on bulk sediment concentrations. In situ AC amendment is a promising yet novel sediment remediation alternative and possible secondary effects on benthic invertebrates by sorbent addition need to be better understood. The presence of ingestible and non-ingestible AC in three reference sediments slightly increased weight loss but had no effect on survival, lipid, glycogen or protein content of *Neanthes arenaceodentata*, a deposit feeding polychaete, which does not discriminate against AC in its diet.

760 Reducing PAH (Bio)availability by In Situ AC Amendment to Soils and Sediments S. Hale, Norwegian Geotechnical Institute; G. Cornelissen, Norwegian Geotechnical Inst; E. Eek, G. Breedveld, K. Amstatter, M. Elmquist, Norwegian Geotechnical Institute; T. Hartnik, L. Jakob, Soil and Environment Division, Norwegian Institute for Agricultural and Environmental Research (Bioforsk); T. Henriksen, Lindum Ressurs og Gjenvinning AS; J. Gunnarsson, J. Hedman, G. Samuelsson, Stockholm Univ, Dept of Systems Ecology; O. Stokland, Marine Bunndyr AS. Activated carbon (AC) has a very high sorption capacity for organic pollutants and when added to contaminated soil or sediment can sequester and reduce the (bio) availability of these pollutants. We present a series of field AC amendments in Norway in which PAH -contaminated soils and sediments have been treated. A variety of innovative analysis techniques were used to assess the effectiveness of the amendment, such as the deployment of in situ porewater passive samplers and benthic diffusion flux chambers. At Trondheim harbor, AC was applied as a thin layer cap to a marine underwater sediment. Caps consisting of AC-alone, AC+clay and AC with a sand layer on top were compared to sand only and no cap. Underwater imaging showed successful cap placement and up to 60 % of the AC was recovered for the AC+clay cap. The sediment-to-water PAH flux was reduced for all AC treatments and the greatest reduction (factor of 10) was observed for the AC+clay. Porewater PAH concentrations were reduced up to 50 % in the biologically active 0-5 cm deep sediment layer which contained AC. Bioaccumulation of PAHs to worms and benthic mussels decreased 80-90% for the AC+clay cap. AC+clay was recommended as the best amendment method because it showed; i) best AC recoveries; ii) best chemical and biological effectiveness; iii) lowest detrimental secondary effects to the benthic communities. At Drammen, powdered and granular (PAC and GAC) AC were added to a soil. Freely dissolved aqueous PAH concentrations in drainage water and soil pore water were monitored with passive samplers. More than one year after amendment, the free aqueous concentrations in the drainage water were reduced by 93 % and 55 % for the PAC and GAC, respectively, and the free aqueous PAH concentration in the soil pore water itself, as measured by innovative dug-in passive samplers, was reduced by 93 and 70 % for PAC and 84 and 61 % for the GAC. The secondary chemical effects of the AC amendment were considered by monitoring the concentration of DOC and nutrients. Both PAC and GAC bound DOC while the concentrations of nutrients were variable and likely affected more by external environmental factors than the AC amendment. Biological testing showed that the amendment of 2% PAC had a negative effect on plant growth, but GAC actually improved growth. PAC was toxic to earthworms as it reduced the worm's weight. Both kinds of AC significantly reduced Biota to Soil Accumulation Factors (BSAFs) in earthworms and plants.

761 Activated Biochars for the In Situ Sequestration of Organics, Mercury and Carbon in Sediments J.L. Gomez-Eyles, Univ of Maryland Baltimore County; B. Beckingham, Univ of Maryland Baltimore County, Civil & Environmental Engineering, Univ of Maryland Baltimore County, Dept of Civil & Environmental Engineering; S. Kwon, UMBC; U. Ghosh, Univ of Maryland Baltimore County, Civil & Environmental Engineering. In aquatic environments that are impacted by contaminated sediments, contaminant transport pathways can be interrupted by enhancing the binding capacity of natural sediments. This study evaluates the potential of a series of especially formulated biochars (derived from pine wood, peanut hull, barley straw and acai pit) and activated poultry litter biochars to sequester organic and metal contaminants in sediments, while reducing or even reversing the carbon footprint of sediment remediation efforts. PAH, PCB and DDT isotherm studies were conducted at environmentally relevant concentrations using polyoxymethylene solid-phase extraction (POM-SPE), to evaluate the sorption capacity of the different biochars. Freundlich isotherms were constructed and biochar performance was compared with that of commercially available activated carbons (CACs). Biochars were effective at sorbing organics with Kf values ranging from 6.4 to 7.2 for PCB 47, a mid-range tetra-PCB. This sorption was highly non-linear, with n values ranging from 0.53 to 0.81 for PCB 47. However, CACs consistently removed more PCBs from solution, followed by the activated poultry litter biochars suggesting surface area is a key parameter controlling organic contaminant sorption potential. The difference in sorption potential between CACs and biochars was greater for the less chlorinated PCBs with lower Kow. Sorption studies were also carried out for mercury at a range of pH concentrations (pH 3-11). The activated poultry litter biochars removed >99% mercury from solution over the whole pH range, whilst the CAC's removed between 18 and 95% depending on pH level. This suggests the surface functionality of the biochars make them more effective for mercury removal, than the CACs. A better understanding of how biochar characteristics affect contaminant sorption is necessary to improve biochar quality and to help in the selection of the appropriate biochar amendment necessary to achieve site specific contaminated sediment remediation goals.

762 Biochar-Herbicides Antagonism: Can They Stand Each Other? A. Freddo, Univ of East Anglia; B. Reid, Univ of East Anglia, Environmental Sciences. The benefits on plant growth and improvement of soil structure following biochar addition to soil have been previously reported. However the physic-chemical structure of biochar allows the sorption of organic compounds (for example pesticides), thus, while on one hand biochar might increase crop yields the beneficial role of pesticides might be undermined through alteration of their bioavailability to pests and weeds. The purpose of this study was to establish the efficacy of four herbicides (mesotrione, pendimenthaline, terbuthilazine, isoproturon) upon three common broadleaf weeds (Amaranthus retroflexus, Solanum nigrum and Abutilon theophrasti) when applied to soil amended with 0%, 1% and 5% biochar. The results indicated that in all the treatments the presence of higher concentration of biochar in soil significantly reduced the effectiveness of all herbicides tested. The viability of targeted weeds in the herbicide amended 5% biochar soil was not significantly ($p< 0.05$) different to the number of viable weeds observed in the control treatments (no biochar and no herbicide). Physiologic characteristics were also taken into account. Results regarding stem- and root-length and fresh weight of biomass indicated that weeds present in the 5% biochar plus pendimenthaline treatments were not significantly ($p< 0.05$) different to the control. Thus, biochar was found to be effective in reducing the bioavailability of the dissimilar herbicides to contrasting broadleaf weeds. These results are significant in so much as they suggest biochar incorporation to soil could undermine food security on account of the potential for biochar to deactivate herbicidal activity.

763 An NMR-based Metabolomic Analysis of Cobia Health in Response to Dietary Manipulation T. Schock, National Institute of Standards and Technology, Analytical Chemistry Division; S. Newton, Univ of Arkansas, Pine Bluff; K. Brenkart, J. Leffler, South Carolina Dept of Natural Resources; D. Bearden, National Institute of Standards and Technology, Analytical Chemistry Division, National Institute of Standards and Technology. Commercial aquaculture feeds rely heavily on fishmeal and fish oil, which can be expensive and ecologically unsustainable. The environmental impact of various aquaculture practices because of the need to harvest fish for fish meal and the need to properly handle the waste stream in intensive aquaculture systems leads to investigation of alternative, plant-based foods.

To evaluate the efficacy of reduced fishmeal diets for outgrowth, a dietary study was conducted on the finfish cobia, *Rachycentron canadum*. Juvenile cobia were raised on four different diets: a commericial diet (Control), a diet with conventional levels of fishmeal (FM100), a diet with a 50% reduction in fishmeal (FM50), and a diet with 25% of the conventional level of fishmeal (FM25). The experimental diets substituted varying amounts of soybean meal and poultry meal for fishmeal. NMR-based metabolomic techniques were used to assess the effect of decreasing dietary fishmeal on the health of the cobia. Filtered serum ^{1}H NMR spectra analyzed by principal components analysis (PCA) showed cobia fed reduced fishmeal diets were metabolically different than cobia on control diets. In particular, tyrosine and betaine increased in cobia fed reduced fishmeal diets while glucose decreased, suggesting that these cobia were not receiving the necessary nutritional components required for energy and growth. The formulated control diet contributed to enriched growth and significantly elevated lactate levels suggesting enhanced gut microflora metabolism in response to dietary components. For intensive fish production a natural antibiotic/probiotic enhanced by diet would be ideal, limiting the need for prophylactic antibiotics and addressing the concern of additives in food for human consumption. In addition, these metabolomic studies have laid a foundation for studying the population of wild fish that may be impacted by naturally occurring diet variation in the natural fisheries. The results show that NMR-based metabolomic analysis is a useful tool in aquaculture studies and organism health assessment.

764 Comparison of the Metabolic Responses Elicited via Exposure to Crude and Dispersed Oil Dissolved Components A. Van Scoy, Univ of California, Davis, Dept of Environmental Toxicology, Univ of California-Davis, Environmental Toxicology, Univ of California, Dept of Environmental Toxicology; B. Anderson, Univ of California – Davis, Dept of Environmental Toxicology; B. Phillips, Univ of California – Davis, Environmental Toxicology; J. Voorhees, Univeristy of California – Davis, MPSL – Environmental Toxicology; R. Tjeerdema, Univ of California – Davis, Environmental Toxicology. Crude oil contamination remains a problem along coastal California due to its demand and major economic importance. Resource managers require information on the acute toxicity of treated and untreated oil, and their sublethal effects in wildlife. Investigation of the damage hydrocarbons pose towards marine organisms is becoming more involved, particularly thru the use of metabolomics, which has the potential to examine metabolic responses of organisms exposed to environmental and anthropogenic stressors. This study examined the toxic effects of the water-accommodated fraction (WAF) and the chemically-enhanced WAF (CEWAF, with Corexit 9500) of Prudhoe Bay Crude Oil (PBCO) on adult topsmelt (Atherinops affinis) and pre-smolt Chinook salmon (Oncorhynchus tshawytscha) using NMR-based metabolomics. Muscle samples were analyzed following 96-h exposures to either WAF or CEWAF and principal component analysis (PCA) was applied to identify variation between samples and treatments as a result of exposure. Based on the LC50 values, toxicity to both topsmelt and salmon decreased (i.e., less toxic) when Corexit 9500 dispersant was applied. However, NMR profiles and metabolite responses for both fish species were similar for both WAF and CEWAF, thus suggesting the fish were accumulating similar dissolved hydrocarbon concentrations. Therefore, semi-permeable membrane devices (SPMDs), which specifically accumulate dissolved components within water, were used to confirm this hypothesis. It was found that SPMDs did accumulate two- and three-ringed PAHs at similar concentrations, following exposures to either WAF or CEWAF. Thus it appears that similar hydrocarbon concentrations are eliciting the similar metabolic responses. Since SPMDs specifically target dissolved components, the variation among the measured LC50 values is possibly due to the combined analysis of dissolved and particulate oil (as they are difficult to separate). Overall, NMR-based metabolomics was successful in assessing the sublethal effects of petroleum hydrocarbons on topsmelt and salmon. More importantly, the metabolomics approach has led to confirmation that dissolved (bioavailable) hydrocarbon concentrations, those likely responsible for the toxic actions, are similar in both WAF and CEWAF.

765 Cell-based Metabolomics: A New Tool for Environmental Toxicology Q. Teng, USEPA, National Exposure Research Laboratory, National Exposure Research Lab, USEPA, National Exposure Research Laboratory; D. Ekman, T. Collette, USEPA, National Exposure Research Laboratory. Metabololomics is a powerful 'omic tool that has great potential for ranking and screening large lists of chemicals for exposure and effects, and for developing biomarkers for both human and ecological exposures. The traditional chemical screening methods using rodents as test species are not sustainable in the long term, given the ever increasing number of chemicals that must be tested for safety. The most promising approach to increase the throughput of metabolomics is to use cell cultures instead of live animals. This is consistent with the bold vision laid out by the National Research Council in "Toxicity Testing in the 21st Century". We have made major developments that position cell-based metabolomics as an important, viable, and sustainable approach for rapid chemical screening and prioritization and for developing biomarkers.

766 Earthworm Sub-lethal Responses to Polychlorinated Biphenyls in Freshly Spiked vs. Historically Contaminated (>30 years) Soil Using ^{1}H NMR Metabolomics M. Whitfield Aslund, Univ of Toronto, Physical and Environmental Sciences; M.J. Simpson, A.J. Simpson, Univ of Toronto Scarborough, Dept of Physical and Environmental Sciences ^{1}H NMR metabolomics was used to measure earthworm sub-lethal responses to polychlorinated biphenyls (PCBs) in freshly spiked and historically contaminated soils. A preliminary study examined the metabolic profile of *Eisenia fetida* earthworms exposed to an artificial soil spiked with sub-lethal concentrations of PCBs (0.5 – 25 mg/kg Aroclor 1254). After only two days of exposure, ^{1}H NMR metabolomics provided evidence that PCBs disrupted both energy systems (ATP levels) and membrane functions (betaine levels) in *E. fetida*, which matched well with known toxic mechanisms of action for PCBs. As traditional methods for assessing sub-lethal toxicity of soil contaminants to earthworms require much longer periods of soil exposure (e.g., the earthworm reproduction test requires >50 days), this suggested that metabolomics might provide a more rapid alternative. However, as this soil was freshly spiked, PCB bioavailability likely exceeded that of an aged soil. Soil aging is believed to reduce contaminant bioavailability and toxicity with time and it was unclear how this would alter the earthworm metabolomic response. Therefore, ^{1}H NMR metabolomics was also applied to assess earthworm responses to aged (>30 years) PCB- contaminated field soils. Earthworms exhibited a less defined metabolic response to PCBs in this aged soil than was previously observed for freshly spiked soil, even though the total PCB soil concentrations were higher (91-280 mg/kg Aroclor 1254/1260). For example, PLS regression suggested a stronger relationship between the earthworm metabolic profiles and soil PCB concentration for the spiked soil after two days exposure (cross-validated PLS-regression with 7 components, $R^2X=0.99$, $R^2Y=0.77$, $Q^2Y=0.45$, $p< 0.001$) than for the aged soil after two days exposure (cross-validated PLS-regression with 2 components, $R^2X=83.4\%$, $R^2Y=22.6\%$, $Q^2Y=10.3\%$, $p=0.004$). The comparison between freshly spiked and aged PCB- contaminated field soils indicates that ^{1}H NMR metabolomics of earthworm responses is sensitive to both contaminant concentration and bioavailability. These results also suggest that earthworm metabolomics may be a sensitive tool for risk assessment of contaminated sites.

767 Effects of Oil Dispersions on Key Species in the Atlantic Ocean, Cod *Gadus morhua* L, and Copepod *Calanus finmarchicus*, Studied by NMR Metabolomics T.R. Storseth, SINTEF Fisheries and Aquaculture AS, Marine Resources Technology; B. Hansen, SINTEF Materials & Chemistry, Marine Environmental Technology; K.F. Degnes, SINTEF Materials and Chemistry, Biotechnology; A.J. Olsen, Norwegian Univ of Science and Technology, Biology; D. Altin, BioTrix; T. Nordtug, SINTEF Materials and Chemistry, Marine Environmental Technology. Oil related activity in the North Atlantic Ocean demands risk assessment that includes effect studies on relevant species. Spawning grounds for Atlantic cod, *Gadus morhua* L, are being considered for oil exploration and knowledge on the effects of oil spills on cod larvae is important. In addition, with an annual production of 300 million tons, and as such a considerable source of food for the North Atlantic fish species, the marine copepod *Calanus finmarchicus* is a highly relevant species for risk assessment. We have used 1H-NMR metabolomics to study the effects on the metabolite composition of exposed cod larvae and *C. finmarchicus* to mechanically (MD) and chemically dispersed (CD) oils. concentrations (given in sum of PAH including Naphtalenes in ug/l for MD and CD, respectively) were, low (0.08, 0,66), medium (1.36, 2.32) and high (8.43,8.71). In addition, since we have previously documented oil-induced loss of appetite in cod larvae, we also included a group of cod larvae which was starved in order to compare with the groups exposed to dispersed oil. Cod larvae were exposed to dispersed oil for 96 hrs at which time they were

sampled and analyzed. The metabolic changes were described by principal component analysis (PCA). The high concentration chemical dispersion group was found to be different from the control (Wilcoxon rank sum test on scores from PC1 $p < 0.05$) whereas the medium and low dose groups from chemical and mechanical dispersion did not differ from the control group. Starvation for 96 hours induced larger but similar changes compared to the CD high dose group. *C. finmarchicus* was sampled before and after a 96 hr exposure and in addition after a 96 hr recovery period. Metabolite response trajectories for exposure to MD and CD oils in were based on 2D scores from PCA. Changes in the two PCs show three traits. Low concentrations seem to cause reversible effects compared to control groups, whereas medium and high doses show changes along PC1 after exposure which are reversed after recovery. Along PC2 the medium and high doses showed changes that were not reversed after the recovery period. Thus the 2D scores plot and corresponding loadings may describe reversible and irreversible effects of exposure. A discussion will be given on observed changes in amino acids, glucose and osmolyte levels for both species. Cod data will be compared to previously presented data on effects of exposure to chemically dispersed oil vs. water soluble fractions.

768 Exposure to Elevated Levels of CO_2 Induces a Shift in Metabolic Fingerprint in Different Tissues and Hemolymph in the Shore Crab *Carcinus maenas* K.M. Hammer, Norwegian Univ of Science and Technology, Biology; T.R. Storseth, SINTEF Fisheries and Aquaculture AS, Marine Resources Technology; S.A. Pedersen, Norwegian Univ of Science and Technology, Biology. Carbon dioxide acts as a weak acid when dissolved in water, and the increasing level of CO_2 in the atmosphere may therefore lead to an acidification of the ocean. Further, mitigating alternatives such as storing CO_2 in rock formations under the seafloor may result in leakage of the gas into the water column. In the recent years more focus has therefore been turned towards studying the effects of elevated levels of seawater CO_2 (hypercapnia) on marine fish and invertebrates. Until now the studies have mainly focused on the effect on acid-base balance, metabolic rate, development, growth and calcification. We have looked into the metabolic response of the shore crab *Carcinus maenas* to time and dose dependent exposure to environmental hypercapnia by analyzing water soluble metabolites of gill, leg muscle and hemolymph using ^{1}H nuclear magnetic resonance spectroscopy. Animals were subjected to short-term (1-96 hours) and prolonged (1-4 weeks) exposure to hypercapnic seawater (~1% pCO_2) at pH_{NBS} 6.95, as well as exposure to pH_{NBS} 7.40, 6.95, 6.60 and 6.35 (~0.5, 1, 2 and 3% pCO_2) for two weeks. Multivariate analysis of NMR data showed an increasing difference in the metabolic profiles of tissues and hemolymph with increasing CO_2 levels compared to control, while difference was only found after prolonged exposure in the time series study. The changes in metabolic response were mainly attributed to betaine, glycine, lactate, glutamate, glutamine, proline, alanine and sarcosine. The results indicated that both tissues and hemolymph were suited for ^{1}H-NMR analysis of metabolic response in *C. maenas* subjected to hypercapnic conditions, and that the changes mainly occurred after prolonged exposure.

769 Metabolomics for Biomonitoring of Contaminants of Emerging Concern in the Great Lakes T. Collette, USEPA, National Exposure Research Laboratory; G.T. Ankley, USEPA, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Mid-Continent Ecology Division, USEPA, Mid-Continent Ecology Division; E. Durhan, USEPA, Mid-Continent Ecology Division; D. Ekman, USEPA, National Exposure Research Laboratory; K.M. Jensen, M. Kahl, USEPA, Mid-Continent Ecology Division; K. Lee, USGS; E. Makynen, L. Thomas, USEPA, Mid-Continent Ecology Division; A. Trowbridge, US Fish and Wildlife Service; D.L. Villeneuve, USEPA, Mid-Continent Ecology Division. Metabolomics (and other 'omic techniques) are now well established for studying contaminant-induced alterations to normal biological function. These alterations, typically observed in laboratory-controlled studies, have been used successfully to screen for chemical potency, or to infer a chemical's toxic mode-of-action. But, the use of these techniques for biomonitoring in the natural environment, while often stated as an ultimate goal, has rarely been demonstrated to add value in chemical exposure assessment. We have recently conducted biomonitoring studies in the St. Louis Harbor, Lake Superior, in support of the Great Lakes Restoration Initiative (GLRI), using caged fathead minnows (*Pimephales promelas*). Fish were deployed at four field sites including in the upper St. Louis River, and at locations near wastewater treatment facilities (both proximal and distal to site of discharge). A variety of endpoints were measured in the fish, including targeted gene expression and NMR-based metabolite profiles. In addition, water from these sites was analyzed for an extensive list of contaminants of emerging concern. Metabolomics appears to be particularly useful in this study for characterizing the fishes' exposure to chemical contaminants. For example, the extent of perturbation of hepatic metabolite profiles in females (compared to laboratory controls) generally follows patterns expected based on extent of contamination. Additionally, the availability of extensive chemical monitoring data will help lead to an understanding of the connection between the presence of specific contaminants and specific metabolite perturbations, yielding biomarkers of exposure that can be used in other field applications.

770 Studying the Physiology of Declining *Diporeia* Populations in the Laurentian Great Lakes Using Metabolomics S. Maity, Purdue Univ, graduate student; A. Jannash, Purdue Univ, Bindley Bioscience Center at Discovery Park; J. Adamec, Univ of Nebraska, Dept of Biochemistry, Beadle Center N151; T. Nalepa, National Oceanic and Atmospheric Administration (NOAA), Great Lakes Environmental Research Laboratory; T.O. HOOK, M.S. SEPULVEDA, Purdue Univ, Dept of Forestry and Natural Resources. Since the 1990's, *Diporeia* populations have declined across the Great Lakes region except Lake Superior. Several hypotheses have been put forward to help explain this precipitous decline including introduction and establishment of dreissenid mussels, limited food availability, pathogens, and exposure to contaminants. We applied mass spectrometry-based metabolomics (GC X GC/ TOF-MS and LC-MS) to study the metabolome of *Diporeia* exposed to different stressors through a series of laboratory experiments. *Diporeia* responded with stressor-specific changes in metabolic pathways: 1) a 60 d starvation resulted in altered proline-alanine-glutamate and glycerophospholipid metabolism; 2) co-exposure to quagga mussels affected serine, threonine and glycine metabolism; and 3) exposure to PCB-contaminated sediments induced changes in glutamine and phenylalanine metabolism as well as hydrocarbon receptor mediated pathways. We are currently analyzing the metabolome of ~ 100 *Diporeia* collected from stable and declining populations across the Great Lakes region. Preliminary results indicate a significant "Lake Effect" on the metabolite profile of *Diporeia*. We hope the combined results of our laboratory and field metabolomic studies will help elucidate the potential cause(s) of *Diporeia* declines in the Great Lakes.

771 Temporal Aspects of Water Use in Shale Gas Development: Implications for LCA S.M. Jordaan, Harvard Univ, Dept of Earth and Planetary Sciences, Energy Technology Innovation Policy group; D.P. Schrag, Harvard Univ, Dept of Earth and Planetary Sciences, Dept Environmental Science and Engineering. Life cycle assessment (LCA) has been criticized for temporal aggregation of resource use over the life of a product in the development of inventories. This may have implications for energy transitions when resource requirements change over the life of energy extraction projects. Shale gas is expected to become a large contributor to US energy production over the coming years, with forecasts indicating shale gas may contribute 45% of natural gas production by 2035. Water use implications of increased levels of shale gas production are not well studied, yet they are clearly different from conventional natural gas due to the use of hydraulic fracturing. Previous work has estimated the water consumption for shale gas extraction to be small (0.6 – 1.8 gal/MMBtu) when compared to coal extraction (5 – 15 gal/MMBtu). Hydraulic fracturing, however, typically requires water use prior to production, resulting in a heavy front-loading of water consumption. As water may be scarce in some regions, this front-loading may have implications for water availability and limitations to the rate of expansion of drilling activity. Preliminary estimates indicate that using temporally aggregate water consumption in forecasting water use for shale gas development may result in underestimating the water use by as much as a factor of 3. This indicates a need to develop systematic methods to consider temporal aspects within LCA. A method is proposed to account for the temporal front-loading of water use in shale gas development within LCA, where marginal water use is calculated, rather than the average water use over the life of a product. Life cycle water consumption for electricity generated with shale gas under both methods will be compared to other electricity generation options. This study suggests the use of temporally aggregate assumptions can decrease the accuracy of impact assessment models, particularly for resources with limited availability.

772 Potential Land and Water Impacts Related to Increased Biofuel J.C. Bare, USEPA, MS-466 There is no international consensus on how to conduct land and water use impact assessment for LCIA, yet decisions are currently being made which have the potential for impacts in these areas. The increased agricultural production for the manufacture of biofuels in the US is an issue which could have widespread impacts on water use, irrigation, and aquifer depletion as well as many other land use issues. This paper will provide a LCIA methodology for evaluating water use/depletion impacts with US corn-to-ethanol as a case study. Land use can also cause numerous impacts on the future usability of the land for agriculture and other purposes. Using an ecosystem services tool and GIS inputs available from the USEPA's Future Midwest Landscape Project, a framework will be provided for displaying land use analysis comparing a 2002 land use scenario to a projected 2020 land use scenario, where the principle driver for change is the increased corn production necessary to produce additional ethanol. The potential for increased (or decreased) erosion will be displayed for a 12 state region which makes up the primary corn-to-ethanol production. An additional map will be generated which shows the potential for erosion in the current land use pattern.

773 Dynamic Multi-crop Model to Characterize Impacts of Pesticides in Food for LCIA P. Fantke, Univ of Stuttgart, IER; R. Juraske, Swiss Federal Institute of Technology Zurich; A. Anton, IRTA Carretera de Cabrils; R. Charles, Agroscope Changins-Wädenswil; O. Jolliet, Univ of Michigan, School of Public Health. Human intake of pesticide residues via ingestion of processed food plays an important role for evaluating current agricultural practice. A new dynamic plant uptake model – dynamiCROP – is presented to determine intakes of pesticides residues. The model is based on a set of interconnected compartments customized to six crops (wheat, paddy rice, tomato, apple, lettuce, potato). Modeled residues are compared with measured concentrations of eleven different pesticides. Measurements and model estimates correspond well with total crop-specific residual errors the difference ranging between a factor 1.5 for lettuce up to a factor 37 for rice with an overall residual error a factor 32 over all 12 substance-crop combinations. Intake fractions and related impacts were calculated per unit mass of applied pesticide for 121 substances applied to the six crops. For all crops but potato, intake fractions are usually in the range of 1E-02 and 1E-08 kgintake/kgapplied for typical times between application and harvest. The highest intake fraction are observed for insecticides and fungicides applied to tomatoes and lettuces. The intake fractions obtained after direct application were one to five orders of magnitude higher than intake fractions estimated by USEtox for indirect emissions. The main factors influencing the fate behavior of pesticides are the degradation half life in plants, in plant surface, the residence time in soil surface as well as the time between pesticide application and harvest. A simplified model based on these parameters enables prediction of residues within a factor 10 of those calculated with the detailed model, with R2 higher than 0.8; this simplified model is adequate to assess direct residues for multimedia models such as USEtox. We demonstrate that toxicity potentials can be reduced up to 99% by defining adequate scenarios for pesticide substitution.

774 A Methodology for Inclusion of Terrestrial Ecotoxic Impacts of Metals in Life Cycle Impact Assessment M. Owsianiak, R.K. Rosenbaum, M.Z. Hauschild, Technical Univ of Denmark, Dept of Management Engineering. Terrestrial ecotoxicity is in most cases not addressed or to a very limited extent in life cycle assessment (LCA). We are developing a new method for calculating terrestrial ecotoxicity characterization factor (CF) of metals for application in life cycle impact assessment (LCIA). The method takes into account metal speciation and interactions with soil organic constituents, because these mechanisms control metal bioavailability and influence their toxic properties. Transfer functions and geochemical speciation models are employed to calculate reactive and available fractions of metals in 1300 soils spanning a wide range of properties and pore water chemistry. Site-specific fate factors (FF), bioavailability factors (BF) and effect factors (EF) are then calculated for these soils. The biggest variability is observed for BF, which can vary from 2 to 6 orders of magnitude for the cases of Ni and Cu, respectively. These variations are a result of variability in soil properties such as pH, organic carbon or clay content. Published terrestrial biotic ligand models (TBLM) and free ion activity models (FIAM) are next employed in order to derive terrestrial ecotoxicity EFs. Median EFs predicted with TBLMs for Cu and Ni correspond to average ecotoxicity (range) of 12.4 (6.6 – 364) and 1194 (62 – 42164) µg/L, respectively. EFs derived with FIAMs turn out to be 6.5 (Cu) and 7.5 (Ni) times higher than these derived with TBLMs. The ecotoxicity ratio of Cu to Ni is accurately predicted with both models and the contribution of EF to the CF is within the same order of magnitude or lower comparing to that of the BF. Thus, FIAMs can be employed to calculate EFs for metals for which TBLMs are not available. From a set of spatially explicit CFs, site-generic CFs can be derived at global or continental scales. For applications in LCIA, the tradeoff between the level of geographical detail and the level of uncertainty in both spatially explicit and site-generic CFs remains to be investigated. The method highlights the importance of taking into account variability of soil properties in deriving operational characterization factors for terrestrial ecotoxicity of metals.

775 Including Metal Speciation in LCA: The Case of Terrestrial Ecotoxicity G. Plouffe, Ecole Polytechnique de Montreal, CIRAIG; C. Bulle, CIRAIG, Ecole Polytechnique de Montreal, Chemical engineering Dept; L. Deschenes, CIRAIG, Chemical Engineering. At present, ecotoxicological impacts of metals are often the main contributors to LCA results. This domination does not necessarily reflect a real toxicity but rather indicates the misuse of fate and effect models, which were initially developed for organic compounds. Characterization factors are often obtained using the total emitted concentration as being the toxic concentration, which is inappropriate for metal emissions because of metal speciation. A framework for including metal speciation in freshwater ecotoxicological impact assessment has been developed recently. It relies on the use of a commercially available geochemical model to define the bioavailable metal fraction. Although really interesting, this approach is not directly applicable to soils, mainly because geochemical speciation models were developed for aquatic environments. Soils heterogeneity hinders generalization and could invalidate the hypothesis made in aquatic geochemical modeling. The main goal of this project is thus to develop a method and speciation model specific to soils in order to obtain terrestrial ecotoxicity characterization factors. According to the framework proposed for freshwater ecotoxicity, a bioavailable factor is added to the definition of the characterization factor. This allows determining fate and effect of metals only on the bioavailable fraction, which is the real responsible for toxicity. The bioavailable fraction in soils is computed with a new speciation model specific to soils developed in this project. The speciation model for soil groups the theoretical basis of two available geochemical aquatic speciation models (WHAM 6.0 and MINEQL+) in order to consider organic complexation reactions as well as reactions with inorganic ligands. New characterization factors for Zn, Ni and Cu are obtained for terrestrial ecotoxicity. Their spatial variability will then be quantified, in order to evaluate the importance of integrating speciation in LCA. At present, preliminary characterization factors for terrestrial ecotoxicity are obtained using commercially available speciation models (WHAM 6.0 and MINEQL+) and IMPACT 2002 and confirm the need to develop a speciation model specific to soils.

776 Characterizing the Spatial Heterogeneity of Hazardous Air Pollutant Emissions from On-road Motor Vehicles A. Lobscheid, M. Spears, Lawrence Berkeley National Laboratory; T. McKone, Univ of California, Berkeley, Univ of California and Lawrence Berkeley National Laboratory, Univ of California, Univ of California and Lawrence Berkeley National Laboratory. On-road motor vehicles (MVs) in the United States (US) emit approximately 10^9 kg per year of conserved (non-reactive and non-depositing) hazardous air pollutants (HAPs) to the atmosphere. Within life-cycle impact assessment (LCIA), there is a need to spatially resolve the population impacts associated with these HAP emissions. Primarily, this need centers around identifying the level of resolution that adequately captures the spatial variability of emissions and resulting health impacts associated with atmospheric emissions. In order to explore this spatial variability, we estimate population impacts using the intake fraction (iF)--the ratio of the chemical mass taken in by the population to the mass emitted. The population iF [ppm] is estimated from the on-road MV source-receptor relationships derived from the US Environmental Protection Agency's AERMOD model, which was employed in the latest (2005) National Air Toxics Assessment (NATA). AERMOD is a steady-state plume model that incorporates air dispersion to characterize atmospheric concentrations of MV emissions. AERMOD provides source-receptor (S-R) relationships (X/Q), in mg/m3 per ton/y emitted, for 64,600 census tracts in the conterminous US. The mean S-R-based iF across these census tracts is 8.5 ppm, the median is 3.8 ppm, and the inter-quartile range (IQR) is 0.8 to 8.9 ppm. When census

tracts are aggregated at the county-level, and subject to a unit emission, the mean population iF is 1.3 ppm, the median is 0.4 ppm, and the IQR is 0.13 to 1.2 ppm. We explore alternative methods, or "approximators", that can be easily integrated within an LCA to characterize spatial variability of health impacts. Examples include a box-model approach adjusted for chemical persistence to estimate county-level iF, and correlations between the population density of the source region (county) and the iF obtained from the AERMOD derived S-R (R^2~ 0.8). The population iF estimates can be integrated with HAP emissions to characterize health impacts of transportation fuels. This is particularly useful in LCIAs that relate health impacts from second and third generation cellulosic biofuels, with conventional gasoline.

777 Assessing Drinking Water Intake of Aluminum and Arsenic Emissions A. Henderson, Univ of Michigan, Environmental Health Science, School of Public Health, Univ of Michigan, School of Public Health; O. Jolliet, Univ of Michigan, School of Public Health. In assessment of the fate, transport, and ultimate exposure of metals to humans, correctly accounting for long-term groundwater emissions, e.g., from a landfill, has been challenging. This research offers a new perspective on human exposure to anthropogenic metal emissions to ground and surface water. Existing models, such as the Ecoinvent LCA database (Frischknecht et al. 2004) have assumed 100% of landfill emissions reach surface water. To accurately reflect geochemical and hydrologic processes, this conservative assumption can be reassessed. Other sources of metals, such as mining of aluminum ore, may generate emissions directly to surface water. Models of metals in surface water (e.g., Gandhi et al. (2010)) likewise have potential for improvement; e.g., via accounting for the possibility of precipitation. A multi-component model was developed to assess the total intake by humans of emissions to landfills (for aluminum) and directly to surface water (for arsenic from aluminum ore). For landfill emissions, a kinetic precipitation model was developed to estimate transfer to surface water. In surface water, the geochemical model PHREEQC (Parkhurst 1995), including an implementation of WHAM VI (Tipping 1998), was used to estimate speciation, as well as the potential for precipitation, sorption, and complexation, while hydrological data at the continental level provided estimates of continental flows and residence times. Information at the national level on drinking water source and treatment were aggregated to the continent scale and included in the model, thus providing estimates of the population fraction drinking treated and untreated ground and surface waters. Finally, speciation was used to assess bioavailability of ingested aluminum to humans. The model shows lower estimates of transport from source to receptor than previous studies, which lacked a precipitation module. Uncertainty in input data and modeling assumptions, which will be discussed, allow the model to be applied to large-scale systems as a comparative tool. For example, the ingested intake fraction for aluminum emissions to landfills is lower than previous models by a factor of 1x10^6 or more, depending on the location. The continent of emission, via its hydrology and the fraction of treated, untreated drinking water, plays an important role.

778 Life Cycle Assessment and the Work Environment: Case Study in Municipal Solid Waste End-of-Life Management Methods K. Scanlon, The George Washington Univ, Dept of Environmental and Occupational Health; R. Francis, The George Washington Univ, Dept of Engineering Management and Systems Engineering; S. Lloyd, Concurrent Technologies Corporation. Impacts to occupational health are often neglected in life cycle assessment due to data limitations, methodological limitations, and lack of professional subject matter expertise. However, decisions made in the absence of quantified occupational health data may result in sub-optimization, where one portion of a system may be improved ignoring the effects on another portion of the system leading to unintended consequences. This presentation will demonstrate how publicly-available work-related fatal and nonfatal injury and illness data can be used to characterize impacts to occupational health across a product life cycle. It will introduce a new life cycle impact assessment (LCIA) method for characterizing these impacts. Also, this presentation will describe the method used to develop work environment characterization factors and a new damage impact category indicator, the work environment disability adjusted life year. The findings from a case study in municipal solid waste end-of-life management methods will be presented. The case study will demonstrate the application of the work environment LCIA method and highlight its strengths and shortcomings. The presentation will end with suggestions for future case studies to qualify this new impact assessment method.

779 The Unnatural Nature of Communicating Risks in Natural Disasters M.Y. Lichtveld, Tulane Univ SPHTM, Environmental Health Sciences; J.K. Wickliffe, Tulane Univ, Environmental Health Sciences; L. Bondi-Marschner, C. Mundorf, Tulane Univ SPHTM, Environmental Health Sciences. The Gulf of Mexico Oil spill, the Tsunami-induced nuclear reactor disaster in Japan, and the Morganza flooding in Louisiana demonstrate the myriad of problems in effective risk communication. The lack of effective, action-driven risk- and perhaps more appropriate crisis communication- not only profoundly affects community protection but also science, policy, and practice. Knowledge gaps regarding environmental and toxicological consequences of natural disasters can pose formidable challenges for risk assessors and toxicologists balancing uncertainty and responding to community concerns. This is compounded by the interconnectedness and fluid nature of technological and natural disasters, e.g., the impact of future hurricanes on the Gulf of Mexico Oil spill. In Louisiana, Hurricane Katrina, the Oil spill, and the Morganza flooding provide a unique triad of case studies: First, the qualifications of the messenger go much beyond risk communication or discipline-specific expertise; rather, the successful risk communicator is often homegrown, capable of harmonizing scientific uncertainty and community responsiveness. Secondly, the message has to withstand scientific scrutiny, but also that of victims. Thirdly- and most importantly- the timing, "longevity", and actionable nature of the message are all prerequisites for success. The increasingly powerful role of social media affects the signal transmission speed and multiple stakeholder agendas decrease the signal-to-noise ratio rather than improving the signal. The overarching lesson not learned is that of context and precedent. For example, many communities affected by the oil spill and the Morganza flooding still remain in or were just emerging from a Post-Katrina recovery state. Preliminary findings from disaster research conducted as part of the SECURE Consortium funded by NIH show that disaster recovery is influenced by a series of experiences including loss of livelihood; direct physical adverse health effects; community stress; fear of the unknown; unfounded fear of the known; indicators of family stress; mixed messages and an influx of non-local personnel. Communicating in this context profoundly affects risk perception. Similarly, previous negative risk communication experiences directly impact trust and message actionability. This presentation will present a culturally competent framework for crisis communication in complex interconnected natural and technological disasters.

780 Fishing for Answers in the Willamette River: The Mystery of the Newberg Pool J. Jenkins, Oregon State Univ, Dept of Environmental & Molecular Toxicology. In the early 1990's news reports of a high prevalence of skeletal deformities in fish located in a slow moving reach of the Willamette River near Newberg was concerning Oregonians. Were the fish deformed by unseen poisons that could also endanger human health? Local concern was focused on a new water treatment plant just downstream at Wilsonville. People refused to drink the water. What was in the Newberg Pool? Following additional studies commissioned by the Oregon Dept of Environmental Quality that confirmed the continued high prevalence of fish deformities but were unable to identify a cause, in 2001 the legislature called on Oregon State Univ to find out what was causing fish deformities in the Newberg Pool. A multidisciplinary team was assembled and the mystery of nature was transformed into a researchable question. The team included researchers with expertise in aquatic toxicology, ecotoxicology, environmental analytical chemistry, and fish biology and systematics, fish disease and parasitology, and human health risk assessment and risk communication. The research goal was not only to solve the mystery and report back to the legislature, but also provide a scientific basis for public outreach and risk communication. This case study will present an example of outcome-driven multidisciplinary research and outreach designed to provide risk information useful to individual decision-making and public policy, and to promote transparency and dialogue about risks associated with exposure to environmental agents.

781 Lessons in Communication: Emergency Response, CSX Transportation, Brooks, Kentucky P. Kurzanski, CSX Transportation; J.R. Clarkson, Arcadis US, Inc., Senior Vice President, ENVIRON, ENVRON. On January 16, 2007, at 8:51 a.m., a CSX train en route to Louisville from Birmingham derailed in Brooks, Kentucky. The train consisted of 4 locomotives and 80 cars of which 41 were loaded and 39 were empty. A total of 25 cars derailed of which 12 were carrying hazardous materials. The potential for environmental impacts to the following: air, surface water, sediments,

soil, groundwater, seeps, and residential drinking water (private wells and municipal water supply) were evaluated. Materials from the derailed cars flowed into a storm water management ditch along the railroad track through unnamed tributaries of Floyds Fork, into Floyds Fork (stream) with potential to ultimately reach the Salt River, approximately 3.5 miles downstream. Homes along the creek used the water for recreation, livestock and pets. The creeks, stream, and river were used by aquatic and terrestrial flora and fauna. At the confluence of the Floyds Fork and Salt River was an intake for a municipal water supply. Residents in 15 homes near the train tracks were temporarily displaced until clean up and restoration were completed. Air, surface and subsurface soils and groundwater/seeps around the derailment site were also potentially impacted. A number of constituents of concern were evaluated for human and ecological health depending upon the media and circumstances surrounding the response actions, but the primary constituents associated with the train were 1,3-butadiene, methyl ethyl ketone and cyclohexane. The strategic management of this incident by CSX was excellent and serves as a great model for lessons learned. Communication was a critical component to this successful management. This presentation will highlight strategic risk communication lessons learned during the emergency, post-emergency, and restoration phases of the transportation incident. The oversight by federal, state, and local regulatory agencies, the media, and the public was intense and presented many risk communication challenges that continued to change throughout the three phases of the incident. Communication of potential risks to human and ecological health was critical to the overall successful management and resolution of this incident.

782 Use of Risk Assessment to Demonstrate Benefits to Local Stakeholders of Regional Action to Decrease Greenhouse Gas Emissions R.N. Hull, D.W. Bryant, Intrinsik Environmental Sciences Inc.; E. Sigal, Intrinsik Environmental Science Inc. A risk assessment was conducted as part of a Climate Change Project that had the goal of decreasing Egypt's greenhouse gas emissions, focusing on a cluster of brick factories. While greenhouse gas reduction is an important national and global goal, it is relatively meaningless to those most directly affected by the project (i.e., the brick factory owners, workers, residents of the surrounding communities, and government officials). Brick factories in the Arab Abou Saed region of Helwan, Egypt have been burning heavy fuel oils as the primary fuel source since the mid-1980s. Poorly controlled heavy fuel oil combustion results in the release of many chemicals and particulate matter are released to the surrounding environment. Conversion of the brick factories from the use of heavy oil to natural gas will greatly reduce both the quantity and type of pollutants emitted from brick factories. Risk assessment was used to provide a systematic, scientific means for quantifying, comparing, and prioritizing risks associated with this conversion. The risk assessment addressed the range of local health and environmental risks associated with burning heavy oil, and the potential benefits (risk reduction) after conversion of an increasing percentage of the factories to natural gas. A detailed review of epidemiological data on health benefits of pollution reduction also was included to assist in communication of the benefits of the conversion. The effective communication of the meaning of the potential for improved air quality and reduced risks to the diverse group of stakeholders was crucial to the success of the pilot project and to the potential for future conversion of additional factories. Successful communication of risk assessment results garnered the full support of all stakeholders for the pilot project, which is expected to result in several benefits including improvements in health, the local economy, and reduction of greenhouse gas emissions.

783 Use of HHRA and SLERA Results in a Communication Program to Support Siting a Resource Recovery Facility in Puerto Rico B.J. Locey, ARCADIS, Risk Assessment and Environmental Services; J. Conklin, ARCADIS, RAES; K. Hallinger, ARCADIS; J. Hanisch, ARCADIS, EMPC; J. Smith, ARCADIS, RAES; M. Green, Energy Answers International; A. Molinare, Univ of Puerto Rico and Universidad Metropolitana Cupey Campus, Univ of Puerto Rico, Río Piedras Campus. Permit and Regulations Program, Special Education Division. Universidad Metropolitana, Cupey Campus. Graduate School of Environmental Affairs. Human health (HHRA) and screening-level ecological (SLERA) risk assessments were prepared to evaluate emissions from a proposed resource recovery facility in Puerto Rico. The assessments were part of the Environmental Impact Statement (EIS) submitted and approved by the Puerto Rico Environmental Quality Board in 2010. The results of these risk assessments are being used to support an on-going communication program aimed at providing information about the proposed facility and proactively addressing local residents' concerns. This presentation will provide an overview of the approach used to evaluate potential risks and hazards to human and ecological receptors and will focus on how the results have been used in the communication program. The overview will briefly present the approach used to estimate constituent emissions, complete the air dispersion and deposition modeling, identify geographic areas and populations of interest for both the HHRA and SLERA, perform fate and transport calculations to estimate constituent concentrations in the environment, and evaluate potential risks and hazards. Some challenges and solutions to obtaining area-specific information needed for the assessments will be discussed. The communication program will be described, highlighting the approaches used to address local residents' concerns, navigate the political climate, and accommodate mixed agendas of various groups. The project team has used a proactive, multi-pronged approach to identify specific concerns of local groups and has addressed them in a way that is tailored to their needs. The landscape surrounding the proposed facility includes an urban center, agricultural fields, dairy farms, a drinking water reservoir, and water bodies that are routinely fished by locals. Additional information and clarification have been presented to local residents in meetings with individuals, in town meetings, through radio broadcasts, and in special forums that address concerns about specific chemicals (e.g., dioxins, lead, mercury), health concerns, and the approach used to evaluate the potential impacts of the facility. Unique challenges presented by the local political climate will also be discussed.

784 Risk Communication to Multiple Audiences: A Case Study S.L. Sager, J.S. Beckner, ARCADIS. A former industrial site was dismantled and the land deeded to the county in North Carolina. The County then redeveloped a portion of the property as a year-round school. Later, when the County considered redeveloping other portions of the property, a limited soil investigation was conducted. The results of the investigation indicated that several metals and organic compounds were present in soil samples. Based on the sampling results, it was necessary to collect additional soil and groundwater samples and a communication plan developed. The results of the additional site investigation indicated that no immediate threat to the children existed. Nonetheless, since the some of the soil concentrations were above levels protective of residential exposures and were in student use areas, the decision was made by the stakeholders to reduce soil constituent levels to meet residential standards. As a year-round school, there was a limited window in which the soil removal could occur and not disrupt activities at the school. Thus, there was a lag time between the decision to remove soil and implementation. This set the stage for a risk communication program to inform staff and parents about the findings and removal strategy. The program involved dissemination of the sampling results to the school community and addressed the community's questions and concerns. The initial element in the risk communication program was to discuss with school staff the ways to minimize exposure of the students and staff to constituents in soil. Since the goal was to minimize exposure of the children and still allow use of the playground, once the children returned from the playground, they were directed to sinks for hand washing immediately upon entering the building. Use of other open areas of the property for picnics and gardens was suspended until remediation was complete. Finally, a series of meetings with parents and staff about the studies, results, and remedial strategy were held to communicate the information to the school community and garner their support for the remedial strategy ultimately identified for the parcel. One of the key concerns of the stakeholders was the loss of the use of the playground prior to the end of school. This paper will present the approach taken to characterize and communicate the results of the evaluation.

785 A Comprehensive Evaluation of Risk to Human Health and Ecological Receptors in a PCB-contaminated Floodplain M.H. Henning, A.R. Glessner, A.L. Fogg, D. Pelletier, C. Stubbs, ENVIRON International Corporation; J. Johnson, Bridgestone Americas, Inc. During historical flood events, PCB-contaminated sediment from Stony Creek (Noblesville, IN (USA)) was deposited on both the undeveloped floodplain and residentially developed floodplain surrounding the creek. Risks to human health and ecological receptors from PCBs were evaluated in both the undeveloped and residentially developed areas. The human health risk assessments for the residential properties were conducted using a streamlined, spatially-explicit approach that compared pre- and post-remediation exposure point concentrations to a site-specific risk based closure level. Residents were informed of

the pre-remediation risk assessment conclusions and participated in the selection of remedial actions on their property. In addition, human health and ecological risk assessments were performed on the undeveloped floodplain which is currently under a conservation easement. Risk conclusions were communicated with the property owner, land trust manager, and City of Noblesville. Successful communication with all stakeholders, including the USEPA, led to the Final Decision being issued by the USEPA in December 2010. This presentation will discuss the risk assessments conducted in the floodplains and how successful communication among all parties resulted in a Final Decision.

786 Engaging Stakeholders in Environmental Management Decision Using Formal Decision-Analytical Tools I. Linkov, US Army Corps of Engineers, Engineer Research and Development Center, US Army Engineer Research and Development Center; Z. Collier, M. Bates, US Army Corps of Engineers, Engineer Research & Development Center. Stakeholders often play a major role in decision making involving environmental risks. Traditionally, project teams have informed stakeholders on the course of action and their values and opinions have been integrated qualitatively in an ad-hoc manner, based on verbal or written feedback elicited from stakeholders. This is not ideal due to the large degree of information lost and the tendency of the loudest or most insistent opinion to be the only one heard. Furthermore, a qualitative approach to stakeholder engagement does not allow for the expression of value judgments or for dealing with tradeoffs. Lastly, stakeholders can have a great variety of differing viewpoints that needs to be balanced and integrated. Multi-criteria decision analysis (MCDA) offers a means to integrate value judgments into complex decision-making processes. By visualizing individual and often conflicting stakeholder views, it can also serve as a tool to resolve conflicts which would normally prevent action in an important yet contested area. By quantitatively accounting for stakeholder opinions and concerns, their ideas can be integrated into decision-making in a real and transparent way so that their views are accounted for. This presentation will present multiple examples in which stakeholders' opinions have been integrated into complex environmental decision-making processes. Examples will be presented which show the integration of stakeholders from local communities engaged in management of contaminated sites as well as federal agencies deciding on the best course of action. Integrated risk management and decision analysis tools to resolve stakeholder conflicts will be specifically discussed.

MP001 QSAR and Jumping Fragment for the Assessment of Classification in Ecotoxicology R. Bureau, S. Lozano, CERMN, Univ of Caen; B. Cuissart, G. Poezevara, GREYC, Univ of Caen; L. Alban, CERMN, Univ of Caen; B. Cremilleux, GREYC, Univ of Caen. A new approach combining QSAR analysis and jumping fragments will be presented. Two objectives could be reached. The first one concerns an estimation of the potential classification of a derivative in ecotoxicology. The second objective is the possibility to get more information about the potential mode of action (MOA) associated to a derivative. The QSAR equations were mainly based on the integration of parameters in relation with hydrophobic, steric or electronic characteristics of chemicals. They were designed to estimate the toxicity in relation with a non specific MOA like baseline narcosis, polar narcosis, ester narcosis and some classes of reactive chemicals (the toxicity of high reactive chemicals is underestimated). In these global equations, polar and non polar compounds are handled in the same models. The second point of this study concerns the potential application of jumping fragments for C&L. A recent data mining algorithm was experimented enabling an automatic extraction of substructures which appear frequently in one class (H400) and never appear in another class (H402). Such a substructure was named a jumping fragment. The overall objective of this study was to analyse the potential of these approaches starting from a random set of derivatives for the estimation of their potential classifications.

MP002 Estimating Abraham's Hydrogen Bonding Acidity Parameter Using Quantum Chemistry D.M. Di Toro, Univ of Delaware, Dept of Civil Engineering; O. Rahaman, D.J. Doren, Univ of Delaware, Dept of Chemistry. Linear solvation free energy polyparameter models are widely used to estimate partitioning coefficients between water, air, and environmental phases such as organic carbon and organism lipid. Applying these models to a new chemical requires the chemical's parameters that describe the electrostatic, hydrogen bonding, and dispersion interactions. These can be either measured using various methods such as water-solvent partitioning or HPLC column retention times, or estimated using QSAR techniques. We present a new method for estimating the hydrogen bond donation parameter (the H bond acidity) based on quantum chemically computed gas phase enthalpy of binding to various hydrogen bond accepting molecules (H-bond bases). The method is calibrated using acidity constants that are derived from direct experimental determination between sets of H-bond acids and bases. The accuracy and predictive ability will be presented. In particular the treatment of bidentate binding – where the acid can act both as an acid and a base when interacting with the base – will be discussed.

MP003 Comparison of Theoretical and Experimental Models for Characterizing Solvent Properties Using Reversed Phase Liquid Chromatography (RPLC) L. Tao, Karolinska Institute, Institute of Environmental Medicine (IMM), Unit of Work Environmental Toxicology, Institute of Environmental Medicine (IMM); I. Nicholls, Dept of Biochemistry & Organic Chemistry Laboratory, Uppsala Univ; School of Natural Sciences, Linnaeus Univ; T. Oberg, Linnaeus Univ, School of Natural Sciences. The properties of solvents are critical for determining the behaviour and interaction of molecular structure. We develop quantitative structure retention relationship (QSRR) models to characterize solvent properties in reversed phase liquid chromatography (RPLC). We selected solvents using principal component analysis (PCA) approach to ensure a maximum spread in the solvent properties, and used analyte, the herbicide atrazine, in a system derived from nine organic solutes (methanol, ethanol, 1-propanol, 2-propanol, tetrahydrofuran, acetone, acetonitrile, 1,4-dioxane, 2-methoxythanol) at four different concentration and using three chromatographic columns (C8, C12, C18). Multiple linear regression (MLR) and partial least squares regression (PLSR) were used as statistical approaches. The similarity and difference between modified global linear solvation energy relationship (LSER), semi-empirical, and theoretical molecular models were demonstrated, and the similarity and difference between experimental and theoretical model approaches were compared and discussed. The results showed that the retention factors of new mobile phase can be successfully predicted using both of experimental and theoretical approaches, the prediction of retention phenomena can reduce cost and time consuming in developing chromatographic methods and providing a better understanding of solute-solvent interactions. The results were in accordance with the free energy transfer that sum up van der Waals and polar interactions.

MP004 Using QSPRs, Chemical Fate Models and the Chemical Partitioning Space to Investigate the Fate of Chemical Mixtures with Very High Number of Components A. Gawor, F. Wania, Univ of Toronto, Dept of Chemistry. A number of environmentally relevant substances are chemical mixtures with very high numbers of constituents. This includes industrial substances such as the chlorinated paraffins, unintended by-products such as mixed halogenated dibenzo-*p*-dioxins and -furans, and pesticides such as toxaphene. The mixture constituents are structurally related, yet differ in terms of the degree of halogenation and the substitution patterns. The sheer number of mixture constituents, which can exceed many thousand individual molecules, and the wide range of fate-relevant properties of these molecules make the environmental fate, exposure, and risk assessment of such substances particularly challenging. Even the selection of representative mixture constituents that might be able to serve in the assessment of the entire mixture is not trivial. Here we outline an approach based on the structural identification of mixture constituents, the estimation of their fate relevant properties using different quantitative structure property relationships (QSPRs), and the placement of the mixture constituents on a variety of chemical space maps. The latter allows for a fast, visual assessment of the fate and behaviour in the environment of the mixture and its constituents, including their phase distribution in water, soil and atmosphere, as well as their bioaccumulation and long range transport potential. In particular, the maps reveal how environmental fate changes with, and depends on, structural characteristics such as degree and type of halogenation, or chain length. It further allows for an informed selection of a small number of constituents that are representative of the entire mixture, e.g., for more detailed assessments or the experimental confirmation of the QSPR-predicted fate-relevant properties.

MP005 Application of Ionic Liquid 1-octyl-4-methylimidazolium Hexafluorophosphate as a Recyclable Solvent for Treatment of Mercury(_) Contaminated Water S. Chen, Beijing Univ of Technology; X.W. Wang, Beijing Univ of Technology; Research Center for Eco-Environmental Sciences, Chinese Academy of Science; J. Liu, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences. Room temperature ionic liquid 1-octyl-4-methylimidazolium hexafluorophosphate $[C_8mim]PF_6$ was taken as extraction agent for liquid/liquid extraction of Hg^{2+} in water. After the extraction, Hg^{2+} can be reduced and removal from $[C_8mim]PF_6$ using formic acid through being heated at 50_ effectively. The concentration of mercury in water and ionic liquid was detected by cold vapor atomic absorption spectrometry, respectively. The results show that, the $[C_8mim]PF_6$ is a effective extractor for the extraction of Hg^{2+} in water. When the phase ratio of aqueous phase to ionic liquid phase is not higher than 10:1, the $[C_8mim]PF_6$ shows high extraction efficiency over 90 % for 1 mg/L Hg^{2+} solution at stirring 0.5 hour under 50 _. With the increase of the phase ration, the extraction efficiency decrease. But the extraction efficiency remains close to 60 % when the phase ration is 25:1. On the other hand, formic acid can be highly effective reduction and removal of Hg^{2+} in the ionic liquid, and the reduction process will not produce a serious damage the proprieties of the ionic liquid due to its relatively low temperature and short time. Acknowledgements_This study was supported by the Beijing Natural Science Foundation (project number: 8092008), and by the Air Pollution Control and Innovative Technical Team (number: PHR201007105)

MP006 A Comparative Health and Environmental Hazard Assessment for Antimony Trioxide and Halogenated Flame Retardants C. Kelly, AMEC Geomatrix, Inc.; C. Mackay, AMEC. One of the new inorganic alternative flame retardants finding use today is antimony trioxide (Sb2O3). Sb2O3 is being marketed to replace the organic flame retardants in the textile industry. Here we will present the results of a comparative health and environmental hazard assessment for antimony trioxide (Sb2O3) and halogenated flame retardants. Our research on antimony trioxide indicates that there is little potential for human exposure in various clothing and in bedding materials. We will also highlight evidence that antimony trioxide possesses very low environmental toxicity and does not bioaccumulate in humans or in aquatic or terrestrial food chains. This is in contrast to other flame retardant agents such as the brominated biphenyls, chlorinated paraffins, and perfluoro compounds. These compounds accumulate in human fat tissue, manifest specific toxicities (including carcinogenicity), and are persistent and biomagnify in the environment.

MP007 Contamination Status and Accumulation Features of Brominated Flame Retardants in Raptors from Japan T. Isobe, Ehime Univ, Senior Research Fellow Center, Ehime Univ, Senior Research Fellow; R. Hashikawa, Ehime Univ, Center for Marine Environmental Studies; S.H. Hirata, Tottori Univ, Dept pf Regopnal Environment; K. Nomiyama, Ehime Univ, Center for Marine Environmental Studies (CMES); H. Mizukawa, Ehime Univ, Center for Marine Environmental Studies; T. Hayashi, Tochigi Prefectural Museum; S. Tanabe, Ehime Univ, Center for Marine Environmental Studies. Environmental contamination by brominated flame retardants (BFRs), especially by polybrominated diethyl ethers (PBDEs) and hexabromocyclododecanes (HBCDs), are of public concern due to their persistence, bioaccumulative nature, and possible adverse effects on humans and wildlife. Both chemicals are used as additive flame retardants in a wide variety of commercial and household products to reduce their flammability. As a result, they are ubiquitous pollutants in the environment and biota and accumulate in higher trophic level animals. Raptors, a group of predatory birds, feeding high in the food web and accumulate persistent lipophilic contaminants. Although there are some reports on contamination by organochlorines in predatory birds, information on BFRs are still limited. The present study investigates the contamination status and accumulation features of PBDEs, HBCDs and PCBs in pectoral muscle of raptors from Tochigi Prefecture, Japan. Forty two individuals belonging to nine species including goshawk (*Accipiter gentilis*, *n*=19), owl (*Strix uralensis*, *n*=7), European sparrowhawk (*Accipiter nisus*, *n*=5), black kite (*Milvus migrans*, *n*=4), common buzzard (*Buteo buteo*, *n*=2), grey-faced buzzard-eagle (*Butastur indicus*, *n*=2), peregrine falcon (*Falco peregrinus,* *n*=1), sparrowhawk (*Accipiter gularis*, *n*=1), mountain hawk eagle (*Spizaetus nipalensis*, *n*=1), were collected. Analysis of BFRs (PBDEs and HBCDs) and PCBs were carried out following the procedures described elsewhere. PCBs and PBDEs were determined using GC-MS, whereas HBCDs were quantified by LC-MS/MS. PBDEs and PCBs were detected in all the specimens, and HBCDs were also found in most of the samples (36/42), indicating ubiquitous contamination of terrestrial biota by these organohalogen compounds. PBDEs concentrations ranged from 10 to 46,000 ng/g lipid, which were comparable to a previous report which found 32,500 ng/g lipid of PBDEs in sparrowhawk from Belgium. Concentration range of HBCDs was < 0.005 – 5,700 ng/g lipid and was greater than that in Guillemot (*Uria aalge*) from the Baltic Sea (mean: 65 ng/g lipid). Since HBCDs are extensively used and market demand is still growing in Japan, continuous monitoring surveys of terrestrial ecosystems are warranted. On the other hand, PCBs concentrations (230 – 190,000 ng/g lipid) were one to two orders of magnitude higher than BFRs, suggesting high-volume production in the past, leakage from stockpiles and persistence of these compounds.

MP008 Depositional Trends of Halogenated Flame Retardants to Remote Lake Sediments, Lake Simcoe, and Lake Ontario in the Great Lakes Region L. Shen, Brock Univ; E. Reiner, Ontario Ministry of the Environment; P.A. Helm, Ontario Ministry of the Environment, Environmental Monitoring and Reporting Branch; C. Marvin, Environment Canada; K. MacPherson, T. Kolic, Ontario Ministry of the Environment; D. Muir, Environment Canada; G. Tomy, Fisheries and Oceans Canada; I. Brindle, Brock Univ. Halogenated flame retardants (HFRs) have been used as additive flame retardants in a wide variety of applications including electronics, building materials, carpeting, and textiles, and are detected in the environment as a result of their use. Historical trends of current and past-use chemicals of concern in the Great Lakes region are necessary to evaluate policies for virtual elimination of priority pollutants, and for establishing baseline information to assess new regulatory actions within the basin and globally. In this study, sediment cores were obtained from remote lakes in or near the Great Lakes region from Siskiwit Lake on Isle Royale in L. Superior, Experimental Lakes Area in northwestern Ontario, and Plastic Lake in south-central Ontario. Concentration trends and sedimentation fluxes were compared for several HFRs in the remote cores to those collected from L. Simcoe and L. Ontario, which are both impacted by industrial and urban inputs. HFRs included were Dechlorane Plus (DP), Dechlorane 602 and 603 (Dec 602, Dec 603; all chlorinated FRs) and Dechlorane 604 (Dec 604; a brominated and chlorinated FR), and the brominated FRs decabromodiphenylethane (DBDPE), 1,2-bis (2,4,6-tribromophenoxy) ethane (BTBPE), octabromotrimethylphenyl-indane (OBIND), bis(2-ethly-1-hexyl)tetrabromophthalate (BEHTBP), and BDE-209. In Lake Ontario, Dec 602, 604, and DP concentrations increased in sediments between the mid-1960s and mid-1970s, approximately 10 years after Mirex, for which they are replacements. Maximum concentrations of Dec 602 and DP occurred in the early 1980s, and Dec 604 in the mid-1980s followed by declines which have not been as rapid as for Mirex. The dechlorane compounds were detected in remote lakes and Lake Simcoe, but at lower concentrations than in L. Ontario. Declines in L. Simcoe were smaller than in L Ontario, and recent sediments had the highest concentrations in the remote cores for DP and Dec 602. Several alternative brominated flame retardants, including BTBPE, BEHTBP, OBIND, and DBDPE, were detected in remote and impacted lake sediments. Concentrations were lowest in the remote cores, but the highest concentrations were observed in either the surface or top 2 cm sediment slices. Sedimentation fluxes will be calculated based on dated cores and compared between lakes to estimate the role of atmospheric deposition.

MP009 GPS-based Biotelemetry Meets Ecotoxicology: A Novel Approach for Understanding the Exposure of Avian Species to Organohalogen Contaminants M. Gentes, Environmental Toxicology Research Centre (TOXEN), Dept of Biological Sciences, Univ of Quebec in Montreal; J.F. Giroux, Univ of Quebec in Montreal, Behavior and Animal Ecology Research Group (GRECA), Dept of Biological Sciences; R. Letcher, Environment Canada, National Wildlife Research Centre, Wildlife and Landscape Science Directorate, Science and Technology Branch, Carleton Univ; M. Patenaude-Monette, Univ of Quebec in Montreal, Behavior and Animal Ecology Research Group (GRECA), Dept of Biological Sciences; J. Verreault, Univ of Quebec in Montreal, Environmental Toxicology Research Centre (TOXEN), Dept of Biological Sciences. A large suite of non-reactive flame retardants (FRs) are routinely added to consumer products to comply with fire safety standards. The now largely restricted polybrominated diphenyl ethers (PBDEs) are ubiquitous in nearly all biotic and abiotic media worldwide, and their unregulated replacement products [e.g., decabromodiphenyl ethane (DBDPE), BTBPE (1,2-bis(2,4,6-tribromophenoxy) ethane), pentabromoethylbenzene (PBEB), etc.] are currently being detected in tissues and eggs of avian species (e.g., raptors, gulls). However, analysis of organohalogen contaminant data (including PBDE/FR) collected as part of avian biomonitoring programs is often hampered by the lack of characterization of bird's feeding ecology. These knowledge gaps can lead to critical misinterpretations of exposure sources to organohalogen contaminants. In Canada, studies investigating FR contamination in avian species breeding in the highly industrialized and polluted areas of the St-Lawrence River, a known FR contamination hotspot in Eastern Canada, are particularly scant. PBDEs and some unregulated FRs have been detected in gull eggs (herring and ring-billed), but sources of exposure have never been specifically investigated. Using a novel approach based on GPS-tracking of ring-billed gulls (RBGUs) equipped with miniature dataloggers, movements of individuals have been precisely reconstructed and mapped with ArcGIS. The links between habitat-use (i.e., exposure to suspected sources of FRs such as landfills, wastewater plant, industrial parks, etc.) and contamination profiles of individual gulls (blood plasma and liver) were investigated. Preliminary results confirmed the presence of major emerging FRs (e.g., DBDPE, BTBPE, anti-Dechlorane plus (DP), etc.) in RBGU's blood, and concentrations vary greatly both among individuals and for different compounds. For instance, the highest mean plasma concentration determined for PBDEs was 7.43 ng/g ww, while that of anti-DP was 0.33 ng/g ww. Analyses of remaining plasma and liver samples for PBDE/FR are in progress. Preliminary inspection of GPS tracks revealed important space-use diversity, i.e., some individuals foraged mostly in agricultural or riparian areas, while others visited human impacted areas (landfills, urban cores, etc.). Data analysis is ongoing and detailed results will be presented at the conference.

MP010 Metabolism of Organophosphate Flame Retardants by Human Liver Microsomes and Porcine Esterase E.M. Cooper, Duke Univ, NSOE; H.M. Stapleton, Duke Univ, Nicholas School of the Environment. The organophosphates (OPs) tris (1,3-dichloro-2-propyl) phosphate (TDCPP) and triphenyl phosphate (TPP) are common flame retardants (FRs) present in automobiles and many household products. Levels of TDCPP and TPP measured in indoor environments suggest that chronic exposure is occurring for the general population. However, no studies have examined the risks to human health, and knowledge of the human body burdens and metabolism of these FRs is poorly understood. We investigated TDCPP and TPP metabolism in vitro with pooled human liver microsomes and porcine esterase using solid phase extraction and liquid chromatography tandem mass spectrometry. The microsomes metabolized TDCPP and TPP to their respective diester products, bis (1,3-dichloro-2-propyl) phosphate (BDCPP)

and diphenyl phosphate (DPP), as primary metabolites. Rates of transformation were 95.8±2.7 pmol/mg protein/min for TDCPP and 78.8±2.7 pmol/mg protein/min for TPP. The esterase biotransformed 50% of 1.3 nmoles of TDCPP and 34% of 0.6 nmoles of TPP. DPP accounted for 68% of the mass of TPP lost after incubation with the esterase. However, BDCPP observed was less than 1% of initial TDCPP added, suggesting that BDCPP was further metabolized, and/or that other metabolites were formed that were not monitored. Further experiments will measure the kinetics of their metabolism, explore differences in the extent of the metabolism between the two FRs, the enzyme system involved, and examine tissue specific differences in metabolism.

MP011 Occurrence of Organophosphate Esters in Songhua River and a Municipal Wastewater Treatment Plant in China J. Liu, X. Wang, Y. Yin, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences. Organophosphate esters (OPEs) are widely used as flame retardants and are now broadly present in the domestic and outdoor environment. In this study a high throughput LC-MS/MS method was developed for the determination of twelve OPEs including trimethyl phosphate (TMP), triethyl phosphate (TEP), tris(2-chloroethyl) phosphate (TCEP), tri-n-propyl phosphate (TnPP), tris(2-chloroisopropyl) phosphate (TCPP), tris(2-chloro-1-(chloromethyl)ethyl) phosphate (TDCP), triphenyl phosphate (TPhP), tributyl phosphate (TnBP), tris-(2-butoxyethyl) phosphate (TBEP), tri-3-cresyl phosphate (TCrP), 2-ethylhexyl diphenyl phosphate (EHDPP) and tris(2-ethylhexyl) phosphate (TEHP). Analytes were concentrated by solid phase extraction and then determined by ultra-high performance liquid chromatography (Acquity UPLC, Waters, US) equipped with a triple quadruple mass spectrometer (TSQ Quantum Access, Thermo Scientific, US). The developed new method is capable of baseline separating 11 of the 12 studied OPEs within 11 min with LOQs ranged from 0.5 to 20 ng/L and relative standard deviations in the range of 2-10%. For both reagent water and river water, the spiked recoveries of OPEs ranged from 69-110%, except for the very polar and volatile trimethyl phosphate that has recovery below 10%. This developed procedure was applied to study the OPE contamination status in China for the first time. Water samples collected from 17 sites along the Second Songhua River and Songhua River, which is the main river in the northeast part of China and has a total length of 2214.3 km, were analyzed for the first time. All the target twelve OPEs were detected with total concentrations of OPEs around 1 μg/L in the river waters collected from each sites. The concentration of individual OPEs ranged from 0.85 ng/L for TnPP to 3700 ng/L for TCEP. In all the 17 water samples TCEP (38-3700 ng/L) and TnBP (87-870 ng/L) were the major contaminants, whereas the concentrations of all the other analytes were below 100 ng/L. The OPEs in municipal sewage influent and effluent collected at Qinghe waste water treatment plant in the northwest part of Beijing were also determined by the proposed method. All the twelve OPEs except for TPrP, EHDPP and TEHP were detected in both the influent and effluent, and for most OPEs the concentration in effluent was higher than that in influent. TCEP, TCPP, TnBP and TBEP were the major contaminants that occurred at 170-837 ng/L, whereas TCrP, TPhP_TDCP and TEP occurred at 0.274-66.5 ng/L.

MP012 Spatial and Temporal Trends of MeO-PBDPB Congeners in Herring Gull Eggs from the Laurentian Great Lakes of North America D. Chen, Carleton Univ, Chemistry, Ecotoxicology and Wildlife Health Division, Wildlife and Landscape Directorate, Science and Technology Branch, Environment Canada, National Wildlife Research Centre, Carleton Univ, Ottawa, ON, Canada, Dept of Chemistry; R. Letcher, Ecotoxicology and Wildlife Health Division, Wildlife and Landscape Directorate, Science and Technology Branch, Environment Canada, National Wildlife Research Centre, Carleton Univ, Ottawa, ON, Canada, Carleton Univ, Chemistry; L. Gauthier, S. Chu, Ecotoxicology and Wildlife Health Division, Wildlife and Landscape Directorate, Science and Technology Branch, Environment Canada, National Wildlife Research Centre, Carleton Univ, Ottawa, ON, Canada; R. McCrindle, Univ of Guelph; D. Potter, Wellington Laboratories. An increasing number of brominated flame retardants and other brominated substances are being reported in herring gull eggs from the Laurentian Great Lakes basin. Yet, in extracts from gulls' eggs, numerous bromide anion response peaks in electron capture negative ion (ECNI) mass chromatograms remain unidentified. Using archived herring gull egg homogenates, we characterized the three major and three minor brominated substances as the congeners of novel methoxylated polybrominated diphenoxybenzene (MeO-PBDPB), where four congeners contain five bromines and the other two contain four and six bromines, respectively. Optimized, semi-quantitative analysis revealed sum concentrations of the MeO-PBDBP congeners (∑MeO-PBDPBs) ranged from < 0.2 – 39.1 ng/g wet weight in pooled egg homogenates (collected in 2009) from fourteen herring gull colony sites across the Great Lakes, with the highest concentration being for Channel-Shelter Island in Saginaw Bay (Lake Huron). Temporal analyses for the time period of 1982 – 2009 indicated that the ∑MeO-PBDPBs concentrations peaked around early 2000's and then slightly decreased over time in the Channel-Shelter Island egg pool homogenates. To our knowledge, there are no published reports on the environmental presence and sources of MeO-PBDPBs. We hypothesize that these MeO-PBDPBs are degradation products of the polybrominated diphenoxybenzenes, e.g., tetradecabromodiphenoxybenzene (currently marketed as SAYTEX 120) or polybromo 3P2E. The discovery of MeO-PBDPBs in Great Lakes herring gull eggs indicates their substantial bioaccumulation potential, and raises concerns about their origin, environmental behavior and influences on wildlife and environmental health.

MP013 Alternative Flame Retardants in the Atmosphere Near the Great Lakes M. Venier, Indiana Univ, School of Public and Environmental Affairs, Indiana Univ; Y. Ma, Indiana Univ, School of Public and Environmental Affairs; A. Salamova, Indiana Univ, School of Public and Environmental Affairs, Indiana Univ, SPEA; R.A. Hites, Indiana Univ, School of Public & Environmental Affairs. New flame retardants are continuously being introduced into the market to replace commercial products that are either banned or retired. Examples of this trend are 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (TBB) and *bis*(2-ethyl-1-hexyl)tetrabromophthalate (TBPH), which are replacements for the pentabromo-diphenyl ether commercial mixtures, and decabromodiphenylethane (DBDPE), which is marketed as an alternative for decabromo-diphenyl ether, even though the latter is still largely unregulated. Air (vapor and particulate) and precipitation samples were collected at five sites located on the shores of the Laurentian Great Lakes. The sites ranged from urban (Chicago, Illinois, and Cleveland, Ohio) to rural (Sturgeon Point, New York) and remote (Sleeping Bear Dunes and Eagle Harbor, Michigan). The analytes were an extensive list of alternative flame retardants including hexabromobenzene (HBB), pentabromotoluene (PBT), TBB, and TBPH. Among the brominated benzenes, HBB was detected at the highest levels in the vapor samples with an average concentration of 3.7 ± 0.8 pg/m^3 (average ± standard error). The concentrations of this brominated compound were significantly higher than that observed for BDE-47 (p< 0.001), which is the main component of the Penta-BDE retired commercial mixture. Unlike the PBDEs, the concentration of several other alternative flame retardants did not track human population density (notably pentabromoethylbenzene was particularly elevated art a remote site near Lake Superior), suggesting the presence of localized sources. TBB and TBPH were detected in all filter samples analyzed at levels similar to those measured for PBDEs. No temporal trends were detected for these two compounds in the 3-year data series available at the moment.

MP014 Biotransformation of Emerging Flame Retardants: A Case Study of Ring-billed Gulls Breeding in a Pollution Hotspot in the St. Lawrence River, Canada B. Chabot-Giguere, Environmental Toxicology Research Center (TOXEN), Dept of Biological Sciences, Univ of Quebec in Montreal; R.J. Letcher, Carleton Univ, Dept of Chemistry, Environment Canada, Science and Technology Branch, Ecotoxicology and Wildlife Health Division, Science and Technology Branch, Environment Canada, Great Lakes Institute for Environme, Canadian Wildlife Service; J. Vereault, Environmental Toxicology Research Centre (TOXEN), Dept of Biological Sciences, Univ of Quebec in Montreal. As a result of the most recent regulations on the penta- , octa- and deca-bromodiphenyl ether (PBDE) commercial mixtures, the use of new, alternative halogenated flame retardant (FR) additives have been on the rise. These alternative or replacement products include 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE) and decabromodiphenyl ethane (DBDPE), as well as some chlorinated FRs such as Dechlorane Plus (DP, syn- and anti-isomers). These emerging FRs are as yet unregulated in North America and their usage is assumed to increase in the years to come. These new FRs are receiving growing attention as they have recently been detected in wildlife samples, including eggs of fish-eating birds (gulls) from the North American Great Lakes. There are at present important knowledge gaps on the organism fate (e.g., biotransformation) and biological impacts of current-use FRs in wildlife species. This study aims

at understanding the mechanisms of in vitro (liver microsomal) biotransformation of selected PBDEs (BDE-15, -153 and -209) and emerging FRs (BTBPE, DBDPE, syn- and anti-DP) in the ring-billed gull breeding in a known pollution hotspot in the St-Lawrence River basin (Québec, Canada). The ring-billed gull represents an ideal model to study biotransformation of FRs because of its opportunistic feeding habits and hence exposure to a variety of organohalogen pollutants such as the PBDEs and current-use, non-PBDE FRs. Preliminary analyses of ring-billed gull plasma (n=3) have demonstrated the occurrence of major lower- and higher-brominated BDE congeners as well as emerging FR compounds. Highest mean plasma concentration determined for the PBDEs was 7.43 ng/g ww (BDE-47), while that of other FRs was 0.33 ng/g ww (anti-DP). The PBDE/FR analyses in remaining plasma and liver samples are in progress. The catalytic activity determination of cytochrome P450 (CYP) 1A1-like enzymes based on EROD showed a great variability in CYP induction in this breeding colony. For the 23 investigated adult breeding gulls, there was a 3-fold difference between the lowest and highest EROD activities. In vitro biotransformation assays using liver microsomes of these individuals have been used to assess PBDE and non-PBDE FRs degradation. In summary, the results of this research will be of high interest as they will improve our knowledge on the mechanisms of biotransformation of emerging FRs of potential environmental concern in exposed birds from polluted aquatic environments.

MP015 Emerging Contaminants in Colonial Aquatic Birds of the St. Lawrence River L. Champoux, Environment Canada, Science and Technology Branch; R.A. Lavoie, Queen's Univ, Biology; J. Rail, Environment Canada, Canadian Wildlife Service; P. Martin, Environment Canada, Science and Technology Branch; R.J. Letcher, Carleton Univ, Dept of Chemistry, Environment Canada, Science and Technology Branch, Ecotoxicology and Wildlife Health Division, Science and Technology Branch, Environment Canada, Great Lakes Institute for Environme, Canadian Wildlife Service. Since 2004, eggs of Great Blue Herons, Northern Gannets, Herring Gulls, Double-crested Cormorants and Atlantic Puffins have been collected for contaminant analysis as part of on-going monitoring programs over a large stretch of the St. Lawrence River in Quebec, Canada. Eggs of other species (Black Guillemot, Black-legged Kittiwake, Common Tern, Common Eider, Great black-backed Gull, and Razorbill) have also been collected as part of specific research projects. For analysis of emerging contaminants, PBDE and non-PBDE brominated flame retardant (BFR) analyses were conducted at the National Wildlife Research Centre, in Ottawa, by GC/MSD. Perfluorinated compounds were also measured in a smaller number of species. Mean sum BDE/BFRs ranged from 17 ng/g (wet weight) in common terns from a remote site at Iles-de-la-Madeleine in the Gulf of St. Lawrence to 850 ng/g w.w. in herring gulls from the highly urban Montreal area. BFR levels did not increase with trophic level when using all the data but did when freshwater data from the Great Blue Heron were removed. Contaminant levels are higher in the freshwater, more urbanized section of the River, while trophic levels are higher in the estuarine-marine section, possibly because of a more complex food chain.

MP016 Emerging Halogenated Flame Retardants in Ring-billed Gulls from the St. Lawrence River: Associations Between Ecological Tracers and Diet E. Caron-Beaudoin, Environmental Toxicology Research Center (TOXEN), Dept of Biological Sciences, Univ of Quebec in Montreal; J. Helie, Geochemistry and Geodynamics Research Center (GEOTOP-UQAM); M. Gentes, Environmental Toxicology Research Centre (TOXEN), Dept of Biological Sciences, Univ of Quebec in Montreal; J. Giroux, Groupe de recherche en écologie comportementale et animale (GRECA), Dept of Biological Sciences, Univ of Quebec in Montreal; J. Verreault, Environmental Toxicology Research Centre (TOXEN), Dept of Biological Sciences, Univ of Quebec in Montreal; R.J. Letcher, Carleton Univ, Dept of Chemistry, Environment Canada, Science and Technology Branch, Ecotoxicology and Wildlife Health Division, Science and Technology Branch, Environment Canada, Great Lakes Institute for Environme, Canadian Wildlife Service. Some emerging flame retardants (FRs) additives ([e.g., decabromodiphenyl ethane (DBDPE), BTBPE (1,2-bis(2,4,6-tribromophenoxy)ethane), pentabromoethylbenzene (PBEB), etc.], which are replacement products of the recently banned penta- and octa-bromodiphenylether (BDE) mixtures, have been reported to bioaccumulate in wildlife species. Concentrations of PBDEs and some emerging FRs have been reported in herring gull eggs (*Larus argentatus*) from the Laurentian Great Lakes, and were shown to have increased temporally over the last decade. In order to understand the environmental fate and bioaccumulation dynamics of FRs in aquatic birds, a better understanding of foraging behaviour and space-use is needed. We use the ring-billed gull (*Larus delawarensis*), an omnivorous and opportunistic species breeding close to pollution hotspots in the St-Lawrence River (Montreal, Canada), to investigate the link between diet, space-use and contaminant profiles (PBDE/emerging FRs) of individual gulls using ecological tracers and geolocation data. Feeding ecology and space-use of gulls nesting in a large colony (48,000 pairs) is investigated using bird-borne GPS data loggers that allow detailed tracking (3-5 m) of foraging movements for a 48-72h period. This geolocation technique is used in combination with ecological tracers (stable isotopes of carbon [$\delta^{13}C$] and nitrogen [$\delta^{15}N$]) in blood and liver to explain the transfer of nutrients and contaminants within the food web. The $\delta^{13}C$ is used to determine the carbon source diversity, while $\delta^{15}N$ reveals the trophic position. Results available thus far have shown a wide variability in the stable isotope compositions (C and N) among individuals breeding within this colony, and between males and females. These results suggested high intraspecific variation in dietary preferences. No difference is observed between the $\delta^{13}C$ in liver and plasma. However, the $\delta^{15}N$ signature is different between those tissues. $\delta^{13}C$ and $\delta^{15}N$ are not different between the first and second captures (i.e., after 48-72h) in plasma, which suggested that this time window was shorter than the turnover rate of C and N. Contaminant analyses in plasma and liver are in progress, and results will be presented at the conference. In conclusion, a better understanding of diet documented via the use of stable isotopes and geolocation may be promising for the evaluation of individual contamination profiles in aquatic birds.

MP017 Leaching of Halogen Free and Brominated Flame Retardants from Polymers S. Brandsma, J.d. Boer, VU Univ, Institute for Environmental Studies; P. Krystek, MiPlaza, Philips Research Europe and VU Univ, Institute for Environmental Studies; P. Clarke, P. Patel, P. Cusack, ITRI; P. Leonards, Institute for Environmental Studies, VU Univ, Chemistry and Biology, VU Univ, Institute for Environmental Studies. Information about the production, distribution and consumption of flame retardants in electric and electronic (E&E) equipment (plastics) is well described. However, there is a knowledge gap in the amount of flame retardants leaching from plastics of electric and electronic (E&E) equipment to the environment. In the EU funded project ENFIRO, halogen free flame retardants (HFFR) are studied that are viable alternatives to specific commercial brominated flame retardants (BFR). Leaching studies of BFRs from different types of plastics have been described in literature; however, limited information on leaching of HFFRs is available. ENFIRO studies 15 HFFRs of which 6 are metal-based. Metal-based flame retardants are stable in plastic (polymer) products, but can leach, dissociate and enter the environment. Monitoring of the fate of metal-based HFFRs in the environment is difficult as metals can have various sources of emission. Leaching tests of HFFRs from plastics is an alternative method that may contribute to the exposure and risks assessment and understanding of the fate of HFFRs in the environment. The current study shows leaching properties of different HFFRs from polymers in comparison with BFRs. Thereby, the influences of pellets vs. moulded plates and pH on the leaching properties are studied. Two types of leaching protocols were tested. The TLCP protocol, from the USEPA, use worse-case leaching conditions (low pH) to simulate a municipal waste landfill, and studies if waste has toxic characteristics and is hazardous. The second protocol (DIN 38414-S4) determines leaching by water (neutral pH), and has been widely used for regulatory purposes in Europe. We show that no differences in leaching properties between the DIN and TCLP methods for two metal-based PBT pellets were found. However, higher leaching rate coefficients of HFFRs from PBT pellets than PBT moulded plates were found, which is probably a results of the differences in surface:volume ratio and the porosity of the materials. Additional experiments were performed to study the influence of leaching conditions (salinity, humic acids) to simulate different environmental conditions.

MP018 Occurrence, Distribution, and Transport of (Alternative) Brominated Flame Retardants and Dechlorane Plus in the Global Abiotic Marine Environment A. Moller, Helmholtz-Zentrum Geesthacht, Institute of Coastal Research, Dept for Environmental Chemistry; Z. Xie, Helmholtz-Zentrum Geesthacht, Helmholtz-Zentrum Geesthacht, Dept for Environmental Chemistry, Helmholtz-Zentrum Geesthacht, Institute of Coastal Research, Dept for Environmental Chemistry, GKSS Research Centre, Research Scientist; R. Sturm, R. Ebinghaus, Helmholtz-Zentrum

Geesthacht, Institute of Coastal Research, Dept for Environmental Chemistry. Organic, mainly halogenated flame retardants (HFRs) have been applied for several decades in various industrial and consumer products to reduce their inflammability and protect humans against fire accidents. Besides there positive effects on fire prevention, they are known to be harmful for the environment. One of the most focused HFRs, the polybrominated diphenyl ethers (PBDEs), are persistent, bioaccumulative, toxic and can undergo long-range atmospheric transport (LRAT). They underwent worldwide banishment since the early 2000s, but there are dozens of other, non-regulated non-PBDE HFRs which haven't received much scientific and public interest even if they have been partly used for several decades, too, or if their production is expected to increase. There is little known on their production and emissions, but they are obviously produced and emitted into the environment worldwide. In the present study, we investigated PBDEs, several non-PBDE brominated flame retardants (BFRs) and the highly chlorinated flame retardant Dechlorane Plus (DP) in air and seawater in the Atlantic and Pacific Ocean, and in the Arctic and the Southern Ocean. High volume air and seawater samples were taken aboard the research vessels Polarstern (Germany) and Snow Dragon (China), soxhlet extracted and finally measured by GC-ECNCI-MS. The results showed that HFRs are worldwide distributed in the marine environment, non-PBDE BFRs as well as DP can undergo LRAT into remote regions such as the Arctic and Antarctica, and that the alternative BFRs and DP are meanwhile the predominant HFRs rather than the traditional PBDEs such as BDE-47 and BDE-77. Concentrations were generally highest near the source regions such as Western Europe and East Asia with concentrations in the one- to two-digit pg/m^3 range in air samples (pg L-1 for water), while Asian concentrations where generally higher than European. Among the non-PBDE BFRs, hexabromobenzene (HBB) and 2,3-dibromopropyl-2,4,6-tribromophenyl ether (DPTE) predominated, while especially in the Asian marine environment a wide range of alternative BFRs was observed. DP was deteced worldwide, too, while a different transport behaviour of the two stereoisomers – synDP and antiDP – was observed. This study gives important knowledge for the occurrence and transport behaviour including air-seawater exchange of HFRs, especially of non-PBDE HFRs, showing future directions in the research field of HFRs.

MP019 Capillary Ion Chromatography Mass Spectrometry for Trace Environmental Analysis J. Wang, Thermo Fisher Scientific; M. Miller, Thermo Fisher; W. Schnute, Thermo Fisher Scientific. Ion chromatography (IC) has been used extensively as a complimentary separation technique to HPLC. Recently introduced capillary IC (CIC) further improves trace level environmental analysis in matrices when coupled to mass spectrometry (MS). This study involves the use of CIC for the direct analysis of highly polar analytes of environmental concern without labor intensive derivatization or MS incompatible ion paring; and the modifications of currently available MS electrospray (ESI) source and investigation of interface parameters to improve ionization and transmission efficiency at micro flow levels. This CIC-MS (MS/MS) configuration has been applied for the analysis of endothall (a widely used herbicide) in matrices, ultra-trace perchlorate (low ppt) in rainwater and small organic acids with the details of results to be presented. Significant improvements were observed over previously reported results with respect to method performance such as throughput, sensitivity, precision and system stability. Recommendations for CIC-MS instrumentation and method development will also be presented.

MP020 Comparative Assessment of GC and GC x GC Characterization Techniques for Estimating Aquatic Toxicity of Complex Petroleum Mixtures M.J. Benotti, Battelle, Analytical and Environmental Chemistry; G. Durell, Battelle, Program Manager/Senior Research Scientist; J.R. Thorn, Battelle, Applied Research and Laboratory Operations; A. Frank, E. Strozier, Battelle, Sample Analysis; B. Metzger, Battelle; N. Richardson, Battelle, Environmental Monitoring & Assessment. Evaluation of aqueous toxicity of complex mixtures using chemical characterization, rather than direct toxicity measurements, is challenging given the analytical limitations to chemical identification. This difficulty has been particularly notable when modeling toxicity associated with petroleum mixtures, where chemical analysis has traditionally been conducted using gas chromatography-mass spectrometry (GC-MS) and GC-flame ionization detection (GC-FID), both of which are capable of identifying only a fraction of the compounds typically present. Recently, comprehensive two dimensional GC, combined with either FID (GCxGC FID) or Time of Flight MS (GCxGC-ToF-MS) detectors, has been shown to greatly expand the resolution of compounds in petroleum products. The greater resolving power of GCxGC techniques is useful for determining sample compositional similarity for attributional studies and may also be valuable for assessing potential aquatic toxicity. Approaches for predicting the aqueous toxicity of complex petroleum mixtures to aquatic organisms range from comparison of Total Petroleum Hydrocarbon (TPH) estimates and empirically-derived toxicity thresholds to models such as PETROTOX, which calculate the dissolution of individual compounds representing various hydrocarbon classes ("blocks") into the aqueous phase and utilizes a Target Lipid Model (TLM) to estimate internal exposures. An aquatic toxicological database is then used to derive toxicological endpoints based on an assumed narcosis mode of action and general additivity. This study evaluates the relative performance of four analytical techniques (GC-FID, GC-MS, GCxGC-FID and GCxGC-ToF-MS) by comparing the predicted aquatic toxicity estimates derived from different toxicity assessment approaches across a range of crude and refined petroleum mixtures. A number of petroleum products including various crude oils (including North Slope crude, Campeche Sound heavy/light crude, Kuwaiti Mardomah crude) and refined products (including diesel fuel, kerosene, and gasoline) were included in this study. Predicted toxicity results were compiled for each of the evaluated analytical approaches, and toxicity thresholds derived for each sample. Using the GCxGC-ToF-MS results to benchmark the predicted toxicity estimates of the other analytical techniques along with cost data, a comparative assessment of the various analytical techniques will be presented.

MP021 Mass Balance Analysis on AFFFs: TOF-CIC and LC-MS/MS L.W. Yeung, B. Weiner, S.A. Mabury, Univ of Toronto, Dept of Chemistry. Aqueous film forming foams (AFFFs) were developed in the 1960s by the United States Navy and the 3M company in order to extinguish fires involving inflammable liquid fuels, such as kerosene and gasoline. They have been widely used for emergency or training purposes at military bases, fire Depts, and airports. Fluorinated surfactants are present in AFFFs at 1-5% by weight, which were in the past dominated by perfluorooctanesulfonate (PFOS). However, due to concerns of toxicity and bioaccumulation, PFOS was discontinued in 2002 in North America by 3M. Fluorotelomer-based surfactants that include the 6:2 fluorotelomer sulfonate (6:2 FTS) backbone have since then replaced PFOS as the fluorinated surfactants used in AFFFs. These fluorinated surfactants are considered to be biodegradable and it has been suggested they are not bioaccumulative. Due to proprietary reasons, little is known about the chemical composition of currently available AFFFs. Recent developments in liquid chromatography and mass spectrometry allow the identification and quantification of trace levels (sub parts-per-billion) of perfluorinated components in a sample. Up to date, over 50 poly- and per- fluorinated carboxylates/sulfonates/phosphates have been identified in environmental samples. However, quantitative measurements of the perfluorinated content can only be performed when components are known and all authentic standards are available. In this study, a combined combustion ion chromatography, namely Total Organo Fluorine – Combustion Ion Chromatography (TOF-CIC) is used to measure the total organic and inorganic fluorine content in AFFF samples. The foams were further analyzed for 22 known poly-/per- fluorinated carboxylates/sulfonates using HPLC-MSMS in electrospray ionization (negative mode). Preliminary results suggest that inorganic fluorine was present at

MP022 Development of an Ultra High Performance Liquid Chromatography-Tandem Mass Spectrometry Method for Quantifying Fatty Acids Without Derivatization G. Wei, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences; E.Y. Zeng, Guangzhou Institute of Geochemistry, State Key Lab of Organic Geochem. A simple, rapid and sensitive method based on ultra-high performance liquid chromatography/tandem mass spectrometry (UHPLC/MS/MS) without prior derivatization was developed for quantification of 41 components of fatty acids (FAs, from C10 to C30, consisted of saturated, branched, mono- and polyunsaturated components including trans-cis isomers and double-bond positional isomers). Instrumental analysis was performed in the negative electrospray ionization mode with pseudo-multiple reaction monitoring transitions by selecting [M–H]- as the precursor ions as well as the product ions. Through internal standard calibration, this method obtained satisfactory recoveries for the target FAs (65–119%) and the surrogate standards C18:1-d2 and C16:0-d30 (76–109% and 79–06%, respectively) from spiked blank samples, with relative standard deviations all less than 20%. The recoveries

of the surrogate standards C18:1-d2 and C16:0-d30 in sediment and soil samples were in the ranges of 66–86% and 55–89%, respectively. Limits of instrumental quantification (defined as the quantity with a signal-to-noise ratio of 10 in a standard solution) varied between 2 and 50 pg on column, demonstrating satisfactory detection sensitivity. Compared with conventional gas chromatography/mass spectrometry (GC/MS) techniques requiring complicated derivatization of FAs into volatile derivatives, the UHPLC/MS/MS method developed in the present study required simpler sample processing steps, resulting in good recoveries for a variety of FAs (C10:0–C30:0). The UHPLC/MS/MS method also exhibited sufficient detection sensitivity and superior reproducibility, and had advantage in shorter analysis time over GC-MS for all target FAs. Therefore, UHPLC/MS/MS may serve as a useful tool for quantifying FAs in various fields.

MP023 Toxicological Applications of Cryogenic Laser Ablation Inductively Coupled Plasma Time of Flight Mass Spectrometry (CLA-ICP-TOF-MS) S.M. Lev, M. Monk, Towson Univ, Urban Environmental Biogeochemistry Laboratory. The analysis of acid digested bulk tissue samples by ICP-MS is a primary method for toxicologists when trying to characterize the uptake and storage of a trace metal by an organism. This approach is sensitive, reliable and reproducible but requires the homogenization of the tissue for analysis. This procedure does not provide any information on the distribution of the analyte of interest within the tissue sample. Sub-sampling is a possible alternative method for preserving distribution data but in many cases sub-sampling on the scale necessary for useful information is not an option due to sample size limitations. By coupling a laser ablation system equipped with a cryogenic cell to an Inductively Coupled Plasma Mass Spectrometer (CLA-ICP-MS), it is possible to achieve high-resolution trace metal distribution data on toxicological tissue samples. A cryo cell is critical for proper ablation of soft tissue samples by LA-ICP-MS. The system used for the work presented is a commercially available cryo cell from GeoMed Analytical capable of temperatures as low as -30°C, coupled to a GBC Scientific ICP-Time of Flight-MS (ICP-TOF-MS). The speed of the TOF system is an ideal platform for the analysis of the transient signal produced by laser ablation and has detection limits that are comparable to traditional ICP-MS (i.e., low ppb range). This system is suitable for the ablation of a range of tissues with a spatial resolution of 10 microns for most elements. Results will be presented to demonstrate the detection limits and spatial resolution of CLA-ICP-TOF-MS for a variety of elements in a range of tissue types. Recommended conditions for ablation, suggestions for drift correction, and mass bias correction will also be presented.

MP024 Two-dimensional Liquid Chromatography – High Resolution Mass Spectrometry for the Analysis of Polar Organic Contaminants in the Aquatic Environment G.J. Getzinger, Duke Univ, Nicholas School of the Environment ; L. Ferguson, Duke Univ, Dept of Civil and Environmental Engineering, Duke Univ, Nicholas School of the Environment , Pratt School of Engineering, Dept of Civil & Envionmental Engineering. The emergence of high-resolution mass spectrometry (HRMS) as an analytical tool in environmental chemistry has expanded the scope of research into fate and transport of organic contaminants in complex mixtures. Recent advances in instrumentation have allowed for new approaches in trace organic analysis, including non-target contaminant screening, transformation product identification, retrospective sample analysis, and increased certainty in the identification and quantitation of legacy and emerging contaminants. Currently, most environmental applications of HRMS use the unique capabilities of these instrument platforms (e.g., high mass accuracy and exceptional tolerance for sample complexity) to monitor ultra trace (ppq-ppt) levels of polar and semi-polar organic pollutants by incorporating high performance liquid chromatography (HPLC) and eltectrospray ionization (ESI). However, HPLC-ESI-MS analysis of complex environmental samples such as wastewater often suffers from matrix-related signal suppression and poor chromatographic resolution of target analytes from background contaminants. To address these limitations while maximizing the performance of the LTQ-Orbitrap HRMS/MS instrumentation, we have developed a comprehensive two-dimensional liquid chromatography (2D-LC) method for the HRMS analyses of emerging contaminants in highly complex environmental samples. This method was optimized and implemented for the analysis of both target (e.g xenoestrogens, surfactants, pesticides, herbicides, and fungicides) and non-target anthropogenic contaminants in wastewater and ground water samples from Kiawah Island, SC. In these analyses, the capabilities of 2D-LC-HRMS in environmental analysis, were compared to traditional sample enrichment and clean-up strategies upstream of single dimension LC-HRMS. To reduce the influence of matrix interferences and achieve the necessary sensitivity and specificity demanded in environmental analysis, contemporary LC-MS methods often utilize targeted sample enrichment and clean-up. However, these methods often result in significant losses of non-target and unknown sample components. Our results indicate that the chromatographic resolution achieved by 2D-LC coupled with the high performance capabilities of the LTQ Orbitrap Velos (R>100,000, mass error < 2ppm) provides a new, unique, and powerful tool for the monitoring of target and non-target analytes in highly complex samples.

MP026 Mercury Emissions from Soils as Affected by Soil Moisture and Sterilization R. Pannu, Univ of Saskatcewan, Soil Science, Acadia Univ, KCI Center; N. ODriscoll, Acadia Univ, Earth and Environmental Sciences; S.D. Siciliano, Univ of Saskatchewan, Dept of Soil Science; J. Dalziel, Environment Canada, Air Quality Sciences Section. Mercury is a globally dispersed pollutant due to its long (1.5 – 2 years) atmospheric residence time (Munthe et al., 2001; Lindberg et al., 2007). Accurate prediction of global and regional mercury flux is important for mitigating the mercury burden of ecosystems. Natural emissions and re-emissions of Hg(0) from soils have been identified as a major contributor to the global mercury budget and conservative estimates of global mercury fluxes suggest a total of 700 to 1000 ta^{-1} volatilized from soils (Lindqvist, 1991). There are large variations in published mercury flux values from soil surfaces due to number of uncertainties associated with flux measurements as affected by soil moisture. Rising soil water content can promote the aqueous reduction of Hg(II) to Hg(0) with subsequent volatilization to atmosphere. This research quantifies the effect of soil moisture (measured as percent water filled pore space (WFPS) – 15, 30, 45 and 60%) on the kinetics of elemental mercury Hg(0) production and volatilization to the atmosphere in 13 soils obtained from Nova Scotia, Canada under controlled conditions. The soils maintained at 45% WFPS were found to have the highest Hg(0) production while negligible mercury volatilization was found at near saturation levels (60% WFPS). First-order kinetic model using Maquardt iteration method fitted the cumulative mercury produced data well (R^2= 0.90 to 0.99, P< 0.001) in all the studied soils. Cumulative mercury production curves in soils followed a distinct exponential pattern initially at all PWFPS with mercury leveling off after 5-8 hours. Multiple linear regression analysis with reaction rate constants (k) as dependent variable and soil properties (total Hg, organic carbon, pH and electrical conductivity) as independent variables indicated that rate of reaction can be predicted from a linear combination of soil properties at 15 (R^2 = 0.308, P > 0.05), 30 (R^2 = 0.265, P > 0.05), 45 (R^2 = 0.288, P > 0.05) and 60% WFPS (R^2 = 0.306, P > 0.05). We will also present the data showing effect of soil irradiation on Hg(0) production as influenced by soil biotic activity.

MP027 The Effect of Tidal Flushing on Mercury Fate and Biogeochemistry in Intertidal Sediments J. Canario, IPIMAR, Aquatic Environment Dept, INRB IP/IPIMAR, Aquatic Environment and Biodiversity; M. Caetano, INRB IP/IPIMAR; L. Poissant, Environment Canada; C. Vale, INRB IP/IPIMAR; N. O'Driscoll, Acadia Univ, Acadia Univ, Dept of Earth & Environmental Sciences. Intertidal environments are characterized by complex subsurface hydrologies regulated by topography, sedimentology, groundwater discharge, as well as tidal pressure and wave action. In these environments vertical flow at ebb tide increase hydrostatic pressure at depth and forces the release of pore water to the surface. In order to assess how this force influences mercury fate in intertidal sediments and the associated biogeochemical processes, several inundation experiments were performed in vegetated and non-vegetated intertidal sediments in three sites of the Tagus Estuary (Portugal). Sediments and overlying water were collected at a high temporal resolution after inundation at each sampling site. Dissolved gaseous mercury (DGM) and water-to-air volatilization was measured using a floating dynamic flux chamber. In the laboratory, water (pore water – PW – and overlying water – D) samples were analysed for dissolved mercury species (Hg_D and Hg_{PW}, methyl mercury (MeHg)), dissolved organic carbon and suspended particulate matter (SPM) content. Salinity, dissolved oxygen and pH were measured in situ. Solid sediments were analysed for Hg, MeHg and organic carbon content. In vegetated sediments Hg and MeHg content were also determined in the root biomass. Concentrations of dissolved mercury species in flooded water increased up to 10 times during the first 5 minutes of tidal flooding in vegetated and non-vegetated sediments. Concurrently MeHg concentrations decreased in solids and in pore

waters. A strong correlation (R= 0.99; p< 0.01) was found between mercury volatilization from water and DGM concentrations indicating the escape of recently formed Hg^0 to the atmosphere. During the inundation of vegetated sediments MeHg concentrations in roots decreased as much as 31% in the first 8 minutes after the inundation. This suggests that MeHg is far mobile that would be expected if the sequestration processes in roots was dominated by affinity to cysteine-rich peptides. The short-time variations registered in this work indicates a shift in the mercury equilibrium between pore waters, solid sediments and root surfaces. As water floods salt marsh sediments, MeHg, escapes from the sediments being potentially available to biota living those environments. The results obtained in this study clearly points to the importance of tides in Hg and MeHg export from sediments, DGM formation and Hg volatilization in shallow meso- and macrotidal estuaries.

MP028 Seasonal Variation of Methylmercury Sediment/Water Fluxes in a Meso-tidal Estuary (Tagus-SW Europe) R. Cesario, INRB-IPIMAR National Institute of Biological Resouces, Dept of Environmental and Biodiversity; M. Caetano, INRB IP/IPIMAR; J. Canario, IPIMAR, Aquatic Environment Dept, INRB IP/IPIMAR, Aquatic Environment and Biodiversity; C. Monteiro, M. Nogueira, INRB-IPIMAR National Institute of Biological Resources; C. Vale, INRB IP/IPIMAR. Methylmercury (MeHg) is the most concern mercury species to aquatic systems due to its ability to bioaccumulate in food webs. Methylmercury is mainly produced in sediments by microorganisms and then can be exported to water column by molecular diffusion or other transport processes. The Tagus estuary in Portugal is one of the most Hg contaminated in SW Europe. Recent woks point to the existence of 23 ton of Hg stored only in the first 5-cm sediment depth. In a recent work with 92 surface sediments it was proved that MeHg concentrations varied seasonally with more 32% of MeHg found in summer season. In spite of this findings very little is known about MeHg variation in deeper sediments and mainly if there is any seasonally variation of MeHg sediment/water fluxes. This issue is particularly important because an increase of these fluxes can lead to an increase of aquatic live exposure to MeHg in warmer season. In order to clarify these subjects sediment cores and overlying water were collected in Summer 2010 and Winter 2010/2011 at four sites from Tagus estuary with different degree of mercury contamination. Pore waters were separated from solids by centrifugation and all water and solid samples were analyzed for total mercury, MeHg and other interpretative parameters. Results obtained in both solids and pore waters confirm previous findings found in surface sediments, i.e., higher proportion of MeHg in summer months, not related to the degree of Hg contamination. The amount of MeHg in the all estuary increased up to 20% that may affect sediment/water fluxes. Noteworthy, an upward MeHg diffusive flux was observed in winter that was inverted in summer. These results indicates that, although MeHg production increased in summer, overlying water MeHg levels increase in higher proportion compared to the levels in pore waters. A decrease in demethylation in the water column during summer may explain why levels of MeHg where higher. It is well documented that the environmental conditions found in Tagus waters in summer (decrease of redox potential, lower dissolved oxygen, etc) disfavors demethylation reactions.

MP029 Merganser: An Empirical Model Linking Atmospheric Deposition and Watershed Features to Mercury Levels in Fish and Loons in New England A.C. Simcox, US Environmental Protection Agency, Region 1; J. Shanley, R. Moore, R. Smith, US Geological Survey; E.K. Miller, Ecosystems Research Group, Ltd; N. Kamman, Vermont Dept of Environmental Conservation; D. Nacci, US Environmental Protection Agency; K. Robinson, US Geological Survey; J. Weiss, J.M. Johnston, M. Hughes, US Environmental Protection Agency; C. Johnston, US Geological Survey; D. Evers, K. Williams, Biodiversity Research Institute; J. Graham, Northeast States for Coordinated Air Use Management; S. King, New England Interstate Water Pollution Control Commission. EPA and a team of mercury researchers in the northeast US recently completed development of a GIS-based model called MERGANSER (Mercury Geospatial Assessments for the New England Region). The model, which was developed with data gathered over a decade, uses an empirical approach to relate atmospheric Hg deposition and lake and watershed characteristics to Hg concentrations in fish and fish-eating wildlife (common loons). The model identifies statistically significant watershed features, such as total Hg deposition, watershed area, percent forest canopy and wetland area, that, especially in combination, heighten the risk of high mercury levels in biota. The model estimates the probability that a specified fish species and/or common loon in a given New England lake will exceed a threshold Hg concentration and gives an estimate of Hg concentration in fish tissue and loon blood with error bounds. These qualitative and quantitative measures can be used to identify areas throughout New England where human-health impacts (via fish consumption) and ecological impacts may be occurring. MERGANSER includes 4,404 New England lakes of 8 hectares (about 20 acres) or more in size. A total of 56 independent spatial variables were tested for statistical significance as predictors of Hg concentrations in fish tissue and loon blood. Of these candidate variables, nine were identified as significant predictors. MERGANSER also includes three interaction terms where the effect of one independent variable on the dependent variable (i.e., fish Hg or loon Hg) depends on the value of another independent variable. All of the interaction terms included total Hg deposition. The model explains about 63 percent of the variance in Hg levels of all fish and loon samples included in the model, which is considered a good result given the complexity of Hg transport and fate in the environment. MERGANSER can also be used to explore changes in Hg levels in fish and loons resulting from changes in atmospheric Hg deposition, temperature changes due to climate change, or changes in land use, and to identify optimal locations for monitoring. Additionally, MERGANSER provides a modeling approach for other regions of the US.

MP030 Trends in Mercury Deposition Downwind of Major Canadian Point Sources J.L. Kirk, Environment Canada; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, National Water Research Institute; M. Evans, Environment Canada; H. Hintelmann, Trent Univ; F. Yang, X. Wang, A. Gleason, Environment Canada; J. Coty, Univ of Waterloo; G. Lawson, C. Tunks, Environment Canada. Increased rates of atmospheric inorganic mercury (Hg) deposition have been shown to increase methyl mercury (MeHg) concentrations in fish; however the relative importance of regional versus local Hg sources are generally not known. In Canada, estimates from the global/regional atmospheric heavy metals model (GRAHM) indicate that while in most regions only ~2% of Hg deposition originates within Canada, there are "hotspots" where ~60% of deposition originates from local sources. As part of the Clean Air Regulatory Agenda (CARA) Hg science program, we are quantifying Hg deposition to aquatic ecosystems from local sources using analysis of dated lake sediment cores. In 2009-2010, sediment cores, water samples, and catchment soils were collected from: 18 lakes located varying distances from a metal smelter located at Flin Flon, Manitoba and coal-fired power plants in central Alberta; 5 lakes in Kejimkujik National Park, Nova Scotia where MeHg concentrations in biota are known to be high despite the absence of local point sources; and 5 lakes at the Experimental Lakes Area in Northwestern Ontario, where Hg deposition rates should represent regional background. In Flin Flon lakes, total Hg (THg) fluxes began increasing in the ~1930s, when metal smelting began in this region and peaked in the late 1980s-early 2000s, reaching up to 6529 $\mu g/m^2$/year in lakes near the smelter. However, THg fluxes dramatically decreased with distance from the smelter and flux ratios (FR; $HgF_{post\ 1990}/HgF_{pre\ 1900}$) were 27-47 in lakes within 5 km of the smelter, 10-17 within 40 km, and only 3-5 70 km away. Lake water THg concentrations also decreased with increasing distance from the smelter (r^2=0.51, p=0.03), but were low (1.08±0.40 ng/L) indicating that most of the Hg emitted from the smelter rapidly deposits to lake sediments. In contrast, in Alberta lakes, Hg fluxes showed no trend with distance from the power plants and FRs were only 2-6. Lake water THg concentrations also did not vary with proximity to the power plants and averaged only 0.46±0.34 ng/L. These results suggest that the coal fired power plants are emitting fine particulate-bound or gaseous Hg(0) species which travel long distances after emission. Catchment soils are currently being analyzed for THg and lithogenic elements so that catchment and atmospheric Hg inputs to each lake can be distinguished. Results from the Kejimkujik and ELA lakes will also be presented.

MP031 A Comparison of Mercury Concentrations in Sediment, Water, and Biota of Lakes Near Two Major Hg Emitters in Western Canada K. Bielefeld, Environment Canada, Water Science and Technology Directorate, Univ of Saskatchewan, Biology, Univ of Saskatchewan, National Hydrology Research Center; M. Evans, Environment Canada; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, Environment Canada, National Water Research Institute; J.L. Kirk, Environment Canada, Research Scientist, Environment Canada; J. Keating, Environment Canada, Water Science and Technology Directorate. Environmental contamination due to anthropogenic mercury (Hg) releases is an issue of increasing global

concern. As a part of the Canadian government's commitment to reduce Hg emissions, Environment Canada is investigating the factors affecting spatial and temporal variability in Hg concentrations in sediment, water, and biota of lakes near two major Hg emitters in western Canada. Here we assess the localized impact of Hg pollution from two major industrial emitters in Canada – a base metal smelter at Flin Flon, Manitoba located on the Precambrian shield and a cluster of 4 coal-fired power plants in central Alberta's boreal plain. Shield lakes are relatively isolated, surrounded by boreal forest and have received emissions from the Hudson Bay Mining and Smelting complex in Flin Flon, MB since 1930. Central Alberta lakes are highly productive and receive inputs from the surrounding urban and agricultural landscape in addition to emissions from a complex system of four large coal-fired power plants, in operation since the 1950's. We collected northern pike (Esox lucius), forage fish, benthic invertebrates, zooplankton, water and sediment for Hg analysis from lakes at both study locations. Sediment Hg concentrations are very high in lakes in the immediate Flin Flon area but rapidly diminish with distance while sediment Hg levels are low in all of the highly productive Alberta lakes. Despite notable differences in sediment Hg concentrations, lake productivity, and watershed characteristics between each area, northern pike in the immediate Flin Flon area do not reflect high sediment Hg concentrations and, like Alberta pike, are below consumption guidelines of 0.5 µg/g. Furthermore, lakes ~ 70km northwest of the Flin Flon smelter have exceedingly high pike Hg concentrations despite low sediment Hg and distance from source. Also being discussed is the use of stable isotopes (δ13C, δ15N) to characterize food webs and develop biomagnification rates within each lake. These findings will highlight the importance of implementing emissions controls specific to ecological and environmental factors and will have key implications for future industry.

MP032 Factors Affecting Mercury Biomagnification Through Lake Food Webs in the Canadian High Arctic G. Lescord, Canadian Rivers Institute, Univ of New Brunswick, Biology Dept; K. Kidd, Canadian Rivers Institute, Univ of New Brunswick, Biology; D. Muir, J. Kirk, X. Wang, G. Lawson, Environment Canada; N. O'Driscoll, Acadia Univ. Mercury (Hg) concentrations in landlocked Arctic char (*Salvelinus alpinus*) in the Canadian High Arctic can vary up to 4-fold between neighboring populations. Since Arctic lakes receive most of their Hg from wet deposition and summer snowmelt, their abiotic and biotic Hg concentrations may be affected by the area of the catchment and lake. As in lower latitude systems, chemical or biological features such as dissolved organic carbon (DOC), pH, and the feeding ecology of an organism may also affect Hg uptake and transfer through lake food webs. This study is comparing Hg concentrations in the food webs of six lakes on Cornwallis Island, Nunavut, each with differing physical and chemical features. For example, lake areas, DOC, and chlorophyll a concentrations range between 0.13-1.3 km^2, 0.59 -2.08 mg/L, and 0.05-1.10 µg/L, respectively. The lakes were sampled repeatedly for sediments, invertebrates, and char (August only) during and after the annual spring melt in 2010. Water samples were also collected weekly from each lake to assess temporal changes in Hg concentrations. All samples were analyzed for methyl Hg (MeHg) and total Hg (THg) and the food webs were characterized using stable isotopes; nitrogen isotopes are used to assess trophic level and carbon and sulfur isotopes are used to assess energy source. Mean THg concentrations (0.05-1.38 µg/g, wet wt) in char varied significantly between these lakes (Kruskal-Wallis p< 0.001). Analysis of stable isotopes in biota and MeHg of the lower-trophic-level biota and abiotic samples are ongoing. Preliminary water data show significant differences between several lakes in MeHg (0.01-0.16 ng/L) and THg (0.28-1.1 ng/L), with higher concentrations and percent MeHg in Meretta Lake, potentially due to local nutrient inputs and its higher productivity. Rates of Hg biomagnification through the food web will be quantified by regressing log MeHg versus nitrogen isotopes and these relationships will be compared against results from other studies. Multivariate analyses will be performed to determine the factors that best predict Hg concentrations in char. Results from this study will improve our understanding of the factors underlying the variability in fish and invertebrate Hg in High Arctic lakes and offer critical baseline information for future studies to assess how these systems are changing in response to climate change.

MP033 Evaluation of Hydro-climatic Drivers of Contaminant Transfer in Aquatic Food Webs in the Husky Lakes Watershed, Northwest Territories, Canada N. Gantner, Univ of Victoria, Dept of Geography; T. Prowse, F. Wrona, Water & Climate Impact Research Centre, Environment Canada; H. Hintelmann, Trent Univ, Environmental and Life Sciences; J. Reist, Freshwater Insitute, Fisheries and Oceans Canada. Climate change in the Arctic has the potential to affect mercury concentrations ([Hg]) in freshwater fishes. Mercury can accumulate in apex-predator fish muscle to concentrations exceeding those considered safe for subsistence consumption by humans. Fish species such as Lake trout are typical apex-predators of Arctic lakes and can be a significant source of food for local indigenous peoples. The influence of abiotic factors, which are climate influenced, and biological parameters on Hg accumulation in apex-predators are not well understood. Further, a good understanding of sources of Hg to and processes within water column and food webs is still lacking. Our study aims to investigate the interactions of cryosphere, food webs and Hg transfer in four freshwater systems in the Inuvialuit Settlement region (Canada). The selected Big, Yaya, Noell, and Husky Lakes systems represent a range of cryospheric and ecological characteristics, as well as Hg delivery (marine-, riverine- or freshwater-derived). We investigate how those characteristics affect Hg transfer and fractionation. Biotic and abiotic fractionation of Hg isotopes has recently been shown to occur in aquatic environments and Hg isotope ratios (IRs) are proposed as useful tool to elucidate processes and possibly sources of Hg. All lakes are frequented by the Inuvialuit communities Inuvik and Tuktoyaktuk for subsistence fishing. Sampling includes tissues from harvested fishes, non-target fishes, and food web compartments (periphyton, zooplankton, and benthos). Biological parameters of fishes (age, length, weight, diet) are recorded and invertebrates separated by species. Sample analysis includes total Hg (THg), monomethylHg (MeHg), and stable isotopes of carbon ($\delta^{13}C$), nitrogen ($\delta^{15}N$), and Hg ($\delta^{x}Hg$). Hg IRs are analyzed by multicollector inductively coupled plasma mass spectrometry (MC-ICP/MS). Hg mass independent fractionation (MIF; $\Delta^{199}Hg$) and mass dependent fractionation (MDF; ^{202}Hg) are calculated and evaluated against conditions in the water column, food web transfer and the potentially difference in Hg delivery. [THg] detected in harvested fishes will be compared to consumption guidelines. Food web transfer of MeHg will be evaluated against cryospheric conditions and related lake productivity. We will discuss our preliminary findings in the context of the currently emerging use of Hg IRs with particular focus on implications for future research efforts in a changing Arctic environment.

MP034 Influences of Ingestion Rate on Dietary Accumulation of Mercury in Tilapia (*Oreochromis niloticus*) and the Implications on Somatic Growth Dilution R. Wang, Section of Marine Ecology and Biotechnology, Division of Life Science, The Hong Kong Univ of Science and Technology (HKUST); W. Wang, Hong Kong Univ of Science and Technology. Dietary ingestion constitutes a major pathway for mercury (Hg) accumulation in freshwater fish, and so the ingestion rate (IR) may greatly influence the Hg bioaccumulation through its effect on Hg influx and other biokinetic processes. To explore the complex influence of IR, we conducted long-term bioaccumulation experiments by accurately controlling the IRs in the freshwater tilapia (*Oreochromis niloticus*). The dietary accumulation of both inorganic mercury (Hg[II]) and methylmercury (MeHg) in tilapia under different IRs was monitored over a period of 30 days by feeding the fish with uniformly radiolabeled crustaceans. The biokinetic parameters under various IRs were also concurrently determined. When the IR increased from 0.01 g g-1 d-1 to 0.12 g g-1 d-1, the dietary assimilation efficiency of Hg(II) in the tilapia decreased by 43% while the elimination rate increased by a factor of 1.8; both biokinetic changes slowed down the overall Hg(II) bioaccumulation. In contrast to Hg(II), the biokinetics of MeHg was not significantly influenced, but its bioaccumulation increased disproportionally with increasing IR. We then employed a biokinetic model to simulate the long-term mercury bioaccumulation patterns in tilapia at various IRs. The modeling results indicated that the growth effect could not be ignored in long-term accumulation process, that a rapid growth of fish driven by food availability could significantly reduce the MeHg concentrations in the tilapia. Under the tested condition in this study, a 2.6-fold higher IR could result in 1.7-fold reduction of the MeHg (but not Hg[II]) concentrations in fish primarily as a result of the high sensitivity of MeHg bioaccumulation to fish growth. Our results demonstrated for the first time the contrasting influences of fish feeding on the long-term bioaccumulation of Hg(II) and MeHg and that the somatic growth dilution was much more likely to occur for MeHg than for Hg(II).

MP035 Trophic Transfer Dynamics of Polychlorinated Biphenyls (PCBs) and Cyclic Volatile Methylsiloxanes (cVMS) in Lake Pepin, MN,

USA R.M. Seston, Dow Corning Corporation, Health & Environmental Sciences; D.E. Powell, Dow Corning Corporation, Health & Environmental Sciences, Dow Corning Corporation, Health & Environmental Sciences (C03101); D. McNett, Dow Corning Corporation, Health and Environmental Sciences; J.A. Durham, Dow Corning Corporation, Health & Environmental Sciences; P.W. Bradley, M.J. Zwiernik, Michigan State Univ, Dept of Animal Science. The bioaccumulation potential, or 'B', of a compound is one of the criteria used to classify substances as being PBT (persistent, bioaccumulative, and toxic) materials in the environment. Bioaccumulative substances are defined as substances that biomagnify within a food web. A compound is said to biomagnify when lipid-normalized concentrations of accumulated chemical residues in biological organisms increase with increasing trophic position. Based on this definition, the most relevant criterion for assessing a compound's 'B' potential is the trophic magnification factor (TMF), and the most conclusive evidence to demonstrate that a chemical substance biomagnifies is a TMF > 1. Previous research aimed to determine the 'B' potential of several cyclic volatile methylsiloxanes (cVMS) was conducted in Lake Pepin, Minnesota, USA and concluded that biomagnification of cVMS materials was not occurring. Rather, cVMS materials had TMF values that were < 1.0 (range 0.1 to 0.3), indicating that concentrations of cVMS materials decreased with increasing trophic level and that trophic dilution was occurring across the aquatic food web. The objective of the present study was to verify that Lake Pepin is appropriate for conducting TMF studies by evaluating the trophic magnification behavior of polychlorinated biphenyls (PCBs), which are considered legacy 'B' contaminants and whose environmental behavior has been extensively studied. A subset of moderate to heavily chlorinated PCB congeners were quantified in biota at various trophic levels and TMFs were calculated. As expected, TMFs for the selected PCB congeners were greater than 1, ranging from 1.5 to 5.1. These results suggest that Lake Pepin is appropriate for TMF studies and that the TMFs of < 1.0 for cVMS compounds in the same aquatic food web appear to be valid. Moreover, it has been suggested that TMFs may be improved in instances where there is limited environmental data by using a standardizing benchmark to calibrate trophic level assignments. When PCB 180 data from the present study were used to calibrate trophic level assignments in the aquatic food web of Lake Pepin, the TMFs of the cVMS materials were lower than the originally reported values. Thus based on this data, select PCB congeners behave as expected while cVMS do not appear to be bioaccumulative in Lake Pepin.

MP036 Measured Vegetation Uptake Factors for Selected Inorganics in Wetlands R. Devries, AMEC; T. Sorell, AMEC, Life Sciences; J. Robb, D. Cooke, AMEC. Plant uptake studies were conducted as part of a multi-phase ecological risk assessment in wetlands impacted by historic coal ash ponds. Co-located soil and plant samples (boneset, dewberry and birch leaves or cattail rhizomes) were collected and analyzed from locations near the source areas and from an identified Reference Area. Evaluation of mathematical relationships between soils and plant concentrations of selected coal combustion-related inorganics indicated minimal or no plant tissue increases in response to elevated soil concentrations or compared to background. Where plant tissue concentrations did increase in response to higher soil loading (such as for boron and molybdenum in cattail rhizomes and molybdenum in leaves), the increases were small and described by a log-log relationship in which the vegetation uptake factor (VUF) decreased with increasing soil concentrations, a pattern consistent with published models. This relationship reflects greatly reduced VUFs associated with higher soil levels. Thus the use of fixed VUFs in food chain modeling will typically lead to overestimates of the plant tissue concentrations, especially in areas of higher soil impact, and should be avoided. Overall, the generally flat relationship between wetland soil and plants indicates that plant uptake may be an insignificant or incomplete food chain transfer pathway.

MP037 Relationship Between Water Hardness and Toxicity of Major Anions: Implications for Water Quality Guidelines for Individual Anions and TDS J. Elphick, Nautilus Environmental; G. Gilron, Independent; B. Chalmers, Mining Association of BC; J. Baker, Nautilus Environmental; K. Bergh, All North Consultants; H. Bailey, Nautilus Environmental. Recent investigations have demonstrated that the toxicity of anionic components of total dissolved solids, including sulphate, chloride and nitrate, exhibit considerably elevated toxicity under soft water conditions compared with higher hardness conditions. This relationship appears to occur either as a result of competition by ions for uptake sites at biological membranes, or as a result of the effect of ions that contribute to hardness, in particular, calcium and magnesium, on the permeability of these membranes. The presence of major anions at elevated concentrations almost always co-occurs with elevated hardness, since dissolved anions are balanced by concentrations of cations, which include those constituting hardness. Thus, the interaction of water hardness on toxicological effects of anions is highly relevant in the context of evaluating environmental risk of total dissolved solids. This presentation summarizes the relationships that have been established between water hardness and toxicity of anions, and compares the relationships between anions to establish whether they result from similar mechanisms. The findings have relevance in the context of setting water quality guidelines for the individual anions, as well as for total dissolved solids.

MP038 Sensitivity of Gray Treefrog (*Hyla versicolor*) Embryos, Hatchlings, and Tadpoles to Sulfate and Chloride Exposure B.K. Williams, E.E. Little, H.J. Puglis, E.L. Beahan, USGS, Columbia Environmental Research Center. Identifying sensitive life stages is a critical step in understanding the toxicity of major ions to aquatic life. This need is especially great for infrequently tested organisms such as amphibians. Although amphibian larvae are commonly found in surface water habitats threatened by elevated sulfate and chloride levels, toxicity data are generally lacking, particularly for sulfate. In addition, there is inconsistent evidence that young larvae are the most sensitive aquatic life stage to major ion toxicity, as is often assumed. We are performing standardized 96-hour acute tests with gray treefrog (*Hyla versicolor*) embryos, hatchlings, and young tadpoles, in order to 1) estimate acute LC50 values for the anions sulfate (SO_4^{2-}) and chloride (Cl^-), and 2) identify any life-stage-associated differences in sensitivity to sulfate and chloride exposure. Results thus far indicate that gray treefrog embryos and hatchlings show comparable sensitivity to each of the tested anions, with LC50 values greater than 3200 mg/L for sulfate and greater than 2000 mg/L for chloride. The results of these multi-stage tests will inform the selection of appropriate life stages for future testing efforts, and will help ensure that resultant water quality guidelines are protective of amphibians.

MP039 Acute and Chronic Sulfate Toxicity to Select Freshwater Fish and Aquatic Invertebrates R. Consbrock, US Geological Survey, CERC, Toxicology; D.K. Hardesty, US Geological Survey; C.G. Ingersoll, USGS, Columbia Environmental Research Center; N. Wang, US Geological Survey, Columbia Environmental Research Center. State water quality standards for sulfate have been developed by Illinois and are being considered by other Midwestern states in the United States. These state standards were developed primarily with acute toxicity data. National acute or chronic water quality criteria have not been developed. The objective of this study was to generate acute and chronic sulfate (Na_2SO_4) toxicity data to select freshwater fish and aquatic invertebrates for the USEPA to develop the national criteria and for the states to refine the standards for sulfate. Test water were prepared by diluting well water with deionized water to a hardness of about 100 mg/L as $CaCO_3$ and a pH of about 8.3 (mg/L: Ca 28, Mg 10, K 1.0, Na 10, Cl 12, SO_4 19, and dissolved organic carbon < 1.0). Static renewal, acute toxicity tests were conducted with cladoceran (*Ceriodaphnia dubia*; 2-d exposure), midge (*Chironomus dilutus*; 4-d exposure), unionid mussel (*Lampsilis siliquoidea*; 4-d exposure), and fathead minnow (*Pimephales promelas*; 4-d exposure). Chronic toxicity tests were conducted with the cladoceran (7-d static renewal exposure with survival and reproduction endpoints), the midge (up to 41 d flow through exposure with survival, growth, and reproduction endpoints), the mussel and minnow (28- to 34-d flow through exposure with survival and growth endpoints). Preliminary results based on survival endpoint indicated that acute LC50s ranged from about 1,000 to 10,000 mg SO_4/L and chronic LC20s ranged from about 400 to 1,000 mg SO_4/L for the four tested species. Analyses of growth or reproduction data are ongoing. Further study is needed to evaluate the sensitivity of additional species (e.g., mayflies, oligochaetes) or the potential influence of water quality on the responses of test organisms to sulfate.

MP040 Physiological Effect of NaCl Exposure on the Larvae of Freshwater Mussels L. Nogueira, Federal Univ of Rio Grande – FURG, Instituto de Ciências Biológicas; S. Higgins, McMaster Univ; V.L. Loro, Federal Univ of Santa Maria; A. Bianchini, Federal Univ of Rio Grande – FURG; C.M. Wood, McMaster Univ; P.L. Gillis, Environment Canada – Canada Center for Inland Islands. The application and storage of road salts for winter

road maintenance (i.e., de-icing) is a major anthropogenic source of salt to fresh water environments. In Canada, it is estimated that 5 million tons of salt are applied each year. High chloride levels have also been measured in non-winter seasons. In southern Ontario, chloride level of 4 g/L has been reported during spring snow melt. Freshwater mussel larvae (called glochidia) have been shown to be very sensitive to salt, however the toxicological mechanism(s) involved in this sensitivity are unknown. Therefore, our goal was to evaluate physiological effects using environmentally relevant NaCl concentrations on *Lampisilis fasciola* glochidia. Mussel larvae were exposed to NaCl for 48 h. The gradients of exposure were created from the addition of NaCl (0.25 and 1.0 g/L) in the reconstituted hard water (control solution: 0.04 g/L Na and 0.0013 g/L Cl) and also from diluted control solution (0.01 g/L Na and 0.0005 g/L Cl). Following exposure, Na and Cl influx rates and whole body concentration of these ions were assessed as well the ability of the exposed larvae to close their valves, a measure of acute toxicity. Based on the results, glochidia have the ability to maintain Na and Cl influxes and whole body Na and Cl levels relatively unchanged in low exposure concentrations, but these levels increase at high NaCl exposure. The down-regulation of Na uptake in the 1.0 g/L exposure may involve a closing of Na channels. In contrast, glochidia are not able to maintain low Cl influx. The increase in mortality observed when the animals are exposed to high NaCl concentrations may occur due to Na and Cl accumulation and consequently ionoregulatory dysfunction. (Supported by the International Research Chair Program of the International Development Research Centre and the Canada Research Chair Program).

MP041 Comparative Sensitivity of *Centroptilum triangulifer*, *Ceriodaphnia dubia* and *Daphnia magna* to Standard Salt, TDS and Copper Toxicants J.M. Lazorchak, US Environmental Protection Agency, Office of Research and Development, USEPA Office of Research and Development, National Exposure Research Laboratory, USEPA, Molecular Ecology Research Branch; K. Hammer, The McConnell Group c/o USEPA Cincinnati; P. Weaver, The McConnell Group, c/o USEPA; B. Johnson, C. Nietch, USEPA Office of Research and Development; D. Funk, Stroud Water Research Center, ; D. Buchwalter, North Carolina State Univ. Development of methods for assessing exposure and effects of wastewaters from energy and mineral resource extraction operations on stream invertebrate species is important for establishing protective water quality criteria. *Centroptilum triangulifer* is a parthenogenetic mayfly occurring in depositional habitats of streams and rivers of the Eastern US and Canada. *C. triangulifer* is a relevant insect for monitoring water quality under laboratory and field conditions because of its short life cycle and unique mode of reproduction. In this study, multiple cohorts of *C. triangulifer* was reared using a standardized diet of three diatoms: *Mayamaea atomus* var. *permitis*, *Nitzschia* cf. *pusilla*, and *Achnanthidium minutissimum*. Percent survival (80+%) , fecundity measurements (1000+) and pre-egg laying weights were used as indicators of overall colony health and fitness over five generations. Comparative testing assessed the exposure sensitivity to $NaHCO_3$, standard salt reference toxicants KCl and NaCl, a metal reference toxicant, $CuSO_4$, currently used in EPA's acute and chronic Whole Effluent Toxicity manuals, and a TDS recipe. Sensitivity tests were run simultaneously with *Ceriodapnia dubia* and *Daphnia magna* and were conducted for both acute and chronic endpoints. *C. triangulifer* was less sensitive to KCl but 2.8X more sensitive than other culture species to NaCl and $CuSO_4$. Acute $NaHCO_3$ results indicated *C. triangulifer* was slightly more sensitive than *C. dubia* and *D. magna*. Chronic results suggested *C. triangulifer* may be 8X more sensitive to NaCl than *C. dubia* and 16X more sensitive than *D. magna*. These and other comparative toxicity results will be presented.

MP042 Methods Development for a Spatially Explicit Population-level Risk Assessment, Uncertainty Analyses, and Comparison with Risk Quotient Approaches S. Raimondo, United States Environmental Protection Agency, Gulf Ecology Division, National Health and Environmental Effects Laboratory, US Environmental Protection Agency, Gulf Ecology Division; J. Awkerman, US Environmental Protection Agency, Gulf Ecology Division; B. Hemmer, US Environmental Protection Agency; M.G. Barron, USEPA, Gulf Ecology Division. The standard framework of Ecological Risk Assessment (ERA) uses organism-level assessment endpoints to qualitatively determine the risk to populations. While organism-level toxicity data provide the pathway by which a species may be affected by a chemical stressor, they neither indicate the probability that an effect (i.e., reduced survival, reduced reproduction) will impact the population in a natural system, nor the magnitude of that impact. Population models have the potential to be used in risk characterization; however they are not applied in ERA because uncertainty analyses and minimum data requirements are unknown. To quantify uncertainties in risk estimation (e.g., confidence in parameter estimation), we will apply spatially explicit population models of the sheepshead minnow (*Cyprinodon variegatus*) in a case study risk assessment of the Deepwater Horizon Oil Spill in Barataria Bay, LA. Sediment samples were collected throughout Barataria Bay in the fall of 2010 and will provide an interpolated, quantitative layer of PAH exposure to estuarine organisms. We will conduct full life cycle sediment toxicity tests to obtain chronic dose response functions for the sheepshead minnow exposed to PAHs. Exposure and concentration response layers will be applied to a spatially-explicit, density dependent sheepshead minnow population model. We will conduct several levels of ERA of varying complexity, including a traditional ERA using standard risk quotient based approaches, a simple non-spatial population-level ERA, and spatial population-level ERAs of varying complexity. Uncertainty analyses of each ERA will identify the relationship between ERA complexity, uncertainty, and data requirements.

MP043 Biological Community Monitoring to Evaluate Pulp and Paper Discharge Relocation Success and Effects in the Lower St. Johns River Basin, FL O. Burgess, Univ of Florida, Fisheries and aquatic Sciences, Environmental Resource Consultants; T. Gross, Environmental Resource Consulting, Dr. Timothy S. Gross, Univ of Florida; S. Holm, Georgia-Pacific Corporation, Environmental Affairs. Long-term (1999-2008) assessments of Georgia Pacific's Palatka Mill and biological effects have demonstrated that mill upgrades resulted in reduced biological responses. Results indicate that "masculinization" responses in *Gambusia* are not an appropriate model for assessing effects, while largemouth bass are a viable model to assess effects. The final stage in these long-term mill upgrades will be the relocation of discharge from Rice Creek to the St. Johns River. To evaluate the success and potential biological effects of this relocation a "Plan-of-Study" has been developed focusing on biological community monitoring for two years pre and post relocation. Biological community assessments include evaluations across multiple trophic levels: algae, plankton (phyto and zoo), submerged aquatic vegetation, macroinvertebrates, and fish. Efforts also include a long-term utilization of largemouth bass to assess reproductive, endocrine and health effects. Community assessments focus on levels of biological organization above the organism while evaluations of largemouth bass focus on levels at the organism and below. These efforts are among the first to utilize and apply NCASI's Large River Monitoring Program success and procedures to an evaluation of mill discharge relocation. Efforts have required modification of standard procedures which were developed for wadeable streams. It has also been critical to assess seasonal and annual variance and characterize habitat variance which must both be exceeded to detect effects. Pre-planned comparisons have been established for subsequent analyses. Results indicate similar biological diversity across the 20 km study range (10 km north and south of proposed discharge relocation site). Higher trophic levels have greater diversity due to co-occurrence of marine and freshwater species. Significant effects of record winter cold temperatures, drought, storm events and algal blooms have indicated effects at the community level. Evaluations of biological community effects are likely a critical component in a final assessment of mill discharge relocation, especially when paired with assessments of organism effects.

MP044 Investigation of Estrogenic Effects of Bifenthrin in Rainbow Trout, *Oncorhynchus mykiss* N. Riar, D. Schlenk, Univ of California, Environmental Toxicology. Pyrethroids are a commonly used class of pesticide in California in both agricultural and urban applications. Although pyrethroids are reported as having nominal effects in mammals, they have been shown to have toxic effects in aquatic organisms, especially invertebrates and fish. Their persistence in waterways due to their multitude of uses, require that chronic exposure and effect must be investigated. This study examines Bifenthrin, a third generation pyrethroid that has been seen in levels as high as 73 ng/L in northern California waterways. It is similar to another pyrethroid, Permethrin, which has been shown to have estrogenic activity at concentrations as low as 10 ug/L. Exposures were performed with Rainbow trout (*Oncorhynchus mykiss*) for 10 days at 0, 10, 50, and 150 ng/L. At the end of the experiment, plasma was collected and vitellogenin protein was semi-quantified using Western Blots. Preliminary data showed 33, 29, 40, and 42 ng vitellogenin per mg protein in fish exposed to 0, 10, 50, and 150 ng/L concentrations respectively. This suggests that Bifenthrin

and/or its metabolites result in estrogenic activity in Rainbow trout. Further studies will isolate the specific source of estrogencity. Also, additional factors that may further enhance these effects, including increased salinity in the exposure media, will also be investigated. The results of this study will aid in understanding the synergistic effects of global climate change and low concentrations of persistent pesticides. Such information is essential for understanding the chronic toxicity to important salmonid species in the delicate estuarine ecosystems of northern California.

MP045 Changes in a Common Biomarker (Vitellogenin) Do Not Correlate to Higher-level Reproductive Responses in Mummichog Exposed to 17α-ethinylestradiol T. Bosker, Univ of New Brunswick, Canadian Rivers Institute; K. Munkittrick, Univ of New Brunswick, Canadian Rivers Institute, Univ of New Brunswick, Dept of Biology; A. Lister, Wilfrid Laurier Univ; D. MacLatchy, Wilfrid Laurier Univ, Canadian Rivers Institute, Wilfrid Laurier Univ, Dept of Biology. A recent meta-analysis on short-term reproductive tests demonstrated that there are quantitative relationships between commonly-used biomarkers and egg production, a functional endpoint which can be linked to population-level effects. These relationships were found regardless of fish species or contaminant mode of action. In the current study we investigated the response of mummichog (*Fundulus heteroclitus*), a small-bodied estuarine fish species found along the Atlantic coast of North-America, when exposed to the potent estrogen 17α-ethinylestradiol (EE_2). Fish were exposed in three experiments in a flow-through system to nominal concentrations ranging from 0ng/L to 3,000ng/L EE_2. In the first two experiments, fish were exposed to a concentration series of EE_2 to determine the effect on relative gonad size and functional endpoints. No changes in gonad size or egg production were found even when mummichog were exposed to very high levels of EE_2 (up to 3,000ng/L) for prolonged periods of time (28d). However, low sample size and high variance resulted in low power to make conclusions. In the third experiment, fish were exposed to 100ng/L EE_2 using an optimized adult fish reproductive test study design. No effects of EE_2 on gonad size or egg production were observed while a >35-fold increase in hepatic vitellogenin gene expression ($p< 0.001$) was found. This study demonstrates that fish exposed to high levels of a potent estrogenic compound can respond to a common biomarker without correlating responses in functional endpoints. It is important to be cautious in linking biomarker responses to functional responses without strong species-specific data to support the connection.

MP046 Environmental Influences on the Accumulation of Ethynylestradiol in Marine Teleosts T. Blewett; D. MacLatchy, Wilfrid Laurier Univ, Canadian Rivers Institute, Wilfrid Laurier Univ, Dept of Biology; C. Wood, McMaster Univ, Dept of Biology. The synthetic estrogen 17-α-ethynylestradiol (EE2), an endocrine disruptor originating from birth control and hormone replacement therapy, is discharged in wastewater treatment plant (WWTP) effluents. The present study employed radio-labeled EE2 to examine the impact of temperature and salinity on the uptake of EE2 in male killifish (*Fundulus heteroclitus*). Fish were exposed to a nominal concentration of 100 ng/L EE2 for 2 h. Actual concentrations were lower due to EE2 adsorption to the exposure system, but uptake rates were normalized to 100 ng/L. Oxygen consumption rates (MO_2), whole body EE2 uptake rates, and tissue-specific EE2 distribution were monitored. EE2 uptake by freshly killed fish was negligible. In killifish acclimated to 18^{O}C at 16 ppt (50 % seawater), MO_2 and EE2 uptake were both much lower after 24-h exposure to 10^{O}C and 4^{O}C, and increased after 24-h exposure to 26^{O}C. Transfer of killifish to fresh water for 24-h tended to lower EE2 uptake rate, and long-term acclimation to fresh water reduced it by about 70 %. Long-term acclimation to 100 % sea water (32 ppt) also reduced EE2 uptake rate by about 50 % relative to 16 ppt. However, this was not seen in rainbow trout (*Oncorhynchus mykiss*) where uptake rates were the same in FW- and 16 ppt-acclimated trout. The tissue-specific accumulation of EE2 was found to be the highest (40-60 % of the total) in the liver plus gall bladder across all exposures, and the great majority of this was in the bile in killifish, regardless of temperature or salinity, whereas in trout accumulation was the highest in the carcass at 70 % of the total. The carcass was the next highest accumulator (30-40 %) in killifish, followed by the gut (10-20 %) with only small amounts in gills and spleen. Drinking rate, measured with radio-labeled polyethylene glycol-4000, was about 25-times greater in 16 ppt-acclimated killifish relative to freshwater-acclimated animals. However, drinking accounted for less than 30 % of gut accumulation, and therefore a negligible percentage of whole body EE2 uptake rates. In general, there were strong positive relationships between EE2 uptake rates and MO_2, suggesting similar pathways for uptake across the gills of these lipophilic molecules. These data will be useful in developing a predictive model of how variations in key environmental parameters (salinity, temperature, dissolved oxygen) affect EE2 uptake in estuarine fish, to determine optimal timing and location of WWTP discharges.

MP047 Understanding Effects of Salinity on 17α-ethynylestradiol (EE2) Uptake and Effects in Mummichog (*Fundulus heteroclitus*) D. MacLatchy, Wilfrid Laurier Univ, Canadian Rivers Institute, Wilfrid Laurier Univ, Dept of Biology; T. Blewett, McMaster Univ, Dept of Biology; T. Bosker, Univ of New Brunswick, Canadian Rivers Institute; E. Gilio Meina, Wilfrid Laurier Univ, Canadian Rivers Institute; T. Nadon, A. Lister, Wilfrid Laurier Univ; L. Bragg, Univ of Waterloo; S. Currie, Mount Allison Univ, Dept of Biology; K. Munkittrick, Univ of New Brunswick; M. Servos, Univ of Waterloo; C. Wood, McMaster Univ. We have undertaken a series of experiments exposing the mummichog or killifish (*Fundulus heteroclitus*) to 17α-ethynylestradiol (EE2) at a range of concentrations and salinities. The overall goals of the experiments are to elucidate whether salinity of exposure impacts EE2 uptake and/or effects in this small-bodied, euryhaline fish species. Compared to other model fish species tested, mummichog have a high resistance to the endocrine-disrupting effects of environmentally-relevant concentrations of EE2. EE2 uptake in mummichog significantly changed with salinity (0ppt < 32ppt< 16ppt) with the highest EE2 accumulation (60%) in the liver (including gallbladder). Over repeated exposures of 14-28 days, no effects of EE2 on gonad size or egg production were observed while increases in hepatic vitellogenin (vtg) induction were consistently found. Vtg induction in male mummichog was approximately 10-fold greater in fish exposed to EE2 at 16ppt salinity compared to fresh water ($p< 0.001$). Regardless of salinity (0, 16, 32 ppt), use of steroidogenic precursors in in vitro ovarian incubations decreased 17β-estradiol production at various points in the steroidogenic pathway before, at and downstream of cholesterol conversion to pregnenolone. Increases in ovarian testosterone production in vitro were variable and indicate decreases in aromatase could be a dominant factor affecting 17β-estradiol production. Overall, salinity does not appear to be influencing effects of EE2 on reproduction but does affect uptake and some molecular- and tissue-level endocrine responses. The high degree of EE2 accumulation in the liver and bile could indicate that metabolism and clearance participate in the resistance of mummichog to environmentally-relevant levels of EE2. Studies to understand the interactions of temperature, salinity, uptake, metabolism and effects are underway.

MP048 Development of a Complete Life Cycle Sediment Toxicity Test for the Sheepshead Minnow (*Cyprinodon variegatus*) E. Degner, Gustavus Adolphus College; B. Hemmer, US Environmental Protection Agency; H. Rutter, Student Services Contractor to USEPA; C.R. Jackson, US Environmental Protection Agency; M.G. Barron, USEPA, Gulf Ecology Division; S. Raimondo, United States Environmental Protection Agency, Gulf Ecology Division, National Health and Environmental Effects Laboratory, US Environmental Protection Agency, Gulf Ecology Division. Existing sediment toxicity test methods are limited to acute and chronic exposure of invertebrates and acute exposure of vertebrates, with limited guidance on the chronic exposure of vertebrates, specifically fishes. A series of life stage-specific studies were conducted to determine optimal test conditions for exposing the sheepshead minnow (*Cyprinodon variegatus*) to contaminated sediment throughout its complete life cycle. Specifically, these methods will be used to expose fish to oil-contaminated sediment collected from Barataria Bay, LA. Reference sediment used in these studies was collected from a marsh habitat in Choctawhatchee Bay, FL and had similar grain size characteristics as Barataria Bay. The hatching success of the egg stage was tested in well plates of various sizes (6, 12, 24 wells) with various amounts of sediment under stagnant and agitated conditions. Test chambers for larvae, juvenile and adult stages were developed to accommodate dissolved oxygen and fish density demands, minimize ammonia accumulation, and represent realistic estuarine exposure conditions. Larvae were exposed in static conditions, while studies were conducted to compare static and flow through exposure for juveniles and adults. Comparisons among flow through and static conditions included flow rates and types (pulse, continuous). Studies were also conducted to develop methods to collect spawned eggs from test chambers to determine hatch success of next generation embryos. These test development methods can be used as guidance for future life cycle sediment exposure studies involving fishes.

MP049 Waterborne Zinc Effects at Different Salinities on Oxidative Stress Parameters and Antioxidant Response of the Killifish (*Fundulus heteroclitus*) V. Loro, McMaster Univ, Biology Dept; C. Wood, McMaster Univ, Dept of Biology. We evaluated the effect of waterborne zinc exposure at different salinities on oxidative stress parameters and antioxidant response in *Fundulus heteroclitus*. Killifish were exposed to 500 μgL^{-1} of zinc (96h) at 0%, 10%, 30% and 100% sea water, considering 35 ppt as 100%. Fish exposed to zinc at salinities of 0% and 10% had increased reactive oxygen species (ROS) in gill, liver, intestine and muscle tissues. However exposure to zinc at 30 and 100% salinities resulted in ROS levels similar to control. The total oxidative scavenging capacity (TOSC) was quantified. For gill liver and intestine exposed to zinc and salinities of 0% and 10%, TOSC was decreased. However fish exposed to zinc and salinities of 30% and 100% recovered TOSC. Muscle tissue showed TOSC decreased for zinc exposure at 0% sea water; the other salinity groups and zinc exposure showed levels of TOSC similar to control. Regarding the antioxidant enzymes, superoxide dismutase (SOD) activity was reduced only in the group exposed to zinc 0% sea water. Increased SOD was observed in zinc exposed fish at salinities of 30 and 100%. The activity of catalase showed reduce activity in zinc exposed fish at salinity 0% and no change in other salinities. Glutathione-S-transferase (GST) activity increased in all fish tissues exposed to zinc at salinities (10% until 100%). Only at 0% salinity did zinc exposed fish exhibit reduced activity in liver, intestine and muscle. Glutathione (GSH) lshowed reduced levels for all tissues tested in fish exposed to zinc at 0% salinity. The other salinities exposed to zinc increased this parameter. Our results improve understanding of zinc toxicity in estuarine fish, and highlight the protective role of higher salinities in ameliorating the oxidative stress associated with zinc toxicity. (supported by IRC program of IDRC/CRC (Canada); NSERC CRD Program, ILZRO, ICA, CDA, NiPERA, Teck, & Vale)

MP050 HSP70 Expression as a Biologically Significant Biomarker of Fish Health Under Field Conditions D. Webb, Curtin Univ, Environment and Agriculture; M. Gagnon, Curtin Univ, Dept of Environment and Agriculture, Curtin Univ (Bentley Campus), Dept of Environment and Agriculture, Curtin Univ, Environment and Agriculture. Heat shock protein 70 (HSP70) levels in three tissue types (gill, liver and muscle) from black bream (*Acanthopagrus butcheri*) collected in a highly variable estuarine environment were measured to determine which tissue provides better inter-site discrimination. The usefulness of hsp70 expression to identify anthropogenic stress under field conditions was evaluated. Inter-site differences were detected in HSP70 levels in gill and white muscle of black bream while liver showed no spatial difference. There was high inter-fish variability in HSP70 levels in each tissue group. A post-hoc power analysis of the data sets for each tissue found that in black bream, white muscle provided the best discriminatory power to elucidate spatial variability. Only 11 fish are needed to be sampled under field conditions to identify inter-site differences when using white muscle tissue to obtain a power of 80%, while gill tissue requires at least 14 fish to be sampled and liver needs over 20 fish to reduce the chance of a type II error. Due to a high variability observed between tissues and between individuals, field measurement of hsp70 should be complemented by evidence of changes to metabolic enzyme activity, DNA damage, and/or blood cortisol levels. As part of a suite of measurements, hsp70 expression has some value as a biomarker of fish health.

MP051 Comparative Study of Reproductive Capacity and Oxidative Stress in Blueback Herring in North Carolina P. McClellan-Green, North Carolina State Univ, Ctr for Marine Sciences & Technol. Recent stock assessments by the North Carolina Division of Marine Fisheries (NCDMF) for blueback river herring has established the species as depleted in northeastern North Carolina. Data collected by NCDMF indicate that the spawning stock biomass of bluebacks are declining, that juvenile production in the river system is low and that the mean body length compared to age for the stock is significantly reduced. While each of these factors is related to over harvesting of the population they can also be indicative of anthropogenic impacts on the reproductive physiology of the species. Environmental and anthropogenic factors such as temperature, oxygen levels and pollution can increase the stress experienced by fish inhabiting these environments and thus affect their reproductive capacity (or fecundity). In 2010, a study initiated examining the temporal changes in reproductive potential and oxidative stress of blueback river herring in the Chowan River. Blueback herring were collected each week during their spawning season for a total of 8 weeks. Analysis of physiological parameters indicate their reproductive potential is highest during the initial three weeks of spawning and decreases as the season continues. Levels of steroid hormone, 11-ketotestosterone and estradiol, were also monitored on a weekly basis. Reproductive parameters were then compared to levels of oxidative stress, for example glutathione, LPO and catalase activity. Our results indicate that oxidative stress increases up to the peak spawning period and then declines as the fish enter their regenerative phase. These results could have distinct implications for monitoring of oxidative stress in field studies.

MP052 Acute Effects of Aniline on Two Estuarine Species, *Palaemon serratus* and *Pomatoschistus microps*: Effects on Biomarkers and Swimming Velocity L. Luis, Univ of Porto, CIIMAR & ICBAS; L. Guilhermino, Univ of Porto, CIIMAR & ICBAS, Laboratory of Ecotoxicology, Univ of Porto, ICBAs & CIIMAR, Universidade do Porto. Aniline is one of the Hazardous and Noxious Substances (HNS) transported at highest amounts by sea and thus concerns existing regarding potential accidents resulting in spillages of this substance in the marine environment. It is also commonly used in several industrial activities and thus is an environmental contaminant in several regions, including estuaries. Since the existing information on its toxic effects on estuarine organisms is still scarce, more knowledge is need particularly on benthic species with an ecologically important function. Thus, to contribute to the question, the acute effects of aniline on two benthic species with ecologically relevant functions in a considerable number of European estuaries were investigated. For each species, 96h semi-static bioassays were carried out with animals being exposed individually to aniline through water in temperature and photoperiod controlled rooms. At the end of the exposure period, swimming velocity and several biomarkers were determined. Aniline was found to be able to decrease swimming velocity of animals and to induce changes in several biomarkers. The ecological implications of these findings are discussed. This study was done in the scope of the project "RAMOCS – Implementation of risk assessment methodologies for oil and chemical spills in the European Marine Environment" (ERA-AMPERA/0001/2007), funded by the Portuguese Foundation for the Science and the Technology (FCT) and FEDER funds in the framework of the EU AMPERA ERA-NET (ERAC-CT2005-016165). L. Luís has a grant from FCT (SFRH/BI//51043/2010).

MP053 Histological Studies in Fish for the Monitoring of POPs in Mexico X. Guzman-Garcia, I. Hernandez-Calderas, C. Garcia Gonzalez, V. Ramirez Trejo, J.E. Torres Padilla, J.G. Trejo Ramirez, Universidad Autonoma Metropolitana, Hidrobiologia; P. Ramirez Romero, Universidad Autonoma Metropolitana, Hidrobiologia, U.A.M. Iztapalapa, Depto. De Hidrobiologia. Environmental monitoring of POPs is mostly based on chemical concentrations in the different environmental compartments, including organisms. However, these measurements can't provide information regarding bioavailability and effects of these compounds, therefore the National Monitoring Program (PRONAME by its Spanish acronym) decided to include histopathology analysis in fishes. The objective of this works is to present the results of the comparison of theee PRONAME sites: Yaqui Valley in Sonora (with a strong agricultural influence), Manantlán in Jalisco and Celestún in the Yucatan Peninsula (this last two as reference sites). Samples of carps, mullets and cat fish were collected at the PRONAME sites and brought to the laboratory for histological analysis. Liver, pancreas and intestine tissues were processed in Leica instruments (tissue processor TP 120, inclusion center EG1140H coupled with a chillin plaque EG1140C), three serial 5 µm cuts were obtained with a microtome and stretched in a 50 oC bath. These were HE stained and analyzed under optical microscope. Results showed that carps from Manantlan, a Biosphere Reserve, have few lesions; however catfish from Celestun presented the highest incidence of lesion of the three sites, which was an unexpected results since this site is also a Biosphere Reserve, however this result agreed with chemical analysis, in the sense that more POPs have been reported for this site. Sonora mullets presented an intermediate incidence of lesions in spite of having been captured in coastal water bodies that receive the drainage of the agricultural area.

MP054 Temporal Trend Analysis of Polychlorinated Biphenyls and Organochlorine Pesticides in the Great Lake Fish, 1999-2009 F. Chang, Clarkson Univeristy, Civil and Environmental Engineering; T.M. Holsen, Clarkson Univ; P.K. Hopke, Clarkson Univ, Dept of Chemical Engineering; B. Crimmins, Clarkson Univ; J.J. Pagano, State Univ of New York-Oswego, Environmental Research Center; M.S. Milligan, SUNY Fredonia, Dept of Chemistry. Temporal trend analysis of the newest Great Lake Fish

Monitoring and Surveillance Program (GLFMSP) data showed a statistically significant decrease of persistent bioaccumulative toxic contaminants in Lakes Huron, Ontario, and Michigan over the 1999-2009 period. In contrast, trend analysis showed only minor fluctuations or relatively stable levels in Lakes Superior and Erie during the same period. For the three lakes showing a decrease the average annual decrease of total polychlorinated biphenyl (PCBs) concentrations was 5.0 ± 2.6%. Dichloro-diphenyl-trichlorethane and its metabolites (DDTs), dieldrin, and other organochlorine pesticides showed faster decreases, ranging from 10 ± 4.3% to 20 ± 7.1% per year. With the exception of PCB levels, this current decrease was greater than was shown by an earlier trends analysis which estimated an annual contaminant decrease of about 2-5% for the 1980-2003 period. Our trend analysis of PCBs decrease in Great Lakes fish ranging from 3-8% per year in 1999-2009 agrees well with the reported 3-10% decrease per year in other Great Lakes environmental media. Additionally, characteristics of PCB congener profiles were analyzed within lakes and among lakes fish samples to explore PCBs sources to Great Lakes fish.

MP055 Monitoring for Hydrophobic Contaminants in Urban-impacted Nearshore Waters of the Great Lakes Using Polyethylene Passive Samplers P.A. Helm, Ontario Ministry of the Environment, Environmental Monitoring and Reporting Branch; A. Muscalu, E. Reiner, L. Shen, T. Kolic, A. Tencic, A. Boden, K. MacPherson, D. Morse, Ontario Ministry of the Environment. Urban areas are significant contributors of environmental contaminants to adjacent waterways through atmospheric contributions, direct stormwater discharge, urban tributary inputs, and municipal wastewater discharges. The wide variety of chemicals present in these areas represent both the legacy of past-use of persistent, bioaccumulative and toxic industrial chemicals and pesticides, such as polychlorinated (PCBs) and organochlorine pesticides (OCPs), and of current-use chemicals related to use in consumer products, such as flame retardants, and continued combustion by-product compounds like polycyclic aromatic hydrocarbons (PAHs). In this study, passive polyethylene (PE) samplers were deployed in urban streams in the Toronto, Ontario area and in Lake Ontario in nearshore waters adjacent to urban areas from Hamilton Harbour in the west end of the lake to waters off Pickering, Ontario, east of Toronto. Lake sites included those influenced by municipal wastewater discharges and long term nearshore monitoring sites. PE sampler extracts were subjected to multi-dimensional gas chromatography (GCxGC)-electron capture detection (ECD), in addition to analyses for PAHs, polybrominated diphenylether (PBDE) and non-PBDE flame retardants. GCxGC-ECD provides excellent separation of target analytes with minimal coelution, and can also be used for analytical triage to screen for additional halogenated compounds. The GCxGC screening indicated the presence of a considerable number of compound classes at several stations, including chlorinated paraffins, PBDEs, chlorinated dibenzo-*p*-dioxins and dibenzofurans, as well as several unknown halogenated substances. The greatest concentrations, and number and diversity of substances, were observed in PE samplers deployed at locations more influenced by municipal wastewater and urban/industrial development, such as Etobicoke Creek and the Don River in Toronto, and Hamilton Harbour. In addition to presenting 2D chromatograms, the presentation will highlight estimated concentrations for legacy and current-use compounds.

MP056 Bioaccumulation of Selected Halogenated Organic Flame Retardants in Remote Lakes and in the Great Lakes D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, Environment Canada, National Water Research Institute; C. Teixeira, J. Epp, T. Young, X. Wang, M. Keir, S. Backus, Environment Canada. In this study the bioaccumulation and concentrations in surface waters of a wide range of non-legacy halogenated organic compounds (HOCs) was determined in remote lakes within the Canadian shield and in the open Great Lakes. Large volume samples of surface waters (100 L) were collected from two remote lakes Lake Opeongo (Algonquin Provincial Park, ON) and Siskiwit Lake (Isle Royale National Park, MI) as well as from surface waters of the lower Great Lakes over the period 2005-2010. Zooplankton (>100 um), mysids, forage fish and lake trout were obtained from Lakes Erie, Ontario and Opeongo while only lake trout were available from Siskiwit Lake. Extracts were screened for 27 individual BDEs (Br3-Br10) and 20 Br3-Br6 compounds/ PBDE replacements and other HOCs using GC-electron capture negative ion mass spectrometry (GC-EC NIMS) with a HP-5MS and RTX-1614 capillary columns. Br3-Br6 compounds and Dechlorane Plus (DP) were non-detect (< 0.1 pg/L) in Siskiwit and near detection limits in Opeongo lake waters. Pentabromo-ethylbenzene (PBEB), 1,3,5-tribromo-2-methoxy-4-methylbenzene (Br3MeBz), allyl 2,4,6-tribromophenyl ether (ATE) and dibromopropyl 2,4,6-tribromophenyl ether (DPTE) were the most prominent non-PBDE HOCs in Opeongo lake waters; present at sub-pg/L concentrations. A larger suite of HOCs were detectable in Lake Ontario waters including DP, Br3MeBz, PBEB, DPTE, 12345-pentabromobenzene (Br5Bz), penta- and hexabromotoluene, and 2-ethyl-1-hexyl 2,3,4,5-tetrabromobenzoate (EHTeBB) although concentrations were near or at MDLs. The tris-chloroalkyl phosphates (TCEP, TCPP, TDCP) were present at 5-50 ng/L in central Lake Ontario waters. A wide range of Br3-Br6 compounds were detected in zooplankton from Lake Ontario including Br3MeBz, 1,3,5-tribromobenzene (TBB), tetrabromoxylene (TBX), bis(tribromophenoxy)ethane (BTBPE), PBEB, and BPTE. Lake Opeongo zooplankton had a more limited suite, with Br3MeBz, ATE and Br5Bz present at low pg/g (wet wt) concentrations. BDE47, BDE153 and Br3MeBz had the highest trophic magnification factors based on the slope of the log (lipid wt) concentrations versus trophic level. TBX, 1,3,5-TBB and BTBPE showed trophic dilution while other compounds e.g., BDE202 (and other hepta- and octaBDEs) were detectable in most samples but showed limited increases with trophic level.

MP057 Organophosphate Flame Retardants and Benzothiazoles in Open Waters and Tributaries of the Great Lakes D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, National Water Research Institute; C. Teixeira, A. Sett, B. Lee, T. Peart, Environment Canada. Triaryl/alkyl phosphates/tris(haloalkyl) phosphates) (TAAPs/THAPs) and benzotriazoles (BTZs) are of interest as contaminants in Great Lakes waters because they are high production volume chemicals with relatively high log Kows and molecular structure indicative of slow biodegradation. Production of TAAP/THAPs is reported to have increased by 11% in the USA and 57% in Asia from 2005 to 2008 due to their use as replacements for the brominated flame retardants. BTZs are widely used as corrosion inhibitors, and in aircraft deicing fluids and as UV absorbers in polymers. All 3 classes are thus directly emitted to the environment via volatilization and abrasive losses from polymers and indirectly via poor removal in waste water treatment. TAAP/THAPs were extracted from 1L water samples using solid phase cartridges and then analysed by LC-MS/MS using positive Electron Spray Ionization (ESI+). Nine TAAP/THAPs were found in sewage treatment plant influent and effluent samples at low ng/L to mid µg/L levels, with tris-butoxyethyl-phosphate (TBEP) and tris-chloroalkyl phosphates (TCEP, TCPP, TDCP) present at highest concentrations. TBEP, TCEP, TCPP, and TDCP were also the major TAAP/THAPs at the 3 mid lake sites in of Lake Ontario (west, central and eastern basins) at

MP058 Perfluoroalkylated Compounds (PFCs) in Great Lakes Fish as Part of the Great Lakes Fish Monitoring and Surveillance Program (GLFMSP) B. Crimmins, X. Xia, P. Hopke, Clarkson Univ; M. Milligan, SUNY Fredonia; J. Pagano, SUNY Oswego; T. Holsen, Clarkson Univ. The Great Lakes Fish Monitoring and Surveillance Program (GLFMSP) was recently tasked with exploring non-legacy contaminant distributions in the Great Lakes' top predators. Perfluoroalkylated compounds are one such class of compounds and have received a significant amount of attention in the past decade. Previous quantifications have been hindered by interferences, ion suppression and lack of comprehensive quantitation and recovery standards. Interlaboratory comparisons have also shown significant variability among laboratories and procedures. While there is typically a trade-off between instrument sensitivity, specificity and quantitative linearity we have developed a method for PFCs using newly developed UPLC-QTOF technology addressing each of these concerns. The current platform describes the methodology, instrumentation specifications and performance evaluation of this method on Great Lakes' biota. In addition, concentrations in lake trout and walleye (Lake Erie) collected from 2004-2009 will be presented with an emphasis on spatial and temproal trends.

MP059 The Relative Sensitivity of Macrophyte and Algal Species to Herbicides and Fungicides: An Analysis Using Species Sensitivity Distributions J. Giddings, Compliance Services International. In January 2008, at a SETAC workshop on Aquatic Macrophyte Risk Assessment for Pesticides (AMRAP), a Species Sensitivity Distribution (SSD) working group was formed to address uncertainties about the sensitivity of *Lemna* and other standard test species to pesticides relative to other aquatic macrophyte

species. For 11 herbicides and 3 fungicides for which relevant and reliable data were found for at least 6 macrophyte species (considered the minimum for SSD analysis), SSDs were fitted using lognormal regression. The position of *L. gibba* in each SSD was determined. The sensitivity of standard algal test species relative to the macrophytes in each SSD was also considered (algae were not included in the SSD). In recognition of the known sensitivity of *Myriophyllum* species to some herbicides and ongoing activities to develop standardized test methods for these species, the position of *M. spicatum* in each SSD was also determined where data were available. Results indicated that *L. gibba* is among the most sensitive macrophyte species for approximately half of the chemicals examined. In the majority of cases, the lowest standard algal test species endpoint was lower than the most sensitive macrophyte endpoint. *M. spicatum* was among the most sensitive macrophytes for approximately one-quarter of the chemicals. While no single species consistently represents the most sensitive aquatic plant species, for 12 out of 14 compounds algae and *L. gibba* include an endpoint that is near or below the 5th percentile of the macrophyte SSD. For the other two compounds, *M. spicatum* is the most sensitive species of all aquatic plants considered. The AMRAP SSD workgroup includes Stefania Loutseti (DuPont, workgroup chair), Gertie Arts (Alterra), Nina Cedergreen (U. Copenhagen), Heino Christl (APC), Jo Davies (Syngenta), Michael Dobbs (Bayer CropScience), Mark Hanson (U. Manitoba), Udo Hommen (Fraunhofer Institute), Joy Honegger (Monsanto), Phil Manson (Cheminova), Giovanna Meregalli (Dow AgroSciences), and Gabe Weyman (Makhteshim-Agan).

MP060 Is the Sensitivity of Lemna and Lemna Endpoints to Metsulfuron-methyl Representative of Other Macrophyte Species and Endpoints? G.H. Arts, Alterra Wageningen Univ and Research Centre, Centre for Water and Climate, Environmental Risk Assessment; A. Jonas, E. Dorsman, Alterra Wageningen Univ and Research Centre. Is the sensitivity of Lemna and Lemna endpoints to metsulfuron-methyl representative of other macrophyte species and endpoints ? To investigate this topic, toxicity values were collected from laboratory tests with a range of macrophyte species (incl. Lemnaceae) and from literature. Laboratory experiments followed test methods under non-axenic, controlled conditions (21 days; 17°C; 14/10 light/dark regime; 400 W Philips HPI-T lamps; illumination 160 ± 65 µmol.m-2.s-1 at water surface level; 1.5 L glass test vessels; Barko and Smart growth medium; fine clay sediment; 3 apical, unbranched macrophyte shoots (10 cm) or 10 fronds of Lemnaceae; treatments 1 – 3300 ng/L metsulfuron-methyl). We plotted the resulting toxicity data and calculated log-normal distributions: I. Endpoint EC50 distributions of Lemnaceae at days 4, 7, 14, 21. II. Lognormal distributions including all macrophyte EC50 values. III. Lognormal distributions of all macrophyte EC50 values excluding the Lemnaceae toxicity values. The results show that despite the non-axenic nature of the tests, the sensitivity and variability of Lemna endpoints fitted well within published ranges. Variability is only larger at day 7. When considering all macrophyte EC50 values including Lemnaceae toxicity values, the distribution did not pass the Anderson-Darling goodness-of-fit test. However, when excluding the Lemnaceae toxicity values, the data did pass this test and fitted a log-normal distribution. This suggests that the distribution of toxicity values from Lemnaceae does not fit the distribution of toxicity values from submerged aquatic macrophytes. The range of macrophyte sensitivity is rather broad, with a 100 to 1000-fold difference between the most sensitive and least sensitive species and endpoint. Resulting HC5 values from distributions including all macrophyte endpoints are lower than published ones. HC5 values from distributions with Lemnaceae are within the ranges of published values. The representativity of Lemna and Lemna endpoints of other macrophyte species and endpoints very much depends on the endpoint considered. Root and new shoot endpoints are very sensitive endpoints for submerged aquatic macrophytes. Specific leaf area is a very sensitive endpoint for Lemnaceae.

MP061 The Little Plant that Could: 7 Years of Effluent Testing at Canadian Metal Mines L. Taylor, Environment Canada; R. Scroggins, Environment Canada, Ecotoxicology and Wildlife Health Division. Under the 2002 Canadian Metal Mining Effluent Regulations (MMER), there is a requirement to conduct an Environmental Effects Monitoring (EEM) program to evaluate the effects of mine effluent on local fish species, fish habitat and uses of fisheries resources. As part of this program, sublethal toxicity tests were conducted twice per year for the first three years for regulated mines and once per year in subsequent years. For a final discharge point at a mine, effluent testing needs to be conducted using a fish, an invertebrate, an aquatic higher plant and an algal species. The purpose of sublethal toxicity (SLT) testing in this context is to answer the question: "is there evidence from sublethal toxicity testing that mine effluent may affect fish, invertebrates and aquatic plants?" Specifically, effects data using standardized methods would provide an indication of the degree of variability in effluent quality and temporal trends. The Environment Canada biological test method for assessing the effects on macrophytes uses Lemna minor (EPS 1/RM/37) as the representative aquatic higher plant species. Toxicity data collected over 7 years (2003-2009) was reviewed for mines across Canada. A total of 660 individual Lemna tests revealed that an inhibition of growth (as seen by a reduction in frond number) is a sensitive endpoint for metal mine effluents; whereas the reduction in growth based on dry weight was less so. An improvement in effluent quality across Canada was evident from the first three years of monitoring (2003-2005) to the second three years (2006-2009), where the number of tests reported to have no effect (IC25 >100% or undiluted effluent) increased from 27 to 41%. The greatest improvement was seen with iron ore mines, followed by uranium and precious metal (e.g., Ag, Au, Pd) mines. Relatively small improvements were seen with base metal (e.g., Cu, Zn, Ni) and other mine types. An investigation was also completed into potential relationships between Lemna toxicity and regulated chemical parameters measured for compliance purposes.

MP062 Protection of Pollinating Species from the Effects of Pesticides: From Concerns to Protection Goals and Decision Making Criteria A. Alix, Ministry of Agriculture, DGAl – SDQPV – BRMMI, Ministry of Agriculture, DGAl – SPRSPP – SDQPV – BRMMI; M. Miles, Dow Agrosciences, Field Effects and Exposure. A global SETAC Pellston workshop was organized in January in Pensacola (FL) which aimed at bringing together the best available science regarding exposure and effects assessment methods for honey bees (*Apis mellifera*) and non-*Apis* bees. A review of existing regulatory texts, testing methodologies, risk assessments, scientific papers and monitoring data highlighted an important diversity in scientific knowledge. This indicated a need to identify scientific information and testing methodologies that are relevant for risk assessment and decision making purposes for pollinators which should be related to clearly defined protection goals. Ideally protection goals should be defined to be i) relevant with regard to the decision to be made; ii) justified in relation to up-to-date scientific knowledge; iii) consistent with regard to the level of protection; iv) harmonized within a specific legal framework; v) proportionate to the problem and vi) practicable i.e., reasonably easy to reach. With respect to these criteria the workshop sought to define protection goals for pollinating species which could be linked to assessment and measurement endpoints from studies. E.g., pollination may be easily recognized as a relevant protection goal for decision making that easily matches with most of the criteria. The protection of pollination implies the presence in the crop of pollinating species in sufficient abundance over the flowering period, as assessment endpoints. In the case of honey bees, it implies to protect colony survival and strength and for non-*Apis* species, to protect population size and persistence over time. Pollination is also identified as an ecosystem service and the need to protection both ecosystem services and the biodiversity of agricultural landscapes was recognized. Possible protection goals were established that can be considered further within countries and competent authorities based on their legal context. The important achievement of this workshop is to provide a basis to construct and define protection goals on a common knowledge and reasoning. This, for pollinators as for other areas of protection, will facilitate communication between countries and competent authorities, enable work sharing and achieve protection goals at a global scale.

MP063 Generic Problem Formulation for Assessing Pesticide Risks to Pollinators D.L. Fischer, Bayer CropScience, Global Development North America, Ecotoxicology, Bayer CropScience, Dept of Ecotoxicology; P. Delorme, Pest Management Regulatory Agency, Health Canada. As part of a Pellston Workshop, generic problem formulations for assessing risk to honey bees were prepared for two pesticide application scenarios: (1) foliar spray application of a non-systemic product and (2) application of a systemic product to seeds or soil. While not covering all scenarios of interest (for example, non-*Apis* species were not covered), these documents aided workshop participants in understanding the risk assessment process and the need to clearly identify up front the objectives and scope of the assessment. The PF also helped clarify the linkage between identified management goals, assessment endpoints, and measures of exposure and effects for both honey bee colonies and individual bees. Assessment and measurement endpoints,

conceptual models, risk hypotheses and analysis plans for each scenario will be presented.

MP064 Assessing the Comparative Risk of Plant Protection Products to Honey Bees, Non-target Arthropods and Non-*Apis* Bees M. Miles, Dow Agrosciences, Field Effects and Exposure; A. Alix, Ministry of Agriculture, DGAl – SDQPV – BRMMI, Ministry of Agriculture, DGAl – SPRSPP – SDQPV – BRMMI; V.J. Kramer, Dow AgroSciences, LLC. Risk assessments are conducted for plant protection products (PPP) with respect to potential impacts on non-target species. These include pollinators such as the honey bee but also to other non-target arthropods (NTA). In common with other areas of ecotoxicological risk assessment sentinel species are employed aiming at ensuring a high level of protection/conservatism. Tier I screening risk assessments are intended to rapidly exclude those substances which pose a low risk to non-target organisms and to focus resources on those for which a potential risk cannot be excluded and further studies may be undertaken to characterize the conditions and occurrence of risks. In the European Union a Hazard Quotient (HQ) approach is used to assess the risk to both honey bees non-target arthropods at Tier I. This is calculated by dividing application rate by the LR50 (Lethal Rate 50). In other regions such as North America, a contact toxicity trigger of 11 µg active substance/bee is currently employed. At the Pellston workshop it was suggested that for a risk assessment for sprayed products the honey bee could be a suitable surrogate species. However, to account for potential differences in the sensitivity between the honey bee as a test organism and other non-*Apis* bees a safety factor of 10 (for interspecies differences) was suggested. On the basis of ecotoxicological data of the European data sets for honey bees and NTA, the relative risk of PPP to NTA, honey bees and non-*Apis* bees, as depicted by HQ values is compared and where possible data on NTA pollinators (e.g., Syrphids) and non-*Apis* bees (e.g., Bombus sp.) are also included. At tier I using HQ trigger of 50 for honey bees, 2 for NTA, in accordance with the current EU legislation, and 5 (i.e., 50 divided by the extra factor of 10 abovementioned) for non-*Apis* bees, the NTA scheme identified more compounds and uses to move forward for further evaluation. The suggest non-*Apis* HQ trigger of 5 gave a similar pass, fail rate to the NTA scheme but was slightly confounded by a lack of determined end points. However, even taking this into consideration the most restrictive tier I assessment was that for NTAs. This poster examines the potential for a tier I risk assessment to cover NTA, honey bees, non-*Apis* bees and other arthropod pollinators as part of a tiered risk assessment scheme and compares the empirical HQ approach with methods using more specific species exposure estimates.

MP065 Review of Higher Tier Methods for Assessment of the Risk of Pesticides to Honey Bees M. Miles, Dow Agrosciences, Field Effects and Exposure; A. Alix, Ministry of Agriculture, DGAl – SDQPV – BRMMI, Ministry of Agriculture, DGAl – SPRSPP – SDQPV – BRMMI; V.J. Kramer, Dow AgroSciences, LLC. Risk assessment procedures have been developed for domesticated honeybees (*Apis mellifera*) potentially exposed to residues of insecticides. After initial tier I screening risk assessments further studies may be conducting for those substances for which a potential risk cannot be excluded. Higher tier studies are often performed in cages or tunnels containing colonies of honey bees which can forage on treated crops. Cage test are typically smaller in size than tunnels but allow for the testing of more treatments often with more replication than can be offered by the larger scale tunnel tests. Field tests can be conducted to establish the effects of the product under more realistic conditions but due to use of free flying colonies there is less control than in the tunnel and cage studies. Finally, post-registration monitoring can offer additional information on specified uses of the product under commercial conditions and can be used to give feedback on the outcome of the risk assessment and the effectiveness of any risk management practices put in place to protect bees. This paper will review the various higher tier methods with respect to their ability to accurately predict the potential effects of pesticides to honey bees and how they can be employed in a robust risk assessment. The range of parameters investigated typically include; mortality, foraging, behavior, brood and colony development. The ability of higher tier studies to predict potential adverse effects will be evaluated and how these parameters can be employed in a risk assessment with clear decision making linked to honey bee and pollinator protection goals.

MP067 Movement of Soil-Applied Systemic Insecticides into the Pollen and Nectar of Squash: Are Concentrations High Enough to Impact Pollinators? B. Eitzer, Connecticut Agricultural Experiment Station, Analytical Chemistry Dept; K. Stoner, Connecticut Agricultural Experiment Station. There has been much recent interest in the threat to honey bees and other beneficial insects posed by the use of pesticides. In particular, there is a concern that systemic insecticides can translocate from the soil into pollen and nectar of plants, where they are then liable to be ingested by pollinators. We report here on the movement of two such systemic neonicotinoid insecticides, imidacloprid and thiamethoxam, into the pollen and nectar of flowers of squash (Cucurbita pepo cvs. "Multipik," "Sunray" and "Bush Delicata"). The insecticide treatments were within labeled rates for these compounds, either after soil application before seeding, or, by a single application through drip irrigation after transplant. Pollen and nectar were collected during the subsequent growing season. Pollen and nectar samples were analyzed utilizing a QuEChERS extraction protocol and liquid chromatography mass spectrometric analysis. With the mass spectrometer operated in a positive ESI-MS/MS mode. The concentrations found in nectar (mean ± s.d : 10 ± 3 ppb for imidacloprid; 11 ± 6 ppb for thiamethoxam and pollen (14 ± 8 ppb for imidacloprid; 12 ± 9 ppb for thiamethoxam) are at the high end of the previously documented ranges for these compounds in these matrixes. These concentrations fall into the range being investigated for sublethal effects on honey bees and other beneficial insects and are therefore of potential concern.

MP068 Field Investigation of the Safety to Honey Bees of Applications of Movento® Insecticide to Citrus During Bloom R.E. Rogers, Bayer CropScience, LP, Ecotoxicology; D.L. Fischer, Bayer CropScience, Global Development North America, Ecotoxicology, Bayer CropScience, Dept of Ecotoxicology; G. Williams, Dalhousie Univ, Dept of Biology. The Asian citrus psyllid (*Diaphorina citri*) is probably the single greatest insect threat to the global citrus industry. *D. citri* transmits the bacteria responsible for Huanglongbing (HLB), or citrus greening disease, which causes premature defoliation, poor fruit production, and eventual death of trees. Movento® (a.i., spirotetramat) is a unique two-way systemic foliar insecticide that is effective in controlling psyllid. Movento is relatively non-toxic to many beneficial arthropods, including adult honey bees, however there were questions whether it might cause toxicity to bee larvae and as a result affect bee colony survival if sprayed during bloom. To address this question, a field trial was conducted in 2009. Twelve colonies were obtained from cooperating commercial beekeepers were placed at the edge of each of two Sweet orange, *Citrus sinensis* (variety Hamlin) groves in Pasco County, FL at the start of bloom and removed after bloom finished. One grove received a single application of Movento at full label rate of 10 oz/ac (730 ml/ha) and the other received no treatments. Colonies were assessed over a 6-mos period post-application for strength and health (i.e., adult and brood populations, food stores, pests, and diseases), and pollen, honey and wax samples were collected and analyzed for presence of residues of spirotetramat and other pesticides. There were no statistically significant differences in any measurements, including colony strength and health, brood success, hive weight change, and intra-hive mortality. Colony health of both the treatment and control groups started declining in July and by the end of the study, 25% and 42 % colony mortality had occurred in the treatment and control groups respectively. At the time of study termination, many of the living colonies of both groups were in a weakened state and in the process of collapsing. All colony losses could be attributed to biotic factors including Varroa, deformed-wing virus, Nosema, queen loss, and co-infections. Residues of spirotetramat and its enol metabolite in bee-collected nectar and pollen peaked shortly after application and were < 0.04 ppm in bee-collected nectar and 0.55 ppm in bee-collected pollen. Whole blossom residues were much higher, with a peak of 3.32 ppm. Movento residues did not persist long in bee hives. No quantifiable residues were present in samples of stored honey, pollen, or wax by day 46 post application. Blossoms were sampled when the trees bloomed again in 2010 to evaluate the potential of residue carry-over from year to year. No detectable residues were present in these samples. A question was raised regarding whether the bees at the treatment site foraged extensively on the pollen from the citrus trees as opposed to pollen from other plants in adjacent areas. A follow up study quantified the proportion of citrus pollen in the diet of bees placed at the same citrus grove in 2011. Based on the results obtained, we conclude that applications of Movento® insecticide to citrus during bloom is unlikely to harm honey bees at the individual bee and brood level as well as at the colony level.

MP069 Effects of Contaminants on the Reproductive Success of American Eels A. Carey, Univ of Massachusetts Dartmouth, Dept of Biology; A. Roe, US Fish and Widlife Service; K. Oliveira, W. Hable, Univ of Massachusetts Dartmouth, Dept of Biology. The recent decline in worldwide populations of Anguillid eels is thought to be caused by pollution, overfishing, climate change, and/or habitat destruction. American eels, *Anguilla rostrata,* are known to inhabit contaminated rivers for the majority of their lives until they migrate to the ocean to spawn. Due to their unique catadromous life cycle, mature adults are not accessible for study and little is known about the effects of contaminants on fertilization and larval development. Using methods similar to the maturation of *Anguilla japonica*, *A. rostrata* males and females were artificially matured with weekly hormone injections. Using these procedures, our objectives were to (1) examine the maternal transfer of environmental contaminants to the eggs, (2) examine the effects of contaminant load on the fertility of females, and (3) examine the effects of polychlorinated biphenyls (PCBs) on the reproductive success of male eels. To examine the maternal transfer of contaminants to the eggs, ovulated eggs and muscle tissue are being analyzed for PCBs, dioxins and furans, pesticides, polybrominated diphenyl ethers, and metals. Results, to date, provide important baseline data and will facilitate development of a model for predicting parental contaminant contribution to offspring. To examine the effects of contaminant load on the reproductive potential of females, time to full maturation, ovulation, and fertilization success were evaluated and will be compared to the contaminant load in eggs. To examine the effect of PCBs on male gametogenesis, fertilization, embryogenesis and early larval development, males were co-injected with 2 different concentrations (1.0 or 10 μg/fish) of PCBs. Fertilization success and embryogenesis were assessed 2-4 hours post fertilization (PF), 24 hours PF, and 48 hours PF. Preliminary results show that males injected with 10 μg of PCBs exhibited lower reproductive success and produced embryos with disrupted early embryonic development. Fertilization success was significantly lower in embryos fertilized with sperm from males injected with 10 μg PCBs compared to the controls. Our results will shed light on whether environmental contaminants are contributing to the decline of *A. rostrata*. These findings will be important for future conservation efforts and the management of the American eel, an ecologically and commercially important species.

MP070 Relative Sensitivity of American Eel, Lake Trout, and Rainbow Trout to Induction of Cytochrome P450 Enzymes by 2,3,7,8-TCDD G.L. Cutler, Queen's Univ, Pharmacology and Toxicology; J.D. Byer, T. Arthur, Queens Univ; M. Alaee, Environment Canada; R.S. Brown, Queen's Univ , Dept of Chemistry; P.V. Hodson, Queen's Univ, School of Environmental Studies. A catastrophic decline in the recruitment of American eel (*Anguilla rostrata*) to Lake Ontario, starting in 1984, resulted in the extirpation of the species and its commercial fishery in Lake Ontario by 2004. One hypothesis to explain this decline is the food-web accumulation of dioxins (TCDDs, TCDFs) and other dioxin-like contaminants (DLCs) to concentrations toxic to their embryos, analogous to impacts on lake trout (*Salvelinus namaycush*) in Lake Ontario. To assess whether eels would be affected to the same extent as lake trout, we compared the relative sensitivity of juvenile eels, rainbow trout (*Oncorhynchus mykiss*), and lake trout to induction of cytochrome P450 (CYP1A) enzymes, a hallmark sign of TCDD exposure and potential toxicity. The relative potency among DLCs for CYP1A induction has been used to establish or reinforce Toxic Equivalent Factors for DLCs in risk assessment. The liver CYP1A enzyme activity of juvenile eels responded more quickly to an injection of TCDD and to a greater extent than rainbow trout, which in turn, was somewhat more sensitive than lake trout. If the sensitivity to CYP1A induction is a reasonable predictor of sensitivity to toxicity, these results suggest that reproduction of Lake Ontario eels could be impaired in the same way as lake trout, i.e., by maternal transfer of embryo-toxic DLCs. Analysis of TCDD toxic equivalent quantities and CYP1A enzyme activity in eels from other locations in eastern Canada indicated that Lake Ontario eels were most exposed to DLCs. Relatively high CYP1A activities of juvenile yellow eels suggest that contamination begins even before they reach Lake Ontario.

MP071 Morpholino Gene Knockdown in Adult *Fundulus heteroclitus*: Role of Serum Glucocorticoid Kinase 1 in Saltwater Acclimation E. Notch, Dartmouth Medical School, Dept of Microbiology and Immunology, Mount Desert Island Biological Laboratory, Dartmouth Medical School, Dept of Physiology; J.R. Shaw, Indiana Univ, The School of Public and Environmental Affairs; B. Coutermarsh, Dartmouth Medical School, Dept of Microbiology and Immunology; M. Dzioba, Mount Desert Island Biological Laboratory; B. Stanton, Dartmouth Medical School, Dept of Microbiology and Immunology. The Atlantic killifish (*Fundulus heteroclitus*) is a euryhaline teleost used extensively for studies related to salt balance due to their ability to acclimate to rapid and considerable alterations in salinity. Acclimation from fresh to salt water requires remodeling of the gill from NaCl absorption to secretion to maintain osmotic balance. Chloride secretion is a multi-step process, requiring uptake across the basolateral membrane by the $Na^+K^+2Cl^-$ co-transporter, prior to secretion across the apical membrane via the cystic fibrosis transmembrane conductance regulator (CFTR) Cl^- channel. Previous research has shown that rapid acclimation of killifish from fresh to salt water (SW) is mediated by trafficking of CFTR from intracellular vesicles to the plasma membrane in the gill within the first hour in SW, without changing overall CFTR protein levels. Acute transition to SW is also marked by an increase in both mRNA and protein levels of serum glucocorticoid kinase 1 (SGK1) within 15 minutes of transfer. Although the rise in SGK1 in gill after SW transfer precedes the increase in plasma membrane CFTR, the direct role of SGK1 in elevated membrane CFTR has not been established. To test the hypothesis that SGK1 mediates the increase in plasma membrane CFTR, we designed two different SGK1 vivo-morpholinos to knock down SGK1, developed a morpholino knock down technique for adult killifish and an approach to measure plasma membrane CFTR in the gill. Although morpholinos have been extensively used in zebrafish and other model organisms, they have not been utilized in adult killifish. Injection (IP) of adult killifish with a splice blocking SGK1 vivo-morpholino resulted in a significant, 66% reduction ($p< 0.05$) in SGK1 mRNA in the gill after transition from fresh to SW for 1 hour. Injected killifish also exhibited a 64% and 53% reduction SGK1 protein levels in the gill for the translational blocking morpholino ($p< 0.05$) and splice blocking morpholino ($p< 0.05$) respectively. Knock down of SGK1 also reduced, by 44% ($p< 0.05$), CFTR in the plasma membrane of the gills of SW fish. Thus, the increase in SGK1 is required for the trafficking of CFTR to the plasma membrane of the gill in killifish transferred from fresh to SW. This is the first report of the successful use of morpholinos in adult killifish, which provides a valuable genetic tool for this environmentally relevant model organism. (Supported by a grant from the NIEHS P42 ES007373).

MP072 The Effects of Ethinylestradiol (EE2) on the Reproductive Axis in Female Mummichog (*Fundulus heteroclitus*) M.A. Doyle, Univ of New Brunswick; C.J. Martyniuk, Univ of New Brunswick, Dept of Biology/ Canadian Rivers Institute, Univ of New Brunswick, Biology; T. Bosker, Univ of New Brunswick, Canadian Rivers Institute; K. Munkittrick, Univ of New Brunswick, Canadian Rivers Institute, Univ of New Brunswick, Dept of Biology. Studies using freshwater fish models have shown that exposure to low concentrations of 17 α-ethinylestradiol (EE_2) will result in a reduction or complete shutdown of egg production. Unlike other teleost fishes, the mummichog (*Fundulus heteroclitus*), an important estuarine fish model, is able to continue to produce and fertilize eggs at >3000 ng/L EE_2. Previous studies have shown that mummichog respond to lower concentrations of EE_2 at the physiological (steroid production) and molecular (vitellogenin induction) levels. The objective of this study was to characterize genomic responses to gain insight into how mummichog are able to produce eggs normally at high concentrations of EE_2. Adult mummichog were exposed under static renewal conditions for 14 d to a solvent control, 50 or 250 ng/L EE_2. A suite of endpoints were assessed for females at different levels of biological organization, including whole organism (relative gonad size, liver size, condition factor, reproductive stage), physiological (steroid hormones) and molecular (real-time PCR in both gonadal and liver tissue). The focus for targeted gene expression responses were lipid mobilization and transport (e.g., apolipoprotein E, lipoprotein Lipase, hepatic lipase, apolipoprotein C-II) in the liver and steriodogenesis (e.g., Hsd11b2) in the ovary, which are two important estrogen-regulated pathways involved in egg production. For higher level endpoints, fish exposed to 250 ng/L EE_2 had a slightly higher condition factor than control fish. However, there were no significant differences in GSI, LSI, or differences in histology based upon the count of follicles in primary and secondary growth in each group. There was a significant induction in hepatic *vtg* mRNA (2 and 20-fold) for 50 or 250 ng/L EE_2 respectively. There were no significant changes in lipid-related transcripts or steroidogenic genes after EE_2 exposure. Based on these results, a mummichog microarray will be used to further probe the mechanisms by which mummichog maintain egg production during high exposure levels to EE_2.

MP073 Using *Fundulus heteroclitus* to Study Reproductive and Developmental Effects of Benzo[*a*]pyrene C. Thornton, Univ of Mississippi, Dept of Pharmacology and Environmental Toxicology Research Program, Univ of Mississippi, Pharmacology; F. Booc, Univ of Mississippi, Pharmacology; X. Fang, Univ of Mississippi; A. Lister, Wilfrid Laurier Univ; D. MacLatchy, Wilfrid Laurier Univ, Canadian Rivers Institute, Wilfrid Laurier Univ, Dept of Biology; K.L. Willett, Univ of Mississippi, Environmental Toxicology Research Program, Univ of Mississippi, Dept of Environmental Toxicol *Fundulus heteroclitus* are exposed to polycyclic aromatic hydrocarbons (PAHs) in the wild, and thus, they are relevant organisms for studying the toxicological effects and mechanisms of PAHs. PAHs are a health concern because they are implicated in cancers and developmental deficits. We hypothesize that benzo[*a*]pyrene (BaP), a model PAH, can deregulate the steroid hormone hypothalamus-pituitary-gonad feedback loop adversely affecting reproductive development and physiology. Our previous work has shown that BaP downregulates aromatase (CYP19) expression. The goal of our current work is to further establish BaP-mediated toxicological endpoints including phenotypic (gonad morphology and reproductive success) and molecular consequences (steroid concentrations, vitellogenin, LH and FSH expression). A short-term reproductive bioassay was done using *Fundulus* adults exposed to waterborne concentrations of BaP (0, 1 or 10 µg/L) for 28 days. Males and females were kept separate days 0-14. The sexes were combined for days 14-28 and egg production and reproductive success was measured. BaP exposure did not alter male or female gonad somatic index (GSI) or liver somatic index (LSI) significantly. Similarly, sperm counts, egg production and fertilization success (n = 6 tanks per treatment; 3 fish of each sex per tank) were not altered by exposure. Oocytes were staged based on diameter of each oocyte, but oocyte size distribution was not significantly different between treatments (n=5 fish/treatment). Vitellogenin was significantly increased in 10 µg/L BaP-treated females compared to control and 1 µg/L BaP- treated females after 4 weeks exposure. Parentally exposed embryos were raised in clean water and collected for: steroid concentrations on 5 and 10 days post-fertilization (dpf) and 1 and 3 weeks post-hatch (wph); aromatase on 10 dpf and 12 wph; vasa at stage 24 (~3 dpf) and 12 wph; and histology at 1, 3 and 12 wph. In conclusion, BaP-mediated changes in aromatase expression have the potential to cause changes in the HPG axis, but reproductive success was not significantly compromised in the parental generation by up to 10 µg/L BaP exposure. Supported by NIEHS R03 ES018962.

MP075 Comparison of Topical Treatment and Nanoinjection to Investigate the Effects of PCB126 in *Fundulus heteroclitus* Embryos C.M. Couillard, Fisheries and Oceans; C. Rigaud, Université du Québec À Rimouski; B. Legare, Fisheries and Oceans. Controlled dosing of fish embryos with lipophilic contaminants to mimic maternal transfer and investigate toxic effects is hard work. In this study, we compare the toxic responses of *Fundulus heteroclitus* embryos following topical treatment or nanoinjection with 3,3',4,4',5-pentachlorobiphenyl (PCB126). A few hours after fertilisation, eggs were treated topically with 3.1 to 50 pg egg-1 PCB126 in DMSO or nano-injected with 1.6 to 25 pg egg-1 PCB126 in triolein. Two experiments were performed with each dosing technique. Four days post-hatching (dph), whole body EROD activity was measured in larvae. The dose-response relationships for EROD activity were compared between replicates for each dosing technique and between dosing techniques. Slopes of the dose-response relationships did not differ between dosing techniques, indicating a similar mode of action with topical or nanoinjection treatments. The intercepts did not differ between replicate experiments for each dosing technique indicating that both these modes of treatments are reliable and accurate methods to expose *Fundulus* embryos to PCB126. As expected, intercepts were lower for the topical treatment than for nanoinjection since only a fraction of the load of PCB126 (14(9-23) %) deposited on the surface of the eggshell reaches the internal tissues of the embryos. Both topical treatment and nanoinjection caused a dose-responsive reduction in body length and in the prey capture ability. Topical treatment is less technically complex, less costly in labour and material, and less invasive than nanoinjection. After validation of the internal dose, topical treatment is a valid alternative to explore biological responses and mechanisms of action of single chemicals such as PCB126. Nanoinjection remains the method of choice to compare the toxicity of different chemicals, to estimate toxic equivalent factors or to assess the toxicity of chemical mixtures.

MP076 CYP1A in South American Cyprinodontiform Fishes: New Models for Toxicological Studies R.S. Ferreira, F.S. Guimaraes, Universidade Federal do Rio Grande, Instituto de Ciências Biológicas; A.C. Bainy, Universidade Federal de Santa Catarina, Bioquimica; J. Stegeman, Woods Hole Oceanographic Institution; J. Zanette, Universidade Federal do Rio Grande, Instituto de Ciências Biológicas. Following the example of the North American Cyprinodontiform killifish (*Fundulus heteroclitus*), South American Cyprinodontiform fishes are potential candidates to be used as model species in toxicological studies. Although poorly studied so far, those fishes possess one or more of the following motivating features: (1) Cosmopolitan and adapted to live in a wide range of stressing conditions (e.g., pollution, salinity, oxygen and temperature stresses); (2) Different from killifish, most are ovoviviparous, being interesting models to understand mother-embryo toxicological interaction; (3) A huge diversity of species exists, and possibly a diversity of adaptative mechanisms/sensitivity to environmental stress; (4) Some species are rare, thus possibly endangered. We sampled three Cyprinodontiform species that occur around Rio Grande (RS, Brazil) and sought cytochrome P450 family 1 subfamily A (CYP1A) sequences, using degenerate primers, Polymerase Chain Reaction (PCR), cloning and sequencing. Partial sequences obtained (540-655 nucleotides) for *Phalloceros caudimaculatus* (Poecilidae), *Poecilia vivipara* (Poecilidae), and *Jenynsia multidentata* (Anablepidae), respectively, shared 89%, 89% and 90% identity in the predicted amino acid sequence with the corresponding region of *F. heteroclitus* CYP1A. The three fish species were exposed for 8 or 24-hrs to 1 µM ß-naphthoflavone (BNF), a potent AHR agonist. *P. caudimaculatus* showed a strong *CYP1A* induction (32-fold) in gill (0.88 ± 0.26 in BNF comparing to 0.03 ± 0.02 in control; $p < 0.0005$), and 49-fold in liver (10.50 ± 6.29 in BNF compared to 0.21 ± 0.13 in control; $p < 0.0005$), after 24-hrs, as quantified by RT-qPCR. This is the first study to identify a *P. caudimaculatus CYP1A* sequence, and to show that this transcript could be a biomarker of exposure to AHR agonists in this species. This would be useful for the environmental monitoring studies, as *P. caudimaculatus* is widely distributed in the South of Brazil. Analyses of *CYP1A* and responses of the other two species are underway. Our objective is to determine whether or not distinct intra- and inter-specific differences in induction of CYP1A occur and whether there may be acquired resistance or increased susceptibility to high-level contaminant exposure in South American Cyprinodontiform fishes, as occurs in *Fundulus* in N. America. (Support: INCT-TA, NIH P42ES007381).

MP077 Bisphenol-A Effects in CYP1A and CYP19A2 Gene Expression in the South American Fish *Poecilia vivipara* J. Zanette, S.M. Abril, Universidade Federal do Rio Grande, Instituto de Ciências Biológicas; C.R. Silveira, L.F. Marins, P.E. Martinez, Universidade Federal do Rio Grande. The guppy *Poecilia vivipara* (Poecilidae, Cyprinodontiform) is widely distributed in estuarine regions of the South American Atlantic coast serving as a potential model specie candidate to be used in toxicological studies. The objective of this study was to identify the brain aromatase sequence in *P. vivipara*, recognized in fish species as the cytochrome P450 of the family 19 subfamily A isoform 2 (CYP19A2), and to evaluate the effects of Bisphenol-A (BPA) exposure (2, 10 and 100 $mg.L^{-1}$) in the CYP19A2 transcriptional regulation in juvenile fish (0.6-0.9cm). The cytochrome P450 1A (CYP1A) gene expression was also evaluated. *CYP19A2* were identified using degenerate primers, PCR, cloning and sequencing, allowing the identification and preliminary annotation of a 159 nucleotide fragment sharing 85 % in the predicted amino acid sequence, with the corresponding region of *Fundulus heteroclitus* CYP19A2. The identified region corresponded to the CYP19A2 SRS4 and helix-I region. Gene expression levels were evaluated by RT-qPCR using *ACT* as normalizing gene. The *CYP19A2* and *CYP1A* did not showed differences comparing the exposed groups with the control group ($p>0.05$). *CYP19A2* is supposed to be up-regulated via estrogen receptor (ER) in fish´s brain and gonad after exposure to the endocrine disruptor BPA. The unexpected absence of *CYP19A2* alteration in this study could indicate that *P. vivipara CYP19A2* regulation differs from the previously studied species. An experiment with adult exposure to BPA and organ-specific RT-qPCR analysis is underway to investigate this hypothesis. A strong positive correlation between gene expression level and BPA concentration was observed for *CYP1A* ($p< 0.05$), but not *CYP19A2*, indicating that BPA could be involved in the *CYP1A* up-regulation. Regulatory mechanisms such cross-talking between AHR and ER receptors could be involved. Interestingly, it has been shown recently in zebrafish, that different to mammals, CYP1A and CYP1C1 are probably the major enzymes iivolved in the estrogen

metabolism in fish. Experiments investigating the possible involvement of CYP1A regulation in the BPA endocrine disruptor effects are underway. This is the first study identifying a partial *CYP19A2* sequence in *P. vivipara* and investigating the gene expression regulation by the endocrine disruptor BPA in this species (INCT-TA).

MP078 Developing the Mosquitofish (*Gambusia* spp.) as a Model Organism for Evaluating the Effects of Endocrine Disruptors in the Environment E.K. Anderson, Univ of Florida, Physiological Sciences; D.S. Barber, Univ of Florida, Dept of Physiological Sciences; Y. Ogino, Okazaki Institute for Integrative Bioscience; T. Bargar, US Fish & Wildlife Service; T. Iguchi, Okazaki Institute for Integrative Bioscience; N.D. Denslow, Univ of Florida, Dept of Physiological Sciences and Center for Environmental and Human Toxicology. Mosquitofish (*Gambusia* spp.) have the potential to become a useful bioindicator organism for endocrine disruptors. Male mosquitofish have a secondary sexual characteristic—an extension of the 3rd–5th anal fin rays used for internal fertilization—that is inducible in females and fry after androgen exposure. Female Eastern mosquitofish (*G. holbrooki*) with masculinized anal fins are still present at a paper mill-impacted site, over 30 years after their first discovery. Issues with using mosquitofish as a bioindicator include the lack of knowledge of how abnormal anal fin growth corresponds to higher-level effects such as reproduction. In addition, the molecular mechanisms that regulate anal fin growth are still unknown. To gain insight into these endpoints, three specific aims were developed: 1) Create a custom mosquitofish microarray, 2) Quantify the hepatic gene expression of vitellogenin (vtg) after androgen exposure, and 3) Observe changes after androgen exposure in the expression of three genes that regulate anal fin growth: sonic hedgehog (Shh), muscle segment homeobox C (MsxC), and fibroblast growth factor receptor 1 (Fgfr1). For aim 1, a *G. holbrooki* cDNA library was developed using the MINT-universal kit (Evrogen). Abundant transcripts were reduced using TRIMMER (Evrogen) to create a normalized cDNA library that was sequenced using the Illumina Genome Analyzer IIx. Annotation produced 20,879 contigs < 180 bp long with an E-score < 10-4. Additional *G. holbrooki* 454 pyrosequencing data will be used to improve annotation and enable probe design. For aim 2, female *G. holbrooki* were exposed to a vehicle control or one of three doses of the androgen 17beta-trenbolone for 3, 7, 14, or 21 days. Body mass, body length, and anal fin length were assessed, and livers were removed for quantitative polymerase chain reaction (qPCR) analysis. Results demonstrate that a high dose of 17beta-trenbolone (10 µg/L) significantly reduced hepatic vtg gene expression while a lower dose (1 µg/L) could induce anal fin growth (one-way ANOVA, $p < 0.05$). For aim 3, the expression of 3 genes with a known role in normal anal fin growth were evaluated in female mosquitofish after exposure to 17beta-trenbolone using in situ hybridization and qPCR to evaluate the pathways involved in androgen-induced anal fin growth. These data will provide critical information on how the mosquitofish can continue to be developed as a bioindicator for endocrine disruptors.

MP079 Quantification of Genetic Changes in the Brown Bullhead (*Ameiurus nebulosus*) Exposed to Environmental Toxins R. Williams, A. Hubberstey, Univ of Windsor, Dept of Biology. Aquatic environments are under a constant influx of pollutants which directly affect organisms living in these bodies of water. One species found in polluted environments is the brown bullhead (*Ameiurus nebulosus*). The bullhead is abundant throughout North America and is found in both clean and contaminated bodies of water in Southern Ontario, Canada. These philopatric, benthic fish undergo prolonged contact with sediment during feeding and other activities (where contaminants in water prominently accumulate), resulting in high levels of exposure. Because of their ability to withstand high levels of contaminant stress, these fish have been used as bio-indicators of genotoxic and contaminant stress to measure pollution induced effects on their population. The ability of bullhead to tolerate toxins has led us to propose that there may be an adaptive response occurring; allowing these fish to survive and reproduce in such areas. This response may either be a physiological acclimation or an evolutionary genetic response driven by natural selection. In order to measure changes occurring in fish and classify the type of adaptation occurring, individual genetic and molecular changes must be monitored to determine what mechanism(s) these fish are using to survive. A number of genetic markers were characterized for gene expression analysis from bullhead exposed to toxic compounds. One gene showing a marked change was p53.To determine whether the effects on p53 expression were observed in natural bullhead populations, fish caught from clean and contaminated sites in Southern Ontario were examined for their endogenous p53 protein levels. Definitive differences were seen between levels of p53 in fish from clean and contaminated sites. Fish caught from clean sites showed lower p53 protein levels than fish from contaminated sites. Bullhead from clean and contaminated sites were also fed benzo[*a*]pyrene (a common PAH) treated food. Fish from clean sites increased their levels of p53 upon exposure to BaP whereas fish from contaminated sites showed decreased levels of p53 although their endogenous p53 levels were higher. This suggests an underlying differential adaptive mechanism of the bullhead living in either clean or contaminated sites. Whether this response is genetic or physiological is currently being examined. Further studies, including measuring gene expression in F1 raised offspring whose parents originated from clean and contaminated sites will also be monitored.

MP080 Biomarkers of Pollution in the Mozambique Tilapia, *Oreochromis mossambicus*, Cichlidae J. van Vuren, Centre for Aquatic Research, Univ of Johannesburg, Zoology, Univ of Johannesburg, Dept of Zoology, Auckland Park Kingsway Campus; V. Wepener, Centre for Aquatic Research, Univ of Johannesburg, Zoology; K. Bremner, Univ of Johannesburg, Zoology; R. Basson, Univ of Johannesburg. The potential adverse effects of different contaminants present in the aquatic environment through industrial, agricultural en urban activities have to be determined to predict maximum tolerable levels for the organisms present. Information on the survival of organisms is useful in water quality management. Carefully selected biomarkers are recognised indicators of the levels of pollution that could compromise the health of aquatic organisms. Effects of contaminants on fish physiology and organ function in specific impacted areas were determined with laboratory exposure studies. These toxicity tests were specifically done to determine the molecular effects of selected chemicals and metals present in the study areas. The results obtained from the exposure experiments were also used to supplement the findings obtained during field surveys. The findings can be of use in water quality management where the prediction of environmental effects of toxicants, comparison of toxicity levels and regulation of effluent are important for the survival of organisms. The Mozambique Tilapia, *Oreochromis mossambicus*, an indigenous fish species, was used as an experimental organism in recently completes studies. This species complies with all the requirements for an experimental organism in studies of this nature. Biomarkers were carefully selected to provide specific information on physiological and biochemical changes in the liver, gills and gonads of exposed organisms. Toxic effects of the selected chemicals and metals were determined by using two groups of biomarkers. Metallotheinins, acetylcholine esterase, cytochrome P450 and glutathione-s-transferase are biomarkers of exposure and grouped together. The other group contained biomarkers of effect e.g., cellular energy allocation (indicator of energy reserves – proteins, carbohydrates, lipids; energy expenditure – electron transport system activity), oxidative stress (superoxidase dismutase, catalase, malondialdehyde, protein carbonyls, lipid peroxidase, glutathione-peroxidase), DNA damage (DNA strand length method), Metabolomics (1-D NMR), lactate dehydrogenase, alkaline phosphatise and heat shock proteins. Standard techniques where employed. Results are discussed in view of the importance of the findings to assist in the management of industrial, agricultural and urban effluent. The validity of biomarker responses in toxicity testing as a component of water quality monitoring programmes is considered.

MP081 Addressing the Effects of Wastewater Treatment Work Effluents on the Sustainability of Populations of Fish (Roach, *Rutilus rutilus*) in English Rivers P.B. Hamilton, Univ of Exeter, Biosciences; C.A. Harris, E. Nicol, S. Jobling, T.J. Runnalls, J.P. Sumpter, Brunel Univ, Institute for the Environment; V. Vinciotti, Brunel Univ, School of Information Systems Computing and Maths; A. Henshaw, Environment Agency; D. Hodgson, T.S. Coe, J.R. Stevens, Univ of Exeter; C.R. Tyler, Univ of Exeter, School of Biosciences. Wastewater treatment work (WWTW) effluents can make up a large proportion of the flow of lowland rivers across the world, yet their effects on the sustainability of fish populations are largely unknown. WWTW effluents and some of the endocrine disrupting chemicals (EDCs) they contain induce a range of feminised phenotypes in male fish, including the intersex condition – the presence of developing eggs in the testes of otherwise male fish. Studies on roach (*Rutilus rutilus*) living in rivers in the United Kingdom have found intersex roach at 86% of river locations. We examined the ability of intersex roach to reproduce in competitive breeding scenarios. Wild roach were taken from effluent-contaminated rivers in the United Kingdom, placed in large tanks, and were allowed to breed.

Feminization of male gonads was quantified by counting the number of oocytes present in the testes, and DNA microsatellites were used to assign parentage. The influences on reproductive performance were analysed using multivariate statistics. In the first study, fish length was the only factor found to significantly influence reproductive success. In the second study, in which more fish were moderately-severely feminised, the intersex condition significantly impaired reproductive success, reducing the average contribution for the most feminised fish by 76%. The intersex condition is therefore likely to be an important influence on reproductive performance in rivers in which moderately to severely feminized males are common. Potentially effective population sizes (*Ne*) could be affected and therefore the ability of populations to adapt to environmental change. We are assessing *Ne* across a range of rivers which receive varying levels of WWTW effluents. However, findings to date show high effective population sizes at some heavily impacted sites.

MP082 A Morphological and Molecular Method for Assessing the Effects of Potential Toxins on Zebrafish (*Danio rerio*) A. Shaffer, C. Graham, M. Elrod-Erickson, R. Otter, Middle Tennessee State Univ, Biology. Toxicological studies are often designed to determine the toxicity and/or teratogenic properties of a compound, but may miss or inadequately measure more subtle effects. When developing embryos are subjected to a potential toxin, an effect on the overall rate of development is possible. To enable careful measurement of such an effect, a set of methods was developed for use with zebrafish (*Danio rerio*) embryos. The transparency of these embryos, as well as their rapid development, makes them an ideal choice as a model for vertebrate development. Time-lapse video microscopy was used to record morphological changes continuously throughout embryogenesis. Morphological "milestones" were chosen for their uniqueness in order to minimize ambiguity about the timing of their appearance. Plotting the appearance of these milestones over time yields a clear representation of developmental rate. As a second measure of rate that does not rely on morphology, reverse transcriptase polymerase chain reaction (RT-PCR) was performed on RNA extracted from embryos at specific times after fertilization to monitor the detectable onset of expression of the developmentally regulated genes *shh*, *sox2*, and *tnnt1* (as well as the control gene *ef1a*). These genes are expressed only at specific points in development and thus provide a set of molecular "milestones" that can be used to corroborate the morphological data. The utility of these methods was tested on embryos developing at either the preferred temperature of 28.5°C or at 24.5°C, a temperature known to slow development without causing abnormalities. These methods were also applied to embryos exposed to sublethal doses of silver nanoparticles, where the suggestion of developmental delay has been observed.

MP083 Challenges in Valuing Ecosystem Services D. MacNair, T. Tomasi, Cardno Entrix. Valuing ecosystem services requires integrating basic ecological and economic concepts. The integrated model uses ecological production functions to specify the relationship among the ecological inputs and economic utility functions to specify the value of the resulting ecological outcomes. The integrated model can be used as a decision support tool to evaluate different environmental management options, whereby the scientists specify some ecological change and the stakeholders value the output. However, the devil is in the details. To work successfully, the integrated model must clearly distinguish between the inputs and the outcomes to ensure that scientists and stakeholders are assigned the appropriate tasks. For example, the model will not be reliable if stakeholders are valuing inputs based on their own assumptions about how they affect desired outcomes. This presentation will highlight some of the empirical challenges and impacts of estimating integrated economic and ecological models. SETAC participants will be given the opportunity to participate as stakeholders or scientists in an online survey prior to the conference. The survey concerns hypothetical land management decision about desert habitat. The results of the survey will be presented at the conference and will be used to explore the potential impacts and difficulties in properly specifying ecological production functions and economic utility functions.

MP084 A Decision Framework and Model to Assess Ecosystem Services at Three Military Installation Sites P. Booth, Exponent, EcoSciences; S. Law, Exponent, EcoSciences, Exponent, Environmental Group; J. Ma, Exponent. We developed an analytical decision framework and model to inventory and assess the tradeoffs of ecosystem services at three military installation sites. Each of the sites has a distinctly different biological and physical environment and is required to support different military missions or uses. Implementation of the framework starts with the compilation of relevant data and implementation of a stakeholder engagement process, to elicit specific preferences for ecological services and their relative importance (for use in preference weighting) from installation decision makers as well as other affected parties. The ecosystem services identified by stakeholders are linked by ecological production functions to specific ecological endpoints. Ecological endpoints are quantified using geospatial analysis (preferred) or from field surveys. The relative value of ecosystem services is quantified using existing, scientifically-vetted models or models developed for a site-specific endpoint. The outputs from each ecosystem service model are combined to determine the relative value of all ecosystem services at spatially-explicit locations. At each installation site, the relative value of each ecosystem service is defined and scenarios are presented to stakeholders, to quantitatively illustrate tradeoffs of ecosystem services and their effects on the military mission. An ecosystem services-based scenario building allow stakeholders to make better informed decisions to maximize the value of resource services as well as fully understand mission dependencies on ecosystem services.

MP085 Implications of Life History and Model Choice on Bird Population Recovery Estimates after Pulsed Contaminant Exposure C. Meyer, Arcadis US, Inc.; J. Meyer, Arcadis US, Inc., ARCADIS. Predictions of time to recovery of populations exposed to pulses of contaminants vary depending on the life history of the organism and the population model used. Population models used can range from density-independent models to various density-dependent models such as the ceiling model, Gompertz, Ricker, Beverton-Holt, or theta-logistic models. The models can be deterministic or stochastic. We evaluated how different combinations of models and bird species influence outcomes of pulsed-contamination scenarios. We restricted our evaluation to the dynamics of species at or fluctuating around carrying capacity (K), because most vertebrates that are not threatened and endangered are near K when exposed. Using available time series covering low to high densities, population growth rates near K were estimated by fitting the time series to the theta-logistic model. A species that maintains a high maximum population growth rate until near K (high theta) can recover more quickly from a contaminant pulse than a species with a low population growth rate near K. However, species with such high population growth rates can have high population fluctuations around K. If stochasticity is included in the model, such species show results opposite of expected, with a lower probability of extinction when exposed to contaminants than when unexposed, because the contaminants decrease the population size and thus dampen the fluctuations near K. In contrast, ceiling models of species with high growth rates near K produce rapid recovery without deterministic fluctuations and do not show increased stability in the presence of contaminants. The Gompertz model produces more rapid recovery if populations are depressed to lower than half of K than the Ricker model, and has unrealistically high growth rates at very low densities. Unlike the other models, the Gompertz model can not be applied to a population having one carrying capacity and then be scaled up to a different population having a higher carrying capacity. Ideally, the model that best calibrates to the observed time series and data should be selected; but if the observed time-series data are limited in how far they diverge from K, our results suggest that the model to be used to characterize risk to populations should be carefully selected.

MP086 EPA RSLs for Fish Ingestion: Not Protective Enough? G.I. Greenberg, Gradient Corporation. USEPA's regional screening levels (RSL) are designed to identify areas that warrant further investigation and commonly used to identify contaminants of concern (COC) for various media in risk assessments. USEPA (2010) published RSLs for residents exposed to contaminants via fish ingestion. However, these RSLs may not be conservative enough because they are based on an outdate ingestion rate of 54 g/day, from a 1977-1978 USDA Nationwide Food Consumption Survey published in 1982. This ingestion rate, recommended by USEPA (1991) as a standard default exposure parameter, is the average consumption rate derived from a 3-day study of people who consumed finfish (not dried, canned or raw). More current fish ingestion rates have been published with a wide array of rates that include the consumption of shellfish, which could alter the current USEPA fish screening levels. In addition, USEPA's screening level does not account for the higher fish ingestion rates among subpopulations (e.g., subsistence populations, native American populations, Asian communities) as well as regions (e.g., Michigan, Louisiana). Consequently, sites or COCs with fish tissue concentrations below the screening levels may be improperly

omitted from further investigations due to the outdated ingestion rate. More recent fish ingestion rates, its bases, and how it could alter USEPA's fish regional screening levels will be presented, compared and contrasted with the current standard.

MP087 Levels of Polycyclic Aromatic Hydrocarbons (PAHs) in Community Garden Soils in New York City (NYC) L.G. Marquez Bravo, H.M. Spliethoff, L.N. Ribaudo, D. Briggs, New York State Dept of Health, Center for Environmental Health; M.B. McBride, Cornell Univ, Dept of Crop & Soil Sciences; H.A. Shayler, D.M. Lopp, Cornell Univ, Dept of Crop and Soil Sciences; V.T. Lambert, Cornell Univ, Cornell Cooperative Extension; E. Stone, Green Thumb, NYC Dept of Parks and Recreation. Urban community gardens provide many public health benefits, but little is known about the extent and distribution of soil contaminants in these gardens. As a response to gardeners' concerns about exposure to soil contaminants, we developed a community-research collaboration under NIEHS Partnerships for Environmental Public Health. With the goal of characterizing PAH concentrations, we collected soil from 20 community gardens across five boroughs in NYC that were part of a city-wide program that encouraged importation of clean soil and compost. For each garden, one sample was collected from a non-growing area and another from a vegetable-growing bed. Additional samples were collected from beds where a visual inspection identified factors that could be influential with respect to contaminant concentrations (e.g., immediate proximity to highly trafficked roads, presence of asphalt or cinders, creosote timbers for beds, proximity to deciduous trees, etc.), for a total of 69 soil samples. The median sum of concentrations of EPA's 16 priority PAHs ("EPA PAHs") in these samples was similar to that previously reported for surface soils in NYC (5.4 vs. 6.4 ppm), but the maximum concentration in this study was 6 times higher (150 vs. 24.8 ppm). Forty percent of the sampled gardens and 65% of sampled beds had all PAH concentrations below the New York State Residential Soil Cleanup Objectives (SCOs) (based on health and background) used in this study as guidance values. Concentrations of EPA PAHs were marginally significantly ($p=0.052$) higher in non-growing areas (median=7.4 ppm) than in growing beds without potentially influential factors (median=3.5 ppm), possibly due to practices such as adding clean soil and compost to beds. No significant differences were found between beds with and without influential factors. Results were shared with gardeners along with healthy gardening strategies to reduce exposure to PAHs in gardens. Current and future studies will obtain soil-plant uptake rates in commonly grown vegetables in NYC to estimate human exposure to PAHs through vegetable consumption.

MP088 Human Risk Assessment of Organochlorine Pesticides (OCPs) in Korea S. Lee, Gwangju Institute of Science and Technology (GIST), School of Environmental Science and Engineering; D. Lee, B. Yim, Yeongsan River Environmental Research Center; S. Kim, Gwangju Institute of Science and Technology (GIST), Environmental Science and Engineering. Organochlorine pesticides (OCPs) have been banned several decades ago, but the evaluation of human risk on OCPs is necessary due to their persistence, bioaccumulation and toxicity. Concentrations of seven OCPs were determined in ambient water collected from 28 sampling sites in Yeong-San (YS) and Seom-Jin (SJ) Rivers in Korea. The potential health risk of OCPs associated with consumption of fish and drinking water was also assessed regionally with residual level of OCP in ambient water. Gas chromatography-high resolution mass spectrometry (HRMS) was used for chemical analysis. Uncertainties of risk assessment model and decision rule were resolved by Monte Carlo analysis. Risk characterization for OCPs was performed by calculating the ratio of the measured concentration and the water quality criteria for human protection in YS and RJ Rivers. The ratio (risk quotient, RQ) of hexachlorobenzene and heptachlor epoxide was below one, which indicates that no adverse effects may occur due to OCP exposure in ambient water. Even though RQ shows no adverse effect on human, the under-estimation of RQ may be induced by the calculation of average concentrations from left-censored data in HRMS analysis. Continual monitoring of OCPs in waters with more accurate analytical technique is required to obtain reliable human health risk.

MP089 Pollution Prevention in the State of Sonora, Mexico: Toxic Chemicals in Health Care Centers C. Alvarez-Chavez, M. Arce-Corrales, A. Gomez-Alvarez, E. Bolado-Martinez, Universidad De Sonora. In this study, pollution prevention efforts were started to identify the chemicals currently in use in health care centers of Hermosillo, Sonora, Mexico, that due to their toxic properties must be reduced/eliminated in addition to mercury. The purchasing, consumption, and distribution inventories of a public medical center were revised for the years 2008, 2009, and 2010, obtaining a list of 667 products that contain chemical ingredients and that are used as detergents, disinfecting agents, sterilizers, antiseptics, stripper, paint, solvents, grease removers, chemicals, clinical thermometers, among others. This list was reduced to 87 products through the application of exclusion/inclusion criteria such as purchasing frequency and volume. The qualitative analysis of the composition of the products revealed that these contain ingredients that have a potential of causing adverse effects in human health and in polluting the environment such as glutaraldehyde, formaldehyde, mercury, ethylene oxide, thinner, sodium hypochlorite, among others. One of the barriers found for obtaining detailed information about the products was that the system inventory of the health center does not regularly include data about the composition of them, or facilitates the use and transference of data to other users. This is due to the Federal and State Government's policies that regulate the acquisition of products in public health institutions in which a general code and a generic description of each product are included. It is concluded that being healthcare the objective of these institutions, it is necessary to promote pollution prevention programs that reduce the hazards of the chemicals in use in this workplaces and also to include pollution prevention and occupational safety criteria in the purchasing policies of government. This will contribute to reduce the hazards for the use of hazardous chemicals substances for workers, public and environment, it will be useful as a guide and reference for this workplace and other health institutions in Mexico, and well as to promote innovation maintaining quality and efficiency of the health services without increasing costs, health hazards or environmental pollution.

MP090 Priority Listing for the Reduction of the Use of Toxic Chemicals in Surgery Services of a Medical Center in Hermosillo, Sonora, Mexico C. Alvarez-Chavez, E. Cruz-Mirazo, M. Arce-Corrales, Universidad De Sonora. Nowadays, the existing pollution prevention efforts at the medical centers in México have been focused on reducing and eliminating the use of mercury. Therefore, an analysis and prioritization of those chemicals that because of their harmful effects to the environment and health must be reduced or eliminated were done for chemicals in use in the surgery services of a medical center at Hermosillo. For this, the purchasing, consumption, and distribution inventories for the years 2008, 2009, and 2010 were revised, physical inspections were held, employees and suppliers were interviewed, as well as product labels were checked to identify the products currently in use in these services that contain chemical substances. The previous research threw out a list of 74 products that was reduced to 60 considering those that were purchased in two of the three years and excluding products in use in maintenance and general services. The 60 products are used as disinfectant agents, sterilizers, antiseptics, and in medical devices, etc. An analysis of their composition resulted in the identification of 27 chemicals. After this a methodology considering data available in literature about the harmful effects for health and environment was developed for prioritization purposes. The results showed that mercury, ethylene oxide and formaldehyde, hydrogen peroxide, benzalconium chlorine, glutaraldehyde and iodine top the list that considers these criteria. The highlights of this list, besides mercury, are formaldehyde and ethylene oxide because of their potential to cause cancer and other irritating effects. These results show the need to consider other chemicals besides mercury in pollution prevention programs and policies in the health care sector in Mexico. A qualitative risk analysis to the employers during their activities in the medical center while using these products will contribute to refine this priority listing and will serve as a guide for the efforts leading to occupational health and pollution prevention in this workplace. This can also serve as reference for other health services in the region, for the elaboration or modification of pollution prevention policies in the country and to promote innovation in this field.

MP091 Ecotoxicology and Hematological Changes in Tadpoles of *Lithobates catesbeianus* Exposed to Agrochemicals Mixture in Rice Crops T.C. Paiva, F.M. Franca, Univ of São Paulo, Dept of Biotechnology; A.S. Marantonio, Polo APTA Vale do Paraiba; P.C. Teixeira, Univ of São Paulo, Aquaculture Center; M. Hipolito, Polo APTA Vale do Paraiba, Biological Institute; F.T. Silva, Univ of São Paulo, Dept of Biotechnology; C.M. Ferreira, Polo APTA Vale do Paraiba, Fisheries Institute. In Brazil, the rice crops has a great economical and social importance but make heavy use of agrochemicals, specially herbicides and insecticides The main aim of this

study was to evaluate the potential toxicity to tadpoles of *L. catesbeianus* in rice crop irrigated water that receive high loads of pesticides and to determine hematological parameters. The property chosen to realize the tests is a commercial rice crop farm localized in Tremembé city, São Paulo state, Brazil. This property make use of pesticides commonly applied in the rice crops similar to others properties in the region. After 25 days of planting pregerminated seeds, previously treated with Fipronil, the court was drained for the application of the pesticides: Penoxsulam 240g/L (150ml/ha) + vegetable oil (1L/ha), Bentazom 600g/L (2L/ha) and Permethrin 250g/L (100mL/ha). After 3 days of application, the court was again flooded and the tadpoles were exposed. And after five days about the beginning of the exposition was applied Carbofuran (500g/ha) with the fertilizer. Screened cages measuring 0.8 x 0.8 x 0.4m were fixed inside the rice crops, allowing the tadpoles to access the sediment. In each group it was used 150 tadpoles in the 31 Gosner stagy (1960) with medium weight about 7.08 ± 0.49g. Before the beginning of the tests and in the experimental days 3, 7, 10, 14 and 21 it was take 6 animals/group. These animals were anesthesiated to blood collection to evaluate hematological parameters: hematócrit (Ht), hemoglobine tax (Hb), couting of erytrocyte's number, mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC). After 21 days of exposure, it was verified the survival tax and medium weight was 100% and 6.33 ± 0.31g in the control group; 92.7% and 5.72 ± 0.28g in the exposure group. The medium values of Ht, Er, MCV and MCHC don't show significant differences: (Ht) 19.37 ± 2.29%, (Er) 21.30 ± 4.74 x 104/mm3, (MCV) 1053.19 ± 247.15 fL and (MCHC) 19.41 ± 3.54%. Hb shows significant difference only in the 14th day, medium values of 4.39 ± 0.70g/100mL to control group and 2.74 ± 0.62g/100mL to exposure group. During the others analyzed days the Hb was kept in normal values of 3.56 ± 0.37g/100mL. The tadpoles of *L. catesbeianus* show resistance to agrochemicals used in rice crops observing the small mortality. This mortality was concentrated during the Carbofuran exposure, 6 days without change of water.

MP092 Distributions of Mercury in Fish of the Paraná River, Brazil B.W. Matherne, Univ of North Texas, Dept of Biological Sciences; P.M. Holt, M.M. Chumchal, Texas Christian Univ, Dept of Biology; A.P. Roberts, D.J. Hoeinghaus, Univ of North Texas, Dept of Biological Sciences; A.A. Agostinho, L.C. Gomez, Universidade Estadual de Maringá, Núcleo de Pesquisas em Limnologia. Methylmercury (MeHg) is a chemical contaminant found at measurable concentrations throughout the earth's waterways. MeHg is known to bioaccumulate within the tissues of aquatic organisms and biomagnify through food webs. MeHg contamination has been shown to affect fish survival, reproduction, and behavior as well as pose risks to human health. Biological characteristics such as fish age, size, and growth rate all have varying effects on MeHg bioaccumulation. This study focuses on understanding how MeHg is distributed in the complex food web of the Paraná River, Brazil, and examines relationships between MeHg and ecological parameters that may mediate MeHg bioaccumulation in this highly-connected and species-rich tropical food web. Samples were collected from several locations (e.g., reservoir, floodplain, rivers) along an approximately 500 km stretch of the river basin (216 fish representing 29 species, including individuals acquired from local artisanal fisherman and markets). Fourteen percent of the fish species examined had mean Hg concentrations above 300 µg/kg (wet weight), exceeding the level at which the USEPA recommends limiting consumption to avoid adverse human health effects. Results also demonstrate a positive correlation between standard length, trophic position, and Hg concentration indicating biomagnification in the Paraná River ecosystem. This study has direct applications to the quality of artisanal fisheries as a key ecosystem service utilized by local communities, and may identify species or ecological traits that correlate with low risk for MeHg in fisheries species.

MP093 What Lessons? Phytotoxicity and Tropical Coastal Ecosystems – The Void M. Lewis, USEPA, Gulf Ecology Division. Tropical plant-dominated ecosystems provide at least 21 ecological services valued as great as $28000/h. These ecosystems, intertidal wetlands, seagrass meadows and mangrove wetlands/forests, have declined by as much as 50% worldwide during the last 20 years due in part to urbanization. This presentation evaluates the ability of the published toxicity database for metals, pesticides and petrochemicals to support the risk assessment process and the use of current regulatory effects-based criteria to protect near coastal, plant-dominated ecosystems. The phytotoxicities of contaminated sediments, tissue-accumulated chemicals, and water column contaminants will be summarized and shown to be unknown for most near-coastal temperate and tropical plants based on reviews of almost 900 papers. Dose response tests and traditional LC50, EC50 and NOEC concentrations are uncommon. Toxic effect concentrations, sensitive species, life stages and response parameters are almost unknown for most chemicals. Likewise, the impact of chemicals accumulated in sediment and plant tissues is unknown. Consequently, there is a lack of predictive ability and scientific basis for management of these plant-dominated habitats as related to the presence of contaminants, either alone or in combination with other stressors. The lack of a sufficient database restricts effective risk assessments for chemicals originating from land-based runoff as well as those from episodic events such as large oil spills. The question remains whether current water quality criteria and sediment quality guidelines are protective for coastal emergent and submerged plants in either the temperate or tropical zones. Therefore, a proactive approach is needed to obtain information on the magnitude, temporal variability and biological significance of common shoreline contaminants to coastal plants inhabiting diverse geographical regions.

MP094 A Multi-section Passive Sampler for Measuring Sediment Porewater Profiles of Hydrophobic Organic Chemicals L.J. Bao, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences; S.P. Xu, E.Y. Zeng, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, State Key of Organic Geochemistry. Measurements of hydrophobic organic chemicals (HOCs) in sediment porewater, a central component in assessing the bioavailability and mobility of HOCs in sediment, have been scarce. Here we introduce a multi-section passive sampler with low-density polyethylene (LDPE) as the sorbent phase, which is appropriate for measuring vertical concentration profiles of HOCs in sediment porewater of various depths. The multi-section passive sampler is composed of a series of identical sampling cells insulated with seclusion rings. In each section, sorption of HOCs into LDPE is diffusion-controlled through the water layer separated from the sediment by a glass fiber filtration membrane and a porous stainless steel shield. Laboratory testing indicated that the porewater concentrations of 1,1-dichloro-2,2-bis-(chlorophenyl)ethane (*p,p*'-DDD) and 1,1-dichloro-2,2-bis-(chlorophenyl)ethylene (*p,p*'-DDE) in spiked sediment obtained by the multi-section passive sampler were in the approximate range of those yielded through centrifugation, a conventional technique for sampling sediment porewater, and with an equilibrium partitioning approach. Field deployment of the multi-section passive sampler in an urbanized coastal region was able to obtain vertical concentration profiles of *p,p*'-DDD, *p,p*'-DDE, 1,1,1-trichloro-2,2-bis-(*p*-chlorophenyl)ethane (*p,p*'-DDT), 1-chloro-2,2-bis-(chlorophenyl)ethylene (*p,p*'-DDMU), 2,2-bis(chlorophenyl)ethylene (*p,p*'-DDNU), and 4,4'-dichlorobenzophenone (*p,p*'-DBP) in sediment porewater, which were deemed reasonable with a comparison with sediment concentration profiles of the same target analytes from the proximate location.

MP095 Comparison of SPME Fiber and Tenax Methods to Predict the Bioavailability of Permethrin A.D. Harwood, Southern Illinois Univ, Zoology, Southern Illinois Univ; P.M. Landrum, Southern Illinois Univ; M. Lydy, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology. Recent studies have recognized the ability of chemical techniques to predict bioavailability more effectively than whole sediment concentrations. Two such techniques use SPME fibers and Tenax beads, to estimate chemical activity and bioaccessability, respectively. While the majority of research using these techniques has been conducted using legacy compounds such as PCBs and PAHs, there is great potential for these methods to be utilized for highly toxic, rapidly biotransformed compounds such as pyrethroid insecticides. The widespread contamination and environmental risk of pyrethroids in sediments is well documented. Therefore, an accurate technique to evaluate the bioavailability of these compounds would improve environmental assessments. The objective was to compare the two techniques in their ability to predict the bioavailability of permethrin to two benthic invertebrates (*Lumbriculus variegatus* and *Hexagenia* sp.). In addition, variations of the application of the two techniques were explored. For SPME fibers, fiber co-exposure with the animals during the 28 day bioaccumulation bioassay was compared to fibers exposed separately on a shaker table. Previous studies have determined that a single Tenax extraction time of 6 or 24 hours was effective to predict bioavailability, so the relative ability of these two time periods to predict bioavailability was compared. There was no significant difference between SPME fiber concentrations between species or between the shaker table and co-exposure. This was true

among all concentrations used. There was a correlation between SPME fiber concentrations and both 6 and 24 hour Tenax concentrations. The SPME fiber concentrations, 6 h, and 24 h Tenax extractable concentrations correlated with both the total permethrin (parent plus metabolites) as well the parent permethrin concentration in the tissues of both species. When tissue concentrations were normalized for biotransformation and percent lipid both species tissue concentrations could be predicted with one relationship. This demonstrates the potential value of these methods to predict bioavailability for a range of compounds and multiple species.

MP096 Utilizing a Thin-Film SPE Methodology to Assess the Bioavailability of DDT and Dieldrin Residues in Soils N. Andrade, Univ of Maryland, Civil and Environmental Engineering; L.L. McConnell, USDA-ARS, Environmental Management and Biproduct Utilization Laboratory, US Dept of Agriculture-ARS, Environmental Quality Laboratory; A. Torrents, Univ of Maryland, Civil and Environmental Eng.; M. Ramirez, District of Columbia Water and Sewer Authority; C.J. Hapeman, USDA-ARS. While DDT and dieldrin have been banned in most countries, heavily contaminated agricultural sites exist in many areas. A historical orchard that received routine DDT and dieldrin applications more than 40 years ago is being assessed for potential in situ remediation with organic carbon amendments. The remediation goal is to reduce bioavailability of pollutants to earthworms to reach standards set by USEPA. Testing residue bioavailability using earthworm bioassays is time-consuming and complex; differences in commercially-available species and experimental design may cause variability in results. In order to rapidly estimate bioavailability of these organic pollutants to earthworms and to assess remediation options, a thin-film solid-phase extraction assay has been tested. A recent study has shown that the thin-film polymer can mimic biological membranes and concentrations in the polymer were strongly correlated to residue uptake by mussels in sediment. In this experiment, DDT- and dieldrin-contaminated soil from the orchard site and freshly-spiked control soil were analyzed using this thin-film methodology, and results were compared to concentrations found in native earthworms. Preliminary results show that aged soil 4,4'-DDT reached equilibrium with the film in 10 days, while its metabolite, 4,4-DDE, reached equilibrium only after 110 days and dieldrin in 64 days. We expect that equilibrium times will be shorter for freshly spiked soil. The orchard soil was mixed with 5 different organic carbon amendments, and the change in bioavailability of the residues relative to the unamended soil was determined. Amendments included biochar, composted biosolids, limed biosolids, and two manure composts. This approach may provide a useful, rapid and easy assessment of bioavailability of organic pollutants in aged contaminated soils.

MP097 Comparative Evaluation of Methods for Estimating Bio(accessibility) of Organic Contaminants in Soil B.M. Adedigba, Univ of Lancaster, Lancaster Environment Centre. There is interest in developing a method for estimating bioavailability of hydrophobic organic contaminants (HOCs) in soil. Existing methodologies are inadequate due to limitations imposed by physical and chemical characteristics of contaminants. XAD is a group of hydrophobic resin with high affinity for organic compound in aqueous phase. It has been used to pre-concentrate trace organic compounds in solution thus facilitating their detection by analytical instruments. The aim of this study was to optimize an extraction which relies upon the desorption of organic contaminants from soil in the presence of XAD; this desorption technique may be used to estimate the bioaccessibility of HOCs in soil. The applicability of XAD technique to estimate bioaccessibility of phenantherene (model PAH) across 5 concentrations (0, 0.01, 0.1, 1.0 and 10 mg/kg of soil) was measured. Bioaccessibility was measured in terms of biodegradation of 14C-phenantherene by a culture of *Pseudomonas* sp. The success or otherwise of XAD was assessed by comparing the data with those from the well reported cyclodextrin extraction. Four sequential 22 hourly extractions were required for XAD-2 to accurately estimate biodegradation across all concentrations. In contrast, a single cyclodextrin extraction produces similar results within 12 hours. Linear correlations between cumulative XAD-2 extracted and cyclodextrin extracted data revealed a very good relationship (best fit of r2 = 0.896, slope 1.031). On the contrary, the residual concentrations predicted by XAD-2 underestimate cyclodextrin and biodegradation endpoints by >30% and >33%, respectively. While these data suggest that XAD-2 is a promising method for estimating HOC accessibility to microflora, cyclodextrin extraction remains the most rapid technique for predicting bioaccessibility of HOCs. In view of the limitation of cyclodextrin to predict highly persistent compounds, it is necessary to further optimise XAD adsorption for better performance

MP098 Relationships Between Petroleum Hydrocarbon Concentrations and the Results of Toxicity Tests with Terrestrial Species G.L. Stephenson, Stantec Consulting Ltd., Environmental Management, Stantec Consulting Ltd., Environmental Remediation Services; W. Ma, Stantec Consulting Ltd.; S. Siciliano, Univ of Saskatchewan; B. Zajdlik, Zajdlik & Associates Inc. Two Saskatchewan (Canada) soils amended with commercially-acquired diesel at concentrations ranging from 100 to 30,000 mg/kg soil dry weight were artificially aged and weathered by mechanical mixing twice weekly for three weeks prior to use in toxicity tests with plants and soil invertebrates. At the beginning of the toxicity tests, soil subsamples were extracted with cyclodextrin, a solvent mixture of hexane and acetone (1:1 v:v), and an enzyme mixture which simulated the gastrointestinal fluids of earthworms (SEG extraction). The potential petroleum hydrocarbon exposure concentrations from these extraction methods were measured using GC-FID. Biological effects (survival, seedling emergence, growth or reproduction) of the PHC-contaminated soil were assessed by conducting toxicity tests with two species each of plants (*Elymus lanceolatus* – Northern Wheatgrass; *Hordeum vulgare*- Barley) and invertebrates (earthworm – *Eisenia andrei*; springtail – *Folsomia candida*). The multi-concentration exposure series enabled the estimation of IC50s and IC25s for the various biological endpoints. Multiple regression procedures and the application of data reduction methodologies were used to determine the relationships between the effect data and the measured potential exposure concentrations as determined by the three different extraction methods predicted (correlation) effects. The influence of soil characteristics was also taken into consideration.

MP099 Influence of Molecular Size on Chemical and Biological Availability of Sediment – Associated Contaminants H. Li, State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Graduate School of the Chinese Academy of Sciences, Graduate School of the Chinese Academy of Sciences; J. You, State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy Sciences, State Key Laboratory of Organic Geochemistry. Besides the widely investigated factor of hydrophobicity, molecular size could affect bioavailability of hydrophobic organic contaminants in sediment as well. To evaluate the influence of molecular size on bioavailability, four pairs of contaminants, including a polychlorobiphenyl (PCB) and a pyrethroid insecticide having similar hydrophobicity but different molecular weight in each pair, were selected as the target contaminants in the current study. Bioavailability of the sediment-associated contaminants was assessed using the bioaccumulation testing using the blackworm, *Lumbriculus variegatus*. Meanwhile, the freely dissolved concentrations of the contaminants in sediment porewater were also measured by the two passive sampling techniques including matrix-solid phase microextraction (matrix-SPME) and polyethylene membrane (PE). In addition, uptake kinetics of the contaminants to the SPME fibers and PE membranes were also estimated in water-only testing. Results showed pyrethroids were less bioavailable compared to their PCB counterparts which had similar Kow values, indicating molecular size played an important role on bioavailability. Similarly, sediment-water partition coefficients (Koc) of pyrethroids were higher than those of PCBs while lower elimination rates were noted for pyrethroids compared to the PCBs. When molecular size was taken into consideration, a better relationship between Kow and Koc was achieved across chemical classes.

MP100 Biological Effects of Carbon Amendments in Sediment-dwelling *Lumbriculus variegatus*: Implications for Bioaccumulation Testing and Remediation J. Akkanen, Univ of Eastern Finland, Dept of. Biology; I. Nybom, Univ of Eastern Finland; M.T. Leppanen, Univ of Eastern Finland, Dept of Biology; J.V. Kukkonen, Univ of Eastern Finland, Joensuu Campus, Dept of Biology. Different types of amendments have recently been introduced as a potential remediation method for contaminated soils and sediments. In the case of hydrophobic organic contaminants (HOCs), activated carbon (AC) appears to be the most pre-eminent material studied for this purpose. Past studies have heavily focused on the potential of added AC to reduce availability of HOCs. This is first and an important step for testing if the remediation by AC amendment has any chances to meet its goals i.e., to reduce availability of HOCs for transport and bioaccumulation effectively. Less effort has been invested to study direct biological effects of

AC on organisms, which has importance for both laboratory-scale bioaccumulation testing and field-scale ecological impact assessment. In this study, the goal was to assess possible biological responses in *Lumbriculus variegatus*, a widely used test organism in sediment ecotoxicology, to AC amendment in sediments. We tested the effects of AC particle size and manipulation (boiling, solvent extraction) on feeding, growth and reproduction. The results showed that already low doses of AC decreased feeding and retarded growth of the test organisms. Smaller particle sizes caused the effects at lower doses than the bigger sizes. Reproduction proved to be less clear end point, because the test organisms appeared to reproduce also as a response to stress. Boiling and solvent extraction of the AC had little or no effect on the measured responses. Sediment quality (clean natural sediment, clean artificial sediment, PCB-contaminated sediment) had some effect on the responses caused by the added AC. Changed behavior (avoidance) and reduced growth are important factors when assessing bioaccumulation and ecological quality of the sediment. Therefore, we may need to consider also the possible negative effects of carbon amendments when selecting and evaluating site-specific remediation actions.

MP101 Measuring Remedial Effectiveness of Activated Carbon Amendment in Grasse River, NY B. Beckingham, Univ of Maryland Baltimore County, Civil & Environmental Engineering, Univ of Maryland Baltimore County, Dept of Civil & Environmental Engineering; U. Ghosh, Univ of Maryland Baltimore County, Civil & Environmental Engineering. Legacy toxic pollutants such as polychlorinated biphenyls (PCBs) persist in sediments and bioaccumulate in the aquatic food web. Recent work has shown that uptake in the food web is strongly influenced by the nature of contaminant binding, especially to black carbon surfaces in sediments. We demonstrate for the first time using multiple lines of evidence that activated carbon amendment to sediments in a contaminated river reduces bioavailability of PCBs. After treatment with activated carbon applied at a dose similar to the native organic carbon of sediment, bioaccumulation in freshwater oligochaete worms measured in both laboratory and field exposures was reduced by 62-99% and concentrations of PCBs in water at equilibrium with the sediment by >95% compared to measurements with unamended background sediments in each year. In this presentation, however, we will focus on the information added by surrogate bioavailability measurements, namely, field and laboratory applications of polyoxymethylene (POM) passive samplers, and sediment desorption kinetics. Passive samplers showed that the chemical activities in pore waters of treated sediments were reduced in comparison to untreated sediments, indicating a lower potential for contaminant flux to the overlying water column. Also, the extent of the reduction in passive sampler uptake at the sediment-water interface in the river was similar to the change in bioaccumulation in field exposures of organisms; therefore, passive samplers may be used as a surrogate to monitor change in chemical availability following remediation. Passive sampling tools can potentially provide more spatial coverage than is practical when employing exposures of live organisms. Desorption kinetics tests showed the rapidly desorbing fraction of PCBs from sediments was reduced following AC amendment, which provides evidence of the mechanism for reduced biouptake. We can additionally use these measures of biavailability to attempt to predict biouptake in model organisms. Although aggressive remedies may be appropriate for some highly contaminated sites, we show through this pilot study that PCB exposure from moderately contaminated river sediments may be managed effectively through activated carbon amendment in sediments.

MP102 Synthesis of Nano-Zero Valent Iron in Sand Matrix and the Impact on Microbial Community V. Roland, Tennessee State Univ, Dept of Civil and Environmental Engineering; T. Byl, US Geological Survey, Dept of Interior, Tennessee State Univ., College of Engineering. Little is known about the synthesis of nano-sized particles in sand matrices, and the effects on groundwater bacteria. After conducting literature research on the synthesis of nano-zero valent iron, this study was designed to synthesize the nano-particles in a saturated soil matrix. Nano-iron instantly precipitated in the groundwater solution containing 5 ml of 0.5 M $NaBH_4$ and 1 ml of 0.018 M $FeSO_4$. Additional batch reactions were conducted using 100 mL of saturated aquifer soil collected from a field site contaminated with carbon tetrachloride. Initial CCl_4 concentrations in the porewater ranged from 3.8 – 3.9 ppm, which was consistent with the concentrations observed in water samples collected at a nearby spring. Samples were collected from the batch reactors before the addition of iron and $NaBH_4$, then 30 minutes, 60 minutes, and 20 hours after the addition of $NaBH_4$. Calculations showed that the reaction produced 0.24 L of H_2 gas as seen through production of tiny bubbles. Gas chromatography was used to measure the carbon tetrachloride, chloroform and methylene chloride. Water samples with no $NaBH_4$ retained 80% of their initial CCl_4 concentration over a 20 hour incubation, 65% of the initial CCl_4 concentration was retained in soil-water reactors. Preliminary results indicated that dechlorination of CCl_4 was occurring in soil and water batch reactors treated with $NaBH_4$. Calculations show samples treated with $NaBH_4$ had 1st-order reductive dechlorination reaction rates from 0.04 – 0.1. Additional testing found that the indigenous microbial communities were still healthy despite boron and hydrogen release. The surviving bacteria were fermenting and sulfur-reducing bacteria, which are both important to biological reductive dechlorination. This study showed that nano-zero valent iron particles can be synthesized in saturated soils and reduce halogenated solvents with minimal harm to the geo-bacteria.

MP103 Antimicrobial Resistance to Veterinary Drugs in the Korean Animal Farm Environment J. Kwon, S. Lim, National Veterinary Research & Quarantine Service; H. Yun, College of Veterinary Medicine, Chungnam National Univ.; K. Lee, Dept of Applied Biology & Chemistry, College of Agriculture & Life Science, Chungnam Nat'l Univ. Due to the biological activity of veterinary drug residue in the environment, antimicrobials are potential micropollutants. Furthermore, antimicrobial resistance to antibacterials has increased every year in Korea. This study describes antimicrobial resistance in the Korean animal farming environment. Soil, manure compost, liquid fertilizer and water were collected from 4 swine and 12 chicken farms, located in southern province in Korea, from September to October in 2009. *E. coli*, *Enterococcus faecalis*, and *E. faecium* were isolated animal farm environment. Tetracycline resistances were mainly found in pig farms and amoxicillin resistances were mainly found in chicken farms. In case of *E. coli* from pig farm soil showed relatively highly occurrence of various antimicrobial resistances. *E. faecium* from compost of two pig farms presented diverse occurrence of antimicrobial resistance against pencillin, erythromycin, tetracycline, ciprofloxacin, rifampin etc. Furthermore, relationship between the occurrence of residue and the occurrence of antimicrobial resistance was also identified, for example, when tetracycline residues were determined, tetracycline resistant bacteria were always emerged.

MP104 Dissolved PCB Concentrations in Lotic and Lentic Environments Measured by Passive Samplers S. Reller, Clemson Univ, Environmental Engineering and Earth Sciences, 342 Computer Court; V. Dang, Clemson Univ, Environmental Engineering and Earth Sciences; D. Delach, Clemson Univ, Environmental Toxicology; C.M. Lee, Clemson Univ, Environmental. Engineering and Earth Sciences Dept. In recent years, passive samplers have been employed to monitor and increase our understanding of concentrations of dissolved hydrophobic contaminants in aquatic systems. Results from both dynamic systems (e.g., streams and rivers) as well as more quiescent water bodies (e.g., lakes and reservoirs) have been reported widely. But no comparisons have been made from watersheds with both lotic and lentic components. Passive samplers made of polyethylene (PE) were deployed in a stream in the headwaters of a watershed contaminated with polychlorinated biphenyls (PCBs) and also in a large reservoir in the watershed. More than 200,000 kg of PCBs were released to the watershed from about 1955 to 1975 during operation of a capacitor manufacturing plant. The sediments in tributaries and the reservoir (Lake Hartwell, SC, USA) are part of a Superfund site that has been well studied. The PE samplers (2.5 × 5cm) were attached to stationary posts in the stream for 60 days. Currently research is underway to deploy PE samplers (2.5 × 12 cm) in the reservoir for 90 days. The samplers were extracted by dialysis in methylene chloride, solvent exchanged, and analyzed by gas chromatography with electron capture detector (GC-ECD) to determine concentrations of up to 140 PCB congeners. Total PCB concentrations ranged from 748.86 ± 191.51 (±SD) ng/g PE to 3547.89 ± 475.96 ng/g PE in the stream. Comparisons between the two aquatic environments will be discussed to understand differences in up-take.

MP105 Measuring Soil Oxidation-Reduction Potential in a Patchwork World S.C. Pierce, R. Kroger, Mississippi State Univ, Wildlife, Fisheries, and Aquaculture; R. Reese, C. Griffin, A. Turner, Mississippi State Univ, Electrical and Computer Engineering. In soils and sediments subjected to regular inundation, oxidation-reduction potential (Eh) ranks equal in

importance with more familiar physicochemical soil parameters such as pH, organic carbon, and particle size. Eh, however, experiences temporal fluctuations due to hydrologic variability, temperature, and biotic interactions. Spatial heterogeneity occurs at multiple scales in both in the horizontal and vertical plain. Conventional methods developed for measuring Eh are unable to adequately quantify this inherent variability. Herein, recent advances toward capturing this variability are reviewed, highlighting newly developed field-deployable instrumentation for sampling and recording long-term Eh at short time-intervals and multiple spatial scales. The system, collaboratively developed as a senior engineering project, uses multiple probes and data loggers that have the capability to communicate wirelessly with a central recording device, vastly decreasing sampling effort. Data from tests in the laboratory and field are presented in the context of regulating chemical exchanges of soil and water via hydrologic management.

MP106 Residence Time Distribution Model For Non-ideal Flow Derived From Independent Gamma Distributions of Tracer Travel Distance and Linear Velocity I. Embry, Tennessee State Univ; T. Byl, US Geological Survey, Dept of Interior, Tennessee State Univ., College of Engineering; R. Painter, Tennessee State Univ, College of Engineering, Technology and Computer Science. The Residence Time Distribution (RTD) is the time that a particle will take to complete its path from the injection to the exit point in a closed system. Most RTD models have used the advection dispersion equation (ADE) for tracer breakthrough curves for karst systems. ADE solutions for tracer breakthrough curves exhibiting near plug flow behavior are usually Gaussian (normally distributed) in nature. This symmetric solution often predicts finite tracer concentrations at zero time and this is not often shown in tracer breakthrough curves, which frequently are characterized by relatively long upper tails. There are few quantitative tracer studies modeling karst systems that have tracer concentrations normally distributed about the mean residence time and few of these models graphically display this distribution. The objective of this project was to create an M-file language computer algorithm in MATLAB® Version 6.5.1 and GNU Octave Version 3.2.4 that combined both the numerical and visual aspects of karst tracer studies. This project used the transformed residence time distribution function using the independent gamma distributions of tracer travel distance and linear velocity. This algorithm computes the transformed RTD function from the time inputs and then displays the RTD function versus Time graph, the Tracer Concentration versus Time graph, and the graph of the tracer concentration normally distributed about the mean residence time.

MP107 Using Disposable Polydimethylsiloxane Fibers to Determine the Freely Dissolved Concentration of Polybrominated Diphenyl Ethers (PBDEs) in Sediment F. Jia, Univ of California, Riverside, Dept of Environmental Sciences, UC Riverside, Dept of Environmental Sciences; J. Gan, Univ of California Riverside, Environmental Sciences. Polybrominated diphenyl ethers (PBDEs) have found extensive use as flame retardant additives. Their long persistence and endocrine disrupting potency have raised concerns about their environmental fate. Sediment is the primary sink for PBDEs, where bioavailability likely regulates the exposure of PBDEs to aquatic organisms. The freely dissolved concentration (Cfree) of HOCs is considered to be a good indicator of bioavailability. However, strong sorption of PBDEs to DOM in sediment porewater presents a great challenge to measuring Cfree. In this study, a solid-phase microextraction (SPME) method was developed for determining Cfree of PBDEs in sediments using disposable fibers coated with 35 μm of polydimethylsiloxane (PDMS). We carried out concurrent SPME and traditional solvent extraction to evaluate phase partitioning of PBDEs in several sediments. Substantial association of PBDEs with DOM was observed in the sediment porewater. The Cfree values in sediment porewater were further used to improve the measurement of sorption coefficient KOC and KDOC of PBDEs.

MP108 A Method Based on Florisil Column Cleanup for Analysis of Non-ortho PCB Congeners in Rat Adipose with Exposure to Aroclor 1254 N. Li, N. Cekic, W.J. Bowers, I. Chu, Health Canada, Hazard Identification Division, Environmental Health Science and Research Bureau, HECSB. Non-ortho substituted coplanar polychlorinated biphenyls (PCBs) are highly toxic and have extremely low concentrations in commercial PCB formulations such as Aroclor 1254. Quantitative analysis of the coplanar PCBs with GC need separation of the ortho substituted PCBs from the sample prior to injection because the latter may be thousands times higher in concentration and may interfere with their detection. Florisil was studied as adsorbent to isolate coplanar PCBs from extracts of adipose of laboratory rats with exposure to Aroclor 1254. The retention of 35 representative coplanar and non-planar PCBs and similar persistent chlorinated compounds such as organochlorine pesticides was studied. Florisil (60~100 meshes) was activated at 200_C for 18 hours. The coplanar PCBs have good retention on the adsorbent and at least five of them (PCB77, 81, 126, 127, 169) can be separated from the ortho substituted PCBs with a proper cut point. Moreover, oxychlordane, _-BHC and cis-Nonachlor have similar retention on the Florisil column with above five coplanar PCBs and were used as internal and surrogate standards for analysis calibration and quality control respectively, and were added to the sample before extraction. In comparison with porous graphite carbon which is widely studied for separation of the coplanar PCBs from the non-planar PCBs, one of the advantages of the Florisil column is that for biological samples the lipid can be simultaneously separated. With a column of 8.0 g of Florisil, up to 0.5 g of lipid could be retained and separated from the sample, and the ortho-substituted PCBs were eluted out from the column with 220 mL hexane, and the five coplanar PCBs were then eluted from the column with 50 mL of 30% DCM in hexane. The problem of a method with Florisil column may be found for the minor carryover of the non-planar PCBs when a stronger solvent is used to elute the coplanar PCBs. By using the internal standard and surrogate standards, this can be solved with a second or third separation with a small size of 1g Florisil column so that PCB153 which is major PCB component in commercial formulations and environmental samples is not detected. The method was validated with reagent blank, method detection limit, recovery and relative standard deviation of replicate analysis, and applied for analysis of the rat adipose samples from toxicological study in our laboratory.

MP109 A Non-lethal Approach to Assess and Monitor Mercury Concentrations in Black Basses from a Mercury Impacted Stream in the Shenandoah Valley, Virginia J. Collins, G. Murphy, J. Flanders, URS Corporation. A non-lethal sampling approach utilizing dermal biopsy punches has been developed to assess and monitor total mercury (THg) concentrations in black basses along 26 miles of the South River, Virginia. Fish tissue biopsy samples provide data on spatial, temporal and ontogenetic variations of THg in the muscle tissue of smallmouth and largemouth bass, without causing mortality. Fish were collected through the use of boat and tote-barge mounted electrofishers and held in flow-through live pens prior tissue sampling to minimize handling stress. Tissue samples from up to 30 bass from each biological monitoring location were collected with a mid-dorsal biopsy plug obtained using a 3.5 millimeter (mm) sterile biopsy punch. After sampling a small passive integrated transponder (PIT) tag was inserted beneath the posterior dorsal fin terminus in order to track THg levels in unique individuals over time. Antibacterial salve was applied to the wounds to prevent infection and field observations from the 2009-2011 sampling events indicated that recaptured smallmouth and largemouth bass had complete regrowth of skin and scales between sampling events. Sample results were found to be comparable to traditional lethal sampling techniques and present a sustainable alternative for assessing metals concentrations in fish.

MP110 An Integrated Screening Methodology for Concise Site Decision Making and Chemical Characterization J. Guerrero, Space and Naval Warfare Systems Center; R. Johnston, US Navy, Marine Environmental Support Office-NW; J. Leather, Space and Naval Warfare Systems Center; J. Brandenberger, Pacific Northwest National Laboratory; B. Beckwith, Puget Sound Naval Shipyard & IMF; D. Leisle, Naval Facilities Engineering Command – NW. Risk assessments for sediment sites require decisions based upon thoroughly defensible, high quality, analytical data. An integrated screening methodology in combination with high resolution laboratory analytical support is a practical approach to provide for concise site decision-making while balancing data quality needs and cost effectiveness. The Puget Sound Naval Shipyard & Intermediate Maintenance Facility (PSNS&IMF) in Bremerton, WA consists of industrial, commercial, and ship-support facilities that are regulated under the NPDES program and offshore sediments that are being remediated as part of an active CERCLA clean up. The presence of several divergent classes of chemical contaminants, including metals, PAHs and PCBs, presented particular challenges for chemical characterization. During 2010, screening tools were used as part of a tiered management strategy involving an initial screening assessment followed by traditional laboratory analyses. Within ten working days, over 100 sediment samples were rapidly screened for metals (Cu, Zn, Pb, Fe, etc.) by Field Portable X-ray Fluorescence (FPXRF) and organics (PAHs and PCBs)

using Enzyme Linked Immuno-Sorbent Assay (ELISA). A subset (20%) of the total samples were analyzed by more expensive analytical techniques including ICMP-MS for metals and GC/MS for organics. The high density screening data was able to quickly identify pockets of elevated contamination for follow on investigations and confirmation using more expensive methods. The screening tools provided rapid results that supported near real-time decision-making and resulted in assessment objectives that were more focused and tailored to conditions at the site. The screening results coupled with quantitative laboratory analysis also supported water quality assessments under the Clean Water Act 303(d) listing procedures and compliance with Washington State Sediment Quality Standards.

MP111 Application of Continuous Low-level Aquatic Monitoring Devices to Analysis of Organic Contaminants in Stormwater Retention Ponds on Kiawah Island, SC L.J. Macaulay, G.J. Getzinger, Duke Univ, Nicholas School of the Environment ; B. Hepner, Aqualytical Services Incorporated; L. Ferguson, Duke Univ, Dept of Civil and Environmental Engineering, Duke Univ, Nicholas School of the Environment , Pratt School of Engineering, Dept of Civil & Envionmental Engineering. Assessment of trace environmental organic contaminant levels in surface waters has typically been accomplished by grab sampling, composite sampling, or passive sampler deployment. Grab samples offer only a snapshot of concentrations at the time of sampling, while composite samples allow integrated sample collection over a defined time interval, however sample degradation during storage is a concern. Passive samplers (POCIS and SPMD) offer continuous sampling of organic contaminants, but relating the contaminant levels in the passive samplers to the ambient water concentrations can be challenging. In the current work, we have applied an integrative, real time solid-phase extraction technology, termed Continuous Low-level Aquatic Monitoring (CLAM, Aqualytical Services Incorporated, Maple Valley, WA) to assess the levels of thirty polar organic microcontaminants in golf-course retention ponds on Kiawah Island, South Carolina. CLAM devices are novel, in situ extraction samplers consisting of high-flow filtration media and Waters OASIS HLB discs packaged together in a 47 mm syringe filter format. Sample water is drawn continuously through the media using a peristaltic pump, allowing low flow (3-4 mL/minute), integrated sampling. Sources of microcontaminants to the ponds on Kiawah Island included land application of treated municipal wastewater as an irrigant for turfgrass as well as routine application of turf-management chemicals. Analytes thus included wastewater-derived xenoestrogens (e.g., ethynylestradiol, nonylphenol, octylphenol, and bisphenol A) as well as fungicides, pesticides, & herbicides. CLAM devices were deployed at five sampling locations on Kiawah Island for 24 hour intervals every 2nd day for two weeks, and extracted water volumes were recorded. The OASIS CLAM extracts were analyzed for microcontaminants by ultra performance liquid chromatography (UPLC) with electrospray high-resolution mass spectrometry detection (HRMS, LTQ-Orbitrap Velos). Comparisons were made between concentrations of analytes in CLAM extracts and those measured in discrete grab water samples via conventional, cartridge-based SPE methods in order to assess the reliability of CLAM samplers as field-deployable, integrated contaminant sampling devices. Results to date indicate that CLAM devices hold great promise for assessment of ambient micropollutant concentrations in contaminated surface waters.

MP112 Characterization of Tracer Chemicals to Describe Marine Debris Ingested by Hawaiian Seabirds F. Nilsen; B. Jensen. Seabirds and various other marine organisms ingest plastic fragments on a regular basis as they mistake it for natural food. Previously, the ingested plastics have been characterized based on their physical properties (foam, line etc). There are also abundant amounts of small plastic fragments that are too small to be described by physical properties and typically generically described as "fragments". We developed a method to characterize the ingested marine debris according to the Society of Plastics Industry (SPI) Types (#1-6). Known plastics were analyzed by GCMS for "tracer chemicals" characteristic to each type of plastic (1-6). The tracer chemicals were used as identifiers in the analysis of ingested plastic debris. Retention time and mass spectra were used as the basis for identification. Bolus contents from Laysan albatross at Kure Atoll during the breeding season of 2005 were collected and analyzed. 200 fragments were taken from the total lot to be analyzed by this approach: 129 Fragments, 44 pieces of Foam, 10 pieces of Line, 6 pieces of Sheet and 11 Nurdles. Of the ingested plastic debris analyzed,1% was comprised of High Density Polyethylene (Type 2), 4% was comprised of Polystyrene (Type 6) , 11% was comprised of Polyethylene Terephthalate (Type 1), 20% was comprised of PolyVinyl Chloride (Type 3) and 64% was comprised of Polypropylene (Type 5). The most abundant type of plastic found is a type that cannot currently be recycled. Using this method to further identify the ingested plastic debris can be useful in determining the type of plastic that is most frequently ingested by various species of marine organisms, as well as the plastic that is the most common contributor to marine debris. Identification of these plastics, in this case Polypropylene (Type 5) and PolyVinyl Chloride (Type 3) can be the basis for redirected Point Source Reduction efforts to limit the amount of plastic debris that enters the ocean environment.

MP113 Determination of Thyroid Hormones in the Brain and Thyroid Gland Using Isotope Dilution LC–MS/MS T. Kunisue, New York State Dept of Health, and Dept of Environmental Health Sciences, School of Public Health, State Univ of New York at Albany, Research Scientist, New York State Dept of Health, Research Scientist; K. Kannan, Wadsworth Center, New York State Dept of Health, and Dept of Environmental Health Sciences, School of Public Health, State Univ of New York at Albany; J.W. Fisher, Dept of Environmental Health Science, College of Public Health, Univ of Georgia. Thyroid hormones (THs) play critical roles in the regulation of growth and development, including brain development. Until recently, TH levels were assayed with measurements in serum, using immunoassay (IA)-based methods. IA methods are sensitive but are compromised by the lack of adequate specificity. Further, measurements of TH levels in blood do not necessarily reflect the levels and profiles found in critical organs such as the brain. In this study, we developed a selective and sensitive method for the analysis of six THs: L-thyroxine (T4), 3,3',5-triiodo-L-thyronine (T3), 3,3',5'-triiodo-L-thyronine (rT3), 3,5-diiodo-L-thyronine (3,5-T2), 3,3'-diiodo-L-thyronine (3,3'-T2), and 3-iodo-L-thyronine (3-T1) in the brain and thyroid gland (TG), using isotope (13C-T4)-dilution liquid chromatography (LC)–tandem mass spectrometry (MS/MS). Proteins in the (rat) brain and TG were digested by pronase, and THs were extracted with a solid-phase extraction (SPE) method and analyzed by LC-MS/MS. The instrumental calibration range for each TH ranged from 0.5 to 200 ng/mL and showed excellent linearity (r>0.9995). The instrumental detection limits for THs were in the range of 7.5-13.5 pg, in positive-ion mode, and 13.5-16.5 pg, in negative-ion mode. The optimized procedural recoveries for THs (except for 3-T1), spiked into a brain matrix, were between 97.6 and 109%, with a coefficient of variation (CV) of 1.2 to 8.2%, for the brain, and between 96.4 and 101%, with a CV of 1.8 to 8.6%, for TG. Concentrations of THs in the brain and TG of the five rats were: 2.20-3.65 ng/g T4, 1.56-2.20 ng/g T3, and below the limit of detection (LOD) for other THs, in the brain; 88.9-274 ng/mg T4, 14.1-49.1 ng/mg T3, 2.79-12.0 ng/mg rT3, 0.176-0.535 ng/mg 3,5-T2, 0.340-0.880 ng/mg 3,3'-T2, LOD for 3-T1, in TG. This method can permit more comprehensive evaluation of TH homeostasis in the brain and other critical organs following exposure to environmental contaminants.

MP114 Enhanced Pressurized Liquid Extraction Technique for Dioxins, Furans, and Dioxin-like PCBs from Sediments L. Aguilar Lazaro, Baylor Univ, Environmental Science; S. Usenko, Baylor Univ, Dept of Environmental Science, Baylor Univ, Assistant Professor. The extraction of organics from environmental matrices typically requires solid-liquid extraction followed by a series of cleanup techniques. USEPA methodologies 1613 and 8290A, describing the analysis of polychlorinated dibenzo-*p*-dioxins and furans from sediment, involve Soxhlet or pressurized liquid extraction (PLE) followed by several packed column and gel permeation chromatography steps. Combining the necessary extraction and cleanup techniques into a single step reduces labor, time, and solvent volume associated with sample preparation and may potentially improve the overall method's recoveries and precision. An enhanced PLE technique was developed for analyzing dioxins, furans, and dioxin-like polychlorinated biphenyls from sediments. The method was developed and validated using standard reference material 1944, as well as sediment samples collected from the Houston shipping channel San Jacinto River waste pits superfund site, TX. Target analytes were quantified using high-resolution gas chromatography/electron impact negative chemical ionization mass spectrometry. Target analyte recoveries and sample preparation costs were compared to EPA method 1613.

MP115 Environmental Residue of Veterinary Drugs in Korea J. Kwon, National Veterinary Research & Quarantine Service; H. Yun, College of Veterinary Medicine, Chungnam National Univ.; K. Lee, Dept of Applied Biology & Chemistry, College of Agriculture & Life Science, Chungnam

Nat'l Univ. Environmental contamination through the excretion of animal faeces and urine, and the subsequent dispersion of contaminated manure onto land is an issue of great concern in Korea. Subsequently, the potential exists for quantities of these drugs to be excreted as the parent compound and/or metabolites and enter the environment due to the spreading of manure and slurry on agricultural land, or direct deposition by grazing livestock This study describes the residue of chlortetracycline (CTC), oxytetracycline (OTC), sulfamethoxazole (SMTZ), sulfamethazine (SMT), and sulfathiazole (STZ), mainly used veterinary drugs in Korea, from animal farming environment, Samples water were collected from 4 swine and 12 chicken farms, located in southern province in Korea, from September to October in 2009. Residue concentration (ng/g) were followings: STZ 0.06~0.23, and CTC 0.17~2.05 in swine farm soil, STZ 0.3~0.5, SMTZ 0.01~0.68, SMT 0.19~0.68, OTC 0.2~0.8, and CTC 0.1 in solid manure compost, STZ 0.010~0.042, SMT 0.017~15.886, and OTC 6.704~6.927 in liquid fertilizer and STZ 0.004, SMT 0.004~0.008, SMTZ PQL~0.006, and CTC 0.008~0.016 in ground water from swine farms. STZ 0.09~0.10 SMT 0.08~0.11, SMTZ PQL~0.07, CTC 0.15~0.16, and OTC 0.09~0.22 in chicken farm soil, STZ 0.3~0.4, SMTZ 0.01~0.16, and CTC 0.18 in chick manure compost, and CTC 0.007 in ground water.

MP116 Evaluation of Magnetic Hypercrosslinked Resins for Rapid Solid-phase Extraction of Antibiotics J. Qiu, Shanghai Jiao Tong Univ, School of Life Sciences & Biotechnology; Q. Zhou, Nanjing Univ, School of Environment. A new magnetic hypercrosslinked polymer has been tested as a sorbent for the rapid solid-phase extraction (SPE) of several antibiotics from water samples. The resins had large specific surface area (more than 800 m2/g) and hydrophilic character due to the graft of ammonio moieties. This new rapid extraction method was compared to the typical off-line SPE methods using commercially available sorbent Lichrolut® EN column. The results showed that the magnetic resins were consistently better than the commercial sorbent. The recoveries of the antibiotics (tetracycline, chlorotetracycline, oxytetracycline, sulfadiazine and sulfamerazine) were all excess 85% by the rapid extraction method. Moreover, the magnetic polymer had a long-term stability when reused for extraction of more than 50 times.

MP117 Historical Platinum Group Element (PGE) Deposition in Dated Lake Sediment Cores from Lake Ontario and Nearby Small Lakes F. Yang, Environment Canada; E. Dabek-Zlotorzynska, Environment Canada, Air Quality Research Division; D. Muir, Environment Canada, Aquatic Ecosystem Protection Research Division, Environment Canada, National Water Research Institute; V. Celo, J. Zhao, Environment Canada. The environmental emissions of platinum group element (PGE), particularly platinum (Pt), palladium (Pd), and Rhodium (Rh) have increased enormously in the past 30 years due to their use in automobile catalytic converters and in electronic devices. Landfilling and incineration represent significant pathways in the commercial lifecycle of these elements while open use in automobile catalysts represents a quantifiable pathway to the environment. All these substances are probably entering aquatic systems such as the Great Lakes from waste water treatment plant (WWTP) effluents, road runoff, and atmospheric particle deposition, but the relative extent of contamination from these pathways is unknown. In this study, dated lake sediment cores were used to examine historical PGE deposition in southern Ontario, Canada. Three small lakes located north of the Toronto urban area but undisturbed due their location on private land or in conservation areas, were selected. The input of PGEs to these systems was likely to be primarily from atmospheric deposition. A sediment core from the center of the west basin of Lake Ontario was also examined for comparison with those small lakes. This site is known to be impacted by WWTPs from the surrounding urban area of more than 5 million inhabitants. In this work, PGEs in sediments were measured with a quadrupole inductively coupled plasma mass spectrometer (ICP-MS) after a microwave assisted acid digestion using aqua regia. A cation exchange separation was used to alleviate the matrix-induced spectral and nonspectral interferences prior to ICP-MS analysis. Sediment cores were dated using the 210 Pb dating method. Concentrations and fluxes (ng/m2/yr) of Pt and Pd increased in Lake Ontario with flux ratios of 8 and 10 respectively (post-1990 to pre-1900 horizons). Much lower flux ratios for Pt and Pd were found in sediment cores from small lakes (post-1990 to the 1940-50s) and ranged from 0.88 to 3.5. Rhodium showed no anthropogenic enrichment in Lake Ontario sediments, and in small lake sediments it was present at concentrations near its detection limit (~0.4 ug/kg). Compared to small isolated lakes receiving atmospheric deposition, the higher anthropogenic fluxes of Pt and Pd in Lake Ontario indicate that urban runoff and WWTP effluents are major sources of these PGEs to the Great Lakes.

MP118 Non-lethal Adipose Sampling of Migratory Songbirds for Persistent Organic Pollutant Analysis R. Cooper, Arkansas State Univ, Environmental Science; R. Warby, J. Bednarz, Arkansas State Univ. Current techniques for detecting persistent organic pollutants (POPs) in birds are lacking in accuracy and methodology. These limitations prevent us from assessing accurate toxin patterns and trends in birds, ultimately impeding informed conservation. Adipose is the best tissue to sample for accurate determination of pesticide body burdens, often because POPs have high persistence in fat. However, previous fat tissue studies have usually required sacrificing study subjects or salvaging carcasses. This approach results in limited sample size and biased sampling. We have developed a non-lethal method for sampling songbird adipose tissue that allows us to identify and quantify pertinent POPs. To demonstrate the feasibility of this approach we spiked chicken fat with a POP surrogate and separated the fat from the surrogate using a silica gel column. The surrogate concentration was quantitatively determined by gas chromatography/mass spectrometry (GC/MS). This technique was further verified by spiking chicken fat with six polychlorinated biphenyl congeners and an organochlorine mixture. We have applied this analytical method to facilitate monitoring POP concentrations in adipose tissue sampled from migratory songbirds captured at banding stations in northeastern Arkansas and southwestern Ohio. Additionally, potential adverse effects of the sampling method were evaluated in an aviary experiment involving gray catbirds (*Dumetella carolinensis*) and indigo buntings (*Passerina cyanea*). Survivorship, mass change, subcutaneous fat quantity, and fecal glucocorticoid metabolites were evaluated between control and sampled groups.

MP119 On-line SPE Using Chromolith Guard Columns for Mass Spectrometric Analysis of Urinary Phthalate Metabolites in Exposure Assessment Studies M. Silva, E. Samanda, J. Preau, Centers for Disease Control and Prevention; A. Calafat, Centers for Disease Control and Prevetion. Phthalates are a widely used group of chemicals with a spectrum of industrial applications. Because of their wide use, human exposure to phthalates is common. Urinary monoester metabolites of phthaltes are generally used for exposure assessment of phthalates in humans. For biomonitoring of phthaltes, a number of methods have been reported in the literature. Previously we have developed a method to quantify urinary phthalate metabolites using on-line solid phase extraction (SPE) coupled to high performance liquid chromatography-electrospray ionization tandem mass spectrometry. We modified our method by replacing the SPE column with a second generation chromolith guard column, adjusting the solvent gradient and reducing the SPE wash time. These modifications improved the separation of all analytes, increased the HPLC and SPE column life and resulted in significant cost savings. This method has high selectrivity and accuracy with automatic recovery correction, precision and throughput with minimal matrix effects. The limits of detection for all analytes are in the low ng/mL range.

MP120 One-step SPE Combined with LC-MS/MS for the Simultaneous Determination of 31 Endocrine-disrupting Compounds in Surface Water of Shanghai H. Zhang, T. Xu, D. Yin, X. Hu, Tongji Univ, College of Environmental Science and Engineering. A novel analytical method employing one-step solid phase extraction (SPE) coupled with liquid chromatography tandom mass spectrometry (LC-MS/MS) was developed to detect 31 endocrine-disrupting compounds (EDCs) in surface water samples simultaneously. The target EDCs belong to five classes, including seven estrogens, eight androgens, six progesterones, five adrenocortical hormones and five industrial compounds. In order to simultaneously concentrate the target EDCs and eliminate matrix interferences in the water samples, MCX SPE cartridges were employed for the one-step SPE, and then followed by a simple and highly efficient three-step sequential elution procedure. Two electrospray ionization (ESI) detection modes, positive ion electrospray ionization (ESI+) and negative ion electrospray ionization (ESI-), were optimized for HPLC-MS/MS analysis to obtain the highest sensitivity for all the EDCs. The limit of detections (LODs) were 0.02 to 1.9 ng L-1 for all the compounds, which are lower than or comparable to these reported in references. Wide linear ranges (LOD-100 ng L-1 for ESI+ mode, and LOD-200 ng L-1for ESI- mode) were obtained with determination coefficients (R2) higher than 0.99 for all the compounds. With five internal standards, good

recoveries (84.4% to 103.0%) of all the target compounds were obtained in selected surface water samples. The developed method was successfully applied to investigate the EDCs occurrence in the surface water of Shanghai by analyzing surface water samples from 11 sites. The results showed that nearly all the target compounds (30 in 31) were present in the surface water samples of Shanghai, of which three industrial compounds (4-t-OP, BPA, BPF) showed the highest concentrations (median concentrations were 11.88 ng L-1-23.50 ng L-1), suggesting that industrial compounds were the dominating EDCs in the surface water of Shanghai, and much more attention should be paid to these compounds. Our present research demonstrated that one-step SPE with MCX cartridges combined with HPLC-MS/MS was convenient, efficient and reliable for multiclass analysis of EDCs in surface water.

MP121 Passive Dosing as a Speciation Tool V. Gouliarmou, Aarhus Univ- National Environmental Research Institute , Environmental Chemistry and Microbiology, Aarhus Univ, Environmental Chemistry and Microbiology; K.E. Smith, Aarhus Univ- National Environmental Research Institute ; L.W. de Jonge, Aarhus Univ- Faculty of Agricultural Sciences, Agroecology and Environment; P. Mayer, Aarhus Univ- National Environmental Research Institute. The main feature of passive dosing is control of the freely dissolved concentrations by partitioning from a pre-loaded polymer. In the present study we apply this for the development of a new analytical tool to study speciation and binding of hydrophobic organic compounds (HOCs) in aqueous solutions. Further, passive dosing was applied to several medium constituents covering a wide range of interactions with HOCs. The first step of the new method is to control the freely dissolved concentration of HOCs and the second is to measure the total HOCs concentration in the equilibrated aqueous solution (=Ctotal). The measured concentration in the solution can then be combined with the corresponding equilibrium partitioning concentration in pure water (= Cwater) to determine: 1) speciation properties of aqueous samples (ff= Cwater/Ctotal) 2) partitioning of HOCs with dissolved phases e.g., cyclodextrin, humic acids, micelles for determination of KDOC and KD values 3) the enhanced capacity (E) of solutions for HOCs (E= Ctotal/Cwater) and 4) salting-out effects (Setschenow constants). Application of passive dosing for speciation and binding studies has a number of advantages: 1) it is a precise and simple method, 2) it requires no phase separation step and no mass balance assumption, 3) binding constants can be determined with simple linear regression, 4) it has short equilibration times and reduced fouling problems and 5) it is possible to dose mixtures at defined and environmentally relevant free concentration.

MP122 Reconstruction of Contaminant Profiles in Marine Ecosystems Using Whale Earwax Plugs Matrices E. Robinson, Baylor Univ, Environmental Science, Baylor Univ, The Institute of Earth, Ecological, and Environmental Sciences, Baylor Univ, graduate student; S. Trumble, Baylor Univ, Dept of Biology; S. Usenko, Baylor Univ, Dept of Environmental Science, Baylor Univ, Assistant Professor. Using a recently developed analytical method for quantifying semi-volatile organic compounds in whale earwax, pesticides and polychlorinated biphenyls (PCB) contaminant profiles were identified in a Pacific gray whale earwax plug layers. The Pacific gray whale's earwax plug collected in 1969 along the western coast of the US was analyzed for pesticides, PCBs, and polybrominated diphenyl ethers using gas chromatography-mass spectrometry in electron capture negative ionization mode. Results from analysis of earwax layers from the older, outer earwax layers to the younger, inner earwax layers displayed a consistent PCB profile over the whale's lifespan (averaging ~ 0.49 ng/g) and a decreasing pesticide profile towards the end of the whale's lifespan (for example, trans-chlordane decreased from 3.50 ng/g – 1.72 ng/g). Additional earwax plugs from a blue whale harvested off the California coast in 2007 were also analyzed.

MP123 Using Remote Video Monitoring for Cavity-nesting Waterfowl to Minimize Impact and Maximize Exposure and Productivity Associated Measurement Endpoints M.W. Nadeau, Michigan State Univ Wildlife Toxicology Lab, Animal Science; W.R. Folland, C.A. Grohman, Michigan State Univ Wildlife Toxicology Laboratory; D.L. Tazelaar, J.M. Matousek, R.R. Holem, J.A. Kubitz, CardnoENTRIX; M.J. Zwiernik, Michigan State Univ Wildlife Toxicology Laboratory. Field studies although difficult to perform, provide real interpretable data pertaining to the exposure and adverse effects of environmental contaminants to individuals and subpopulations of exposed wildlife. Laboratory studies with single compounds require a considerable investment of resources, especially for constituents that are transferred through the food web and may not be predictive of affects in the field where receptors may be exposed to multiple contaminants from a variety of sources and exposure pathways. The life history characteristics of wood ducks (Aix sponsa) and hooded mergansers (Lophodytes cucullatus) make these species of cavity-nesting waterfowl ideal for monitoring exposures and effects of environmental contaminants (and mixtures) in aquatic ecosystems. These characteristics include diversity of nesting habitat, high trophic status, dietary composition, foraging range, and the opportunistic utilization of artificial nest boxes. In this study we installed nest boxes with inexpensive weatherproof infrared video cameras. The cameras permitted nest boxes to be routinely checked for the presence or absence of adults, clutch and incubation initiation, eggs and nestlings in a fraction of the time it would take to physically climb the tree and accomplish the same task. Still and video imaging adds transparency to data collection and provides gains in quality assurance and quality control. Additionally, remote monitoring decreases potential stress on nesting hens by reducing flush occurrences and damage to trees during nest access. Furthermore, video monitoring adds precision in identifying clutch and incubation initiation dates resulting in greater opportunities for embryo development specific sampling events. Climbing to access the nest boxes can be limited to maintenance and collection of tissues, reducing both the potential for long term damage to nest trees, the chance of injury to tree-climbing personnel, and labor costs. Utilizing weatherproof infrared video cameras to monitor artificial nest boxes decreases costs and stress to study animals thereby increasing the effectiveness of monitoring reproductive success and contaminant exposure of cavity-nesting waterfowl.

MP124 Occurrence and Profiles of Benzotriazole UV Stabilizers in House Dust from the Philippines J. Kim, T. Isobe, Senior Research Fellow Center, Ehime Univ; G. Malarvannan, Center for Marine Environmental Studies (CMES), Ehime Univ; K. Chang, Dept of Environmental Science and Engineering, Kyung Hee Univ; A. Sudaryanto, Technology Center for Marine Survey; M. Prudente, Lasallian Institute for Development and Educational Research De La Salle Univ; S. Tanabe, Center for Marine Environmental Studies (CMES), Ehime Univ. Benzotriazole ultraviolet stabilizers (BUVSs) are used in a variety of consumer products, such as plastic resins, paints, varnishes, films, sealants, adhesive agents, air fresheners, waxes, coating materials, and some sports equipments. For the general population, dermal contact, inhalation and ingestion of dust can be considered as the most important pathways of BUVSs exposure. However, the primary routes of human exposure to BUVSs are still unclear. In this study, BUVSs were measured in the house dust samples collected from a residential area (Malate: n = 17) and municipal dumping area (Payatas: n = 20) in the Philippines. We also assessed the human exposure to these contaminants via house dust ingestion. Total BUVSs concentrations in the house dust samples ranged from 2.87 to 1020 ng/g in the residential area and from 2.91 to 277 ng/g in the municipal dumping area. The most abundant BUVSs found were UV-234 and UV-326, with a median value of 83.7 ng/g (ND – 813 ng/g) and 40.7 ng/g (ND – 212 ng/g), respectively. Significantly higher concentrations of UV-326 ($p < 0.01$) and UV-327 ($p < 0.05$) were found in house dust samples from Malate than Payatas suggesting that the household appliances are the major sources of the contamination by these analytes. The estimated dietary intakes (EDIs) of BUVSs through house dust ingestion in the Philippines were two to four orders of magnitude lower than the guideline values. However, the EDIs of 7 BUVSs for toddlers in this study was 5 times higher than adults, suggesting that toddlers are at higher risk. To our knowledge, this is the first comprehensive study on BUVSs contamination in house dust samples in a developing country and notably first study in the world for the three BUVSs, UV-9, UV-234 and UV-320.

MP125 Can Hair Be Used as an Effective Biomarket to Link Environmental Exposure to Health Outcome? K. Aleksa, Hosptial for Sick Children, Dept of Clinical Pharmacology and Toxicology, Univ of Waterloo, School of Pharmacy. Over the last 20 years hair has moved from the arena of being a novel and highly questionable biological matrix to a mainstream and acceptable matrix in forensic science where it is primarily used to determine exposure (past and present) to illicit drugs. The use of hair as a conventional matrix to assess exposure to pesticides and persistent environmental pollutants has not yet become common. The applicability of this matrix to assess an individual's body burden to chemicals such as polybrominated diethyl ethers (PBDEs) can provide more insight into current exposure levels but also to past exposure levels, which is not possible

with more traditional matrices such as blood and urine. Further as it has been shown that PBDEs cross the placenta and since a fetus' hair begins to grow during the first trimester, this matrix can be used to assess an infant's in utero exposure. These features of hair can in turn be used to determine if chemicals such as PBDEs may be responsible for any physiological or anatomical abnormalities in infants, children or adults.

MP126 Investigation of Flame Retardants in Indoor Dust from New Zealand: Implication for Human Exposure N. Ali, Antwerp Univ, Pharmaceutical sciences, Toxicology centre; N.V. Eede, A. Dirtu, H. Neels, A. Covaci, Univ of Antwerp, Toxicology Centre; S. Harrad, Univ of Birmingham, Divison of enironmental health and risk managment; A.'. Mannetje, J. Coakley, J. Douwes, Univ of Massey, Centre for Public Health Research. Due to the worldwide regulations on PBDEs, the demand for alternative flame retardants (FRs), such as organophosphate esters (OPEs) and novel brominated FRs (NBFRs), has increased. We investigated the presence of twelve PBDE congeners, five NBFRs and ten OPs in indoor dust from New Zealand homes. Dust samples were taken from living room floors (n=34) and from mattresses (n=16). The following NBFRs were measured: decabromodiphenyl ethane (DBDPE) (< 5-131 ng/g), 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE) (< 2-22 ng/g), 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (TBB) (< 2-22 ng/g) and bis(2-ethylhexyl)-3,4,5,6-tetrabromophthalate (TBPH) (< 2-81 ng/g). Concentrations of PBDEs ranged from 54-7477 ng/g. The PBDE profile was dominated by BDE 209 (< 5-6971 ng/g), while other congeners were present at lower concentrations (BDE 47 (< 2-100 ng/g), BDE 99 (< 2-220 ng/g), BDE 183 (< 2-65 ng/g)). The following OPEs were present in the NZ dust samples: tri-ethyl-phosphate (TEP) (range < 10-72 ng/g), tri-n-butyl-phosphate (TnBP) (< 20-830 ng/g), tris-(2-chloroethyl)-phosphate (TCEP) (< 20-443 ng/g), tris-(2-chloroisopropyl-)phosphate (TCPP) (20-3650 ng/g), tri-(2-butoxyethyl)-phosphate (TBEP) (50-11800 ng/g), tris-(2,3-dichloropropyl)-phosphate (TDCPP) (20-2090 ng/g), tri-phenyl-phosphate (TPhP) (20-3490 ng/g), tri-cresyl-phosphate (TCP) (< 50-1025 ng/g). Levels of BDE 47, 99, 183 and 209, BTBPE, DBDPE, TBPH, TBEP, and TnBP showed significant correlation (p< 0.05) between their concentrations in mattresses and the corresponding floor dust (n=16). Different exposure scenarios were calculated using the 5th, median and 95th percentile concentrations. Exposure scenarios were calculated assuming 100% absorption of intake dust, 70 kg body weight (bw) for adult and 20 kg bw for toddlers, mean dust ingestion (adults=20 mg/day; for toddlers=50 mg/day) and high dust ingestion (adults=50 mg/day; for toddlers=200 mg/day). Typical high end exposure, using median concentrations and high dust ingestion, estimates for adults ranged between < 0.01-0.38 ng/kg bw/d for PBDEs, < 0.01-0.01 ng/kg bw/d for NBFRs and < 0.01-2.20 ng/kg bw/d for OPEs. By comparison, for toddlers, typical high end exposure fell between 0.04-7.05 ng/kg bw/d for PBDEs, 0.01-0.11 ng/kg bw/d for NBFRs and 0.05-30.5 ng/kg bw/d for OPEs. Exposure assessment values were multifold below their RfD values. However, their presence in indoor dust emphasizes the need to evaluate health implications for human exposure.

MP127 Predictors of HBCDs and TBBPA in Milk from Boston Mothers C.C. Carignan, Boston Univ School of Public Health, Dept of Environmental Health; N. Wu, California Dept of Public Health; M. Abdallah, Assiut Univ, Dept of Pharmaceutical Analytical Chemistry; W. Heiger-Bernays, M.D. McClean, Boston Univ School of Public Health, Dept of Environmental Health; S. Harrad, Univ of Birmingham, Division of Environmental Health and Risk Management; T.F. Webster, Boston Univ School of Public Health, Dept of Environmental Health, Boston Univ School of Public, Associate Professor. Hexabromocyclododecanes (HBCDs) and tetrabromobisphenol-A (TBBPA) are flame retardants widely used in consumer products such as building insulation, electronic housing, and circuit boards. Biological measures of HBCD and TBBPA in European populations have been associated with levels in house dust as well as diet, however scant measures exist for North American populations. Our objectives were to characterize levels of these flame retardants in breast milk from Boston mothers (n=43) and identify significant predictors of exposure using questionnaire data. We analyzed samples for TBBPA, ΣHBCDs, α-, β- and γ-HBCD, pentabromocyclododecenes (ΣPBCDs) and tetrabromocyclododecadienes (ΣTBCDs). ΣHBCDs and ΣTBBPA were detected in 100% (359-8,100 pg/g-lw; GM: 1,020 pg/g-lw) and 30% (< 25-549 pg/g-lw; GM: 33 pg/g-lw) of milk samples, respectively. These concentrations are similar to those reported in other countries. ΣPBCDs and ΣTBCDs, two possible metabolites of HBCD, were detected in 42% (< 30-317 pg/g-lw; GM: 35 pg/g-lw) and 56% (< 26-562 pg/g-lw; GM: 49 pg/g-lw) of milk samples, respectively, and are the first reported measurements of these compounds in human samples from the US. Consistent with observations in other populations, α-HBCD was the dominant diastereomer accounting for 40-80% of ΣHBCDs with a slight enrichment of the (-)-α-HBCD enantiomer. Levels of ΣHBCDs were significantly correlated with the HBCD diastereomers (r>0.91) and metabolites (r>0.74), as well as TBBPA (r=0.56). Average concentrations of ΣHBCDs, ΣPBCDs, ΣTBCDs, α-, β- and γ-HBCD were 47 to 71% lower in the milk of mothers who indicated they regularly chose to eat organic foods than those who did not, whereas these levels were 1.2-1.5 pg/g-lw higher for each additional audio-visual appliance in a mother's home (p< 0.05). Our results indicate that both diet and indoor exposures may contribute to levels of these flame retardants in human milk.

MP128 Baseline Monitoring at Sediment Remediation Sites Under the Great Lakes Legacy Act B. Jones, S. Ireland, M. Loomis, USEPA, Great Lakes National Program Office. The Great Lakes Legacy Act (GLLA) was signed into law in 2002 and was reauthorized in 2008. The purpose of the Act is to provide funding to take the necessary steps to clean up contaminated sediment in "Areas of Concern located wholly or partially in the United States." USEPA's Great Lakes National Program Office (GLNPO) is charged with addressing sediment contamination problems under the GLLA. Since fiscal year 2004, GLNPO and our non-federal sponsors, have spent approximately $180 million to address sediment contamination on nine separate remediation projects resulting in approximately 1.3 M cubic yards of sediment remediated. GLNPO performed baseline monitoring at eight GLLA projects, seven sites prior to implementation of sediment remediation, one site post-remediation. The sites are located throughout the Great Lakes basin. This presentation will discuss the approach GLNPO is taking to baseline monitoring of the sites. This approach is part of a strategy to develop guidelines for GLLA remedy effectiveness monitoring as a tool to evaluate program effectiveness. This presentation will present the tools and sampling strategies employed and provide a discussion of the proposed next steps in the monitoring program.

MP129 Hydrologic and Geologic Controls on Carbon Tetrachloride Transport and Biodegradation at the Velsicol Dump, Hardeman County, Tennessee A.C. West, Tennessee State Univ, Civil & Environmental Engineering. An unlined landfill in Hardeman County, Tennessee was used by the Velsicol Chemical Corporation from 1964 to 1973 to dispose of 100,000 to 300,000 barrels of industrial waste. An investigation of groundwater contamination at the landfill was conducted to identify contaminant loads in the tributaries, contaminant sources, mode of contaminant transport and potential for in situ biodegradation. Seepage was measured and water quality samples collected along the tributaries. The seepage investigation and water-quality results identify a two-phase mode of contaminant transport to the tributaries. A diffuse ground-water plume transports contaminants to the streams resulting in relatively low and consistent concentrations and loads in the tributaries. High permeability zones, probably related to gravel in the terrace deposits, and concentrated flow near sand/clay contacts have produced seeps and springs along the banks of the tributaries and the edge of the adjacent wetland. The seeps and springs show concentrations of carbon tetrachloride ranging from 2 to 28 mg/L; notably higher than contaminant concentrations in the tributaries. Geochemical and microbial evaluations from multiple groundwater samples indicate that conditions are favorable for natural or enhanced attenuation of the contaminants. Groundwater along the tributaries and discharge into the wetlands was iron or sulfur reducing. Lab microcosms set up with aquifer materials had carbon tetrachloride half-lives of 90 days and when supplemented with lactate and molasses T1/2 = 2 days. In general, contamination from the landfill continues to migrate from the landfill to a creek to the east, to the Clover Creek wetlands to the north, and to tributaries west of the site. A large contaminant mass remains in the subsurface, and dissolved phase VOCs are being released along the tributaries to Clover Creek and at seeps along the southern edge of the Clover Creek wetland.

MP130 Monitored Recovery from Historical PCB Releases in Stony Creek, Indiana D. Pelletier, M.H. Henning, A.L. Fogg, ENVIRON International Corporation; J. Johnson, Bridgestone Americas, Inc. Clearly defined decision rules and quantifiable success metrics are critical to the success of Monitored Natural Recovery (MNR) as an acceptable remedial

alternative at contaminated sites. Based on data from Stony Creek, a polychlorinated biphenyl (PCB)-contaminated stream in central Indiana (USA), this presentation illustrates the importance of designing a monitoring plan with sufficient statistical rigor to determine when recovery goals have been met. MNR was selected as the preferred remedial alternative for Stony Creek in a 2001 Administrative Order on Consent (AOC) between the responsible party and US Environmental Protection Agency (USEPA), Region 5. The original AOC established threshold PCB concentrations in sediment and fish of 1 milligram per kilogram (mg/kg) and 2 mg/kg, respectively, and monitoring occurred on schedule from 2003 through 2007 under an approved monitoring plan. However, small sample sizes rendered it difficult to differentiate results that were slightly less than the threshold concentrations from those that were slightly greater than the thresholds. Similarly, because the species and size classes of fish collected changed over time, the fish tissue data did not allow for any definitive conclusions regarding trends in tissue PCB concentrations over time. Given the limitations of the old monitoring program, a revised plan was submitted to USEPA in August 2009. The new plan, which USEPA approved, expanded the spatial scope and sample sizes for sediment and fish tissue sampling, while focusing on three fish species representing different feeding guilds. Concurrently, decision rules for determining the need for continued monitoring were reworded for clarity. The primary goal of the updated monitoring plan was to maximize statistical rigor and, consequently, improve clarity and certainty in decision making. Following implementation of the revised monitoring plan, it was possible to demonstrate that continued monitoring of sediment and fish fillets was not necessary, and that monitoring should focus solely on whole body fish tissue concentrations going forward.

MP131 Tenax Absorbent as a Measurement of PCB Bioavailability in Sediment: A Good Surrogate for Biota? E.M. Tripp, Southern Illinois Univ; M. Lydy, Southern Illinois Univ Carbondale, Fisheries and Illinois Aquaculture Center and Dept of Zoology; P.M. Landrum, Southern Illinois Univ; J. You, State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy Sciences, State Key Laboratory of Organic Geochemistry. In the past, bioavailability has been estimated using biota-sediment accumulation factors (BSAF) based on equilibrium partitioning theory. The BSAF is the relationship between the concentration in the organism (lipid normalized) and the concentration in the sediment (organic carbon normalized). This relationship has been shown to be unreliable when using field-collected sediments driven mostly by the character of the organic carbon, particularly the amount of "black carbon". Therefore, developing a more accurate method to determine the bioavailable fraction of contaminants in sediment should improve environmental assessments. One possible method to accomplish this is a single 24 h point extraction using Tenax TA resin. The goal of this technique is to use Tenax to estimate the bioaccessible portion of the sediment-associated contaminant to compare to bioaccumulation in organisms. This study examined the relationship between the bioaccessible fraction of PCBs measured by Tenax and the body residues in oligochaetes. Eighteen field-collected sediments from the Ottawa River (OR) were subjected to 14 d bioaccumulation test with *Lumbriculus variegatus* and a 24 h Tenax extraction. This technique provided a rapid processing time with relatively clean samples for analysis. To validate this technique, data from the OR was combined with data from two other studies using similar methods and one utilizing field-collected oligochaetes. When combined, all of the data follow a single log-log regression when using all congeners (r^2= 0.91). Further separation of data into homologue groups produced variable relationships with correlation coefficients ranging from r^2= 0.76-0.95. Due to the effectiveness of predicting PCB body residues in organisms Tenax extraction can be used in site evaluations as well as assessing the potential success of remediation efforts.

MP132 Advances in Phytoextraction of PCBs from Soils in Southern Ontario Using Weed Species B. Zeeb, Royal Military College, Chemistry & Chemical Engineering Dept; S. Ficko, Royal Military College; A. Rutter, Queens Univ, School of Environmental Studies. Remediation of soil contaminated with low levels of polychlorinated biphenyls (PCBs) and other persistent organic pollutants (POPs) continues to be a significant issue in Canada and around the world. While traditional remediation methods such as excavation and incineration are effective, they are expensive not always sustainable. Research investigating phytoextraction as an alternative strategy has mainly focused on crop species such as *Cucurbita pepo* ssp *pepo* (e.g., pumpkins), which have shown a tendency to accumulate POPs in shoot tissues. In 2010, Ficko et al. documented 27 species of weeds that were capable of accumulating PCBs in plant tissues. Of these, 18 species were theoretically able to extract a similar or greater quantity of PCBs than *C. pepo* plants (when planted at an optimal density). Thus this study demonstrated for the first time that weeds may play a useful role in remediation activities. Advantages of using weeds for phytoextraction include that they are easy to cultivate and propagate, generally self-sustaining, relatively inexpensive, and are often hardier than many cultivated species. In a follow-up experiment, three of the most promising perennial species (*Chrysanthemum leucanthemum*, *Rumex crispus*, and *Solidago canadensis*) were planted in monoculture plots at two historically-contaminated and naturally-weathered PCB field sites, and harvested on a monthly basis over two years. Plant age and life cycle affected total phytoextraction on a per-species-basis and trends were similar between sites. Despite the suboptimal planting densities used in this experiment, all three species were able to extract a greater quantity of PCBs per unit area (4800-10,000 $\mu g/m^2$) than *C. pepo* plants (1500-2200 $\mu g/m^2$). Thus at optimal densities, these species show significant potential to remediate contaminated soil. In addition, analysis along the stem length of *S. canadensis* plants, demonstrated that PCB movement within plant tissues of other species follows a similar pattern as in *C. pepo* plants. Understanding the differences in uptake between species may help elucidate the mechanisms of phytoextraction, ultimately leading to novel remediation strategies that accelerate the attainment of remediation targets.

MP133 Four Decades of Discharge: The Toxic Legacy of the New Idria Mercury Mine K. Manheimer, USEPA, Region 9, Superfund Division; K. Abusaba, Brown and Caldwell, Water Resources. The New Idria Mercury Mine is the second largest historic producer of mercury in North America. Located in the Coast Ranges of California in San Benito County, the mine ceased operations in 1972. Since that time, inadequate closure and maintenance activities have caused a continuous discharge of 10 – 30 gpm acid mine drainage and erosive mobilization of mercury from a massive pile of discarded calcines and waste rock. The mine site has recently been proposed for addition to the EPA's National Priorities List; if approved, one important task will be to assess mercury toxicity and effects on environmental receptors both locally and in the greater Central Valley watershed. This talk will present what is currently known about the environmental effects of mercury released from New Idria, along with uncertainties that need to be addressed. A considerable amount of existing information is available to support the proposed listing. Process studies of mercury in solid waste sources from New Idria indicate that alteration forms of mercury sulfide ore created by the process of roasting and weathering increase the availability of solid mercury for dissolution and biological uptake. Methylmercury measurements in water indicate unfiltered concentrations ranging from 1 – 47 ng/L, confirming that mercury released from New Idria is biologically available to methylating bacteria. Biologically available mercury is transported five miles downstream to a low point where the impacted stream percolates underground during most times of the year, creating a wetland in an otherwise arid landscape. Recent information has shown that during episodic storm events, water can escape the receiving wetland and break through to the Central Valley, transporting bioavailable mercury into a much more extensive ecosystem. Key questions to be addressed in future studies include: (1) are elevated methylmercury concentrations observed in prey items, such as benthic invertebrates, of the receiving wetland? (2) What receptors feed on those prey items (e.g., the nearby Pinnacles National Monument is part of the California Condor Recovery program, and is the home of 30 free-flying California Condors). (3) To what extent does mercury discharged from New Idria affect the food web in the San Joaquin River and the Mendota Pool, which are important fisheries resources for people and habitat resources for wildlife, as well as an important source of irrigation water for the surrounding farmland?

MP134 Using the Trident Probe to Characterize Chloride Contamination at the Groundwater-Surface Water Interface (GSI) D. Lavoie, F. Dillon, J. Johnson, G. Dyke, CH2M Hill; B. Chadwick, Coastal Monitoring Associates, Marine Environment Branch. Code 2362; C. Smith, Coastal Monitoring Associates. Historical investigations at an industrial facility in the Midwest identified elevated chloride concentrations in groundwater. In 2006, on- and offsite cone penetrometer testing (CPT)/electrical conductivity (EC) logging and groundwater sampling suggested chloride might be venting into an adjacent lake at concentrations exceeding the state ecotoxicological benchmark. Although EC probes showed indirect chloride

concentration measurements in the lake at the groundwater-surface water interface (GSI) were lower than in deep grab samples, no direct chloride measurements in shallow sediment pore water had previously been collected. Therefore, 2 phases of sediment pore water sampling were conducted to survey chloride venting zones using the Trident Probe, a direct-push, integrated conductivity/temperature (CT) sensor and GSI sampler. Phase 1 (April 2008) was conducted to verify the existing hydrogeological CSM, identify specific venting hotspots and gauge concentration magnitude. Phase 2 (May 2010) was conducted to refine the delineation of Phase 1 hotspots, establish a potential relationship between onsite groundwater and offsite sediment pore water, and support potential corrective action measures. For both studies, the Trident Probe was configured with 2 CT sensors and 3 pore water sample probes. Each probe consisted of a 6" sand-pack pre-filter to minimize potential clogging from fine-grained sediment, and attached to peristaltic pumps to facilitate low-flow sampling. The midpoint of the sample probes were set to penetrate to depths of 4", 16" and 29" below the sediment surface, with CT sensors set to collect measurements within the shallowest and deepest depth ranges. In addition to temperature and conductivity, surface water and pore water was further analyzed ex situ for conductivity and temperature as well as pH, ORP, TDS. Split samples were analyzed for chloride both in the field, using titrator test strips for real-time screening purposes, and in the lab for definitive results. Both Phase 1 and 2 results were consistent with the existing hydrogeological CSM. Two venting zones, where chloride exceeded the benchmark at the GSI, were identified and delineated in the nearshore of the lake. Data from these studies clearly established the site-specificity of the sediment-associated chloride source and facilitated a focused path forward for onsite corrective measures.

MP135 Characterizing Volatile Organic Compound Contamination at the Groundwater – Surface Water Interface (GSI) Using the Trident Probe J. Johnson, F. Dillon, E. Kroger, D. Boehnker, L. Raterink, D. Lavoie, CH2M Hill; C. Smith, B. Chadwick, Coastal Monitoring Associates. Historical investigations at an industrial facility in the Eastern United States identified elevated volatile organic compounds (VOCs) in site groundwater (TCE, PCE, DCE, vinyl chloride, chlorobenzene, dichloropropane, dichloroethane and naphthalene). Recent site-related groundwater data were evaluated to identify potential groundwater plume venting areas in the river adjacent to the facility where ecological receptors might be exposed at the groundwater-surface water interface (GSI). Multiple investigation phases of pore water sampling were conducted to identify potential VOC venting zones and determine if VOC concentrations in sediment pore water potentially pose unacceptable ecological risks to aquatic biota. Each phase of the investigation involved collection of pore water for VOC analysis using the Trident Probe, a direct-push, integrated conductivity/temperature (CT) sensor and GSI sampler. The Trident Probe was configured with two CT sensors and three pore water sample probes. The CT sensors were set to collect measurements within the biologically active zone (shallow sediment) as well as from the surface water. The first phase of the investigation included collection of pore water from 15 nearshore locations opposite areas of elevated onshore groundwater VOCs in 7 of the 9 site remediation areas. The initial phase confirmed the presence of VOCs in pore water in exceedance of ecological screening values opposite 6 of the site remediation areas. Subsequent investigations were designed to facilitate additional pore water characterization in identified venting zones and in areas not previously investigated, to establish plume-specific attenuation factors for application towards refinement of groundwater performance criteria at each onsite remediation area. The Trident Probe data was also used to refine the hydrogeological conceptual site model in regards to the relationship of site groundwater with the GSI. This presentation presents the Trident Probe methods employed, summarizes the pore water and groundwater data and conclusions generated from the study.

MP136 Hydrologic and Geologic Controls on Carbon Tetrachloride Transport and Biodegradation at an Unlined Landfill, Hardeman County, Tennessee T. Byl, US Geological Survey, Dept of Interior, Tennessee State Univ., College of Engineering; M.J. Bradley, Smithers Viscient, Sediment Ecotoxicology; A.C. West, Tennessee State Univ, Civil & Environmental Engineering. An unlined landfill in Hardeman County, Tennessee was used by the Velsicol Chemical Corporation from 1964 to 1973 to dispose of 100,000 to 300,000 barrels of industrial waste. An investigation of groundwater contamination at the landfill was conducted to identify contaminant loads in the tributaries, contaminant sources, mode of contaminant transport and potential for in situ biodegradation. Seepage was measured and water quality samples collected along the tributaries. The seepage investigation and water-quality results identify a two-phase mode of contaminant transport to the tributaries. A diffuse ground-water plume transports contaminants to the streams resulting in relatively low and consistent concentrations and loads in the tributaries. High permeability zones, probably related to gravel in the terrace deposits, and concentrated flow near sand/clay contacts have produced seeps and springs along the banks of the tributaries and the edge of the adjacent wetland. The seeps and springs show concentrations of carbon tetrachloride ranging from 2 to 28 mg/L; notably higher than contaminant concentrations in the tributaries. Geochemical and microbial evaluations from multiple groundwater samples indicate that conditions are favorable for natural or enhanced attenuation of the contaminants. Groundwater along the tributaries and discharge into the wetlands was iron or sulfur reducing. Lab microcosms set up with aquifer materials had carbon tetrachloride half-lives of 90 days and when supplemented with lactate and molasses T1/2 = 2 days. In general, contamination from the landfill continues to migrate from the landfill to a creek to the east, to the Clover Creek wetlands to the north, and to tributaries west of the site. A large contaminant mass remains in the subsurface, and dissolved phase VOCs are being released along the tributaries to Clover Creek and at seeps along the southern edge of the Clover Creek wetland.

MP137 An Integrated Approach to Developing a Total Facility Estrogen Budget at a Swine Farrowing CAFO E. Yost, North Carolina State Univ, Environmental and Molecular Toxicology; M.T. Meyer, United States Geological Survey, Organic Geochemistry Research Laboratory; B. Lee, Duke Univ; S.W. Kullman, North Carolina State Univ, Environmental and Molecular Toxicology. Naturally occurring estrogens from concentrated animal feeding operations (CAFOs) present an emerging risk to terrestrial and aquatic environments through their potential action as endocrine disruptors. Here, we present our findings on the concentrations, fate, and biological availability of estrogens in a commercial swine farrowing CAFO, which houses 5,000 pregnant and lactating female swine. Analysis of estrogens was made in relation to: 1) reproductive status and estrogen excretion by individual animals; 2) the stability of estrogens in open pit holding lagoons; and 3) attenuation of estrogens following spray field application of swine waste as fertilizer. Yeast estrogen screen results indicate 17β-estradiol equivalents (EEQ) in sow urine ranging from 1ng/l to 196μg/l, and in sow feces ranging from 16ng/kg to 208μg/kg (dry weight), with a defined gradient of estrogenic activity observable in relation to the reproductive stage of the animal. LC/MS-MS results indicate that the natural estrogens contained in the raw swine excreta (e.g., 17β-estradiol, 17α-estradiol, estrone, estriol) are largely transformed to estrone during their holding period in the waste lagoon, resulting in estrone concentrations averaging 6.2μg/l in lagoon wastewater liquids and 1.7g/kg (dry weight) in lagoon suspended solids. Phytoestrogens, most notably equol, were also found to persist at high concentrations in the lagoon. Analysis of the CAFO spray field indicates that estrogens from the lagoon wastewater are largely retained in the top 6 inches of soil. Estrone was found to persist in this topsoil at parts-per-trillion concentrations for at least 2 months following the land application of lagoon waste. The end goal of our analysis is to develop a hierarchical structure where assessments of estrogen fate can be "parameterized" and used for input into a Bayesian network model, which will be used to explore and predict the behavior of estrogens in the CAFO system. The anticipated result of this project is prioritization of operational practices in regards to waste management strategies and contributions of total estrogens to the environment.

MP138 Caged Fish Studies to Detect and Monitor Contaminanets of Emerging Concern in the Great Lakes M. Kahl, G. Ankley, USEPA, Mid-Continent Ecology Division; T. Collette, USEPA, National Exposure Research Laboratory; E. Durhan, USEPA, Mid-Continent Ecology Division; D. Ekman, USEPA, National Exposure Research Laboratory; K.M. Jensen, USEPA, Mid-Continent Ecology Division; K. Lee, US Geological Survery; E. Makynen, L. Thomas, USEPA, Mid-Continent Ecology Division; A. Trowbridge, US Fish and Wildlife Service; D.L. Villeneuve, USEPA, Mid-Continent Ecology Division. Effects-based monitoring studies were conducted in the St. Louis Harbor, Lake Superior, in support of the Great Lakes Restoration Initiative (GLRI). The overall goal of the research was to develop and validate methods using caged fish exposures to detect and monitor contaminants of emerging concern (CECs) around the Great Lakes. In 2010, four field sites including the upper St. Louis River (Fond du Lac),

two locations near the Western Lake Superior Sanitary District (WLSSD), and one location near the Superior Municipal Treatment Plant (SMTP) were investigated. Caged fish exposure systems and integrated water sampling devices were developed, and sexually mature fathead minnows (*Pimephales promelas*) were deployed at each location for 2 to 10 days. A number of endpoints were examined in the fish, including plasma vitellogenin and steroid concentrations, expression of different genes that could be impacted by specific CECs, and NMR-based hepatic metabolite profiles. In addition, an extensive suite of CECs were measured in water from the sites where fish had been deployed. Survival and recovery of the fish from the in situ exposure system was excellent, and initial results suggest the presence of estrogenic and/or steroidogenesis-altering chemicals or conditions at sites proximal to waste water treatment plant discharges. Preliminary chemical analyses indicate substantial difference among the sites with regard to CEC profiles. This presentation will provide an overview and synthesis of the biological and analytical work done to date, as well as recommendations for conducting future studies of this type at other Great Lakes sites. The contents of this abstract do not reflect USEPA policy.
